TECHNICAL REPORTS

No.		Page
1342.	A Variational Theorem for Creep with Applications to Plates and Columns. By J. Lyell Sanders, Jr., Harvey G. McComb, Jr., and Floyd R. Schlechte, NACA	117
1343.	A Phenomenological Relation Between Stress, Strain Rate, and Temperature for Metals at Elevated Temperatures. By Elbridge Z. Stowell, NACA	125
1344.	A Simplified Method for Approximating the Transient Motion in Angles of Attack and Sideslip During a Constant Rolling Maneuver. By Leonard Sternfield, NACA	131
1345.	The Response of an Airplane to Random Atmospheric Disturbances. By Franklin W. Diederich, NACA	142
1346.	Differential Equations of Motion for Combined Flapwise Bending, Chordwise Bending, and Torsion of Twisted Nonuniform Rotor Blades. By John C. Houbolt and George W. Brooks, NACA	179
1347.	Ditching Investigations of Dynamic Models and Effects of Design Parameters on Ditching Characteristics. By Lloyd J. Fisher and Edward L. Hoffman, NACA	197
1348.	Ground Simulator Studies of the Effects of Valve Friction, Stick Friction, Flexibility, and Backlash on Power Control System Quality. By B. Porter Brown, NACA	225
1349.	A Low-Speed Experimental Investigation of the Effect of a Sandpaper Type of Roughness on Boundary-Layer Transition. By Albert E. von Doenhoff and Elmer A. Horton, NACA	239
1350.	Methods for Obtaining Desired Helicopter Stability Characteristics and Procedures for Stability Predictions. By F. B. Gustafson and Robert J. Tapscott, NACA	255
1351.	Theory of Self-Excited Mechanical Oscillations of Helicopter Rotors with Hinged Blades. By Robert P. Coleman and Arnold M. Feingold, NACA	267
1352.	Effect of Fuel Variables on Carbon Formation in Turbojet-Engine Combustors. By Edmund R. Jonash, Jerrold D. Wear, and William P. Cook, NACA	309
1353.	An Experimental Investigation of Sting-Support Effects on Drag and a Comparison with Jet Effects at Transonic Speeds. By Maurice S. Cahn, NACA	327
1354.	Effect of Chord Size on Weight and Cooling Characteristics of Air-Cooled Turbine Blades. By Jack B. Esgar, Eugene F. Schum, and Arthur N. Curren, NACA	359
1355.	A Theoretical and Experimental Study of Planing Surfaces Including Effects of Cross Section and Plan Form. By Charles L. Shuford, Jr., NACA	373
1356.	Investigation of Separated Flows in Supersonic and Subsonic Streams with Emphasis on the Effect of Transition. By Dean R. Chapman, Donald M. Kuehn, and Howard K. Larson, NACA	419
1357.	Experimental Determination of Effects of Frequency and Amplitude on the Lateral Stability Derivatives for a Delta, a Swept, and an Unswept Wing Oscillating in Yaw. By Lewis R. Fisher, NACA	461
1358.	On Flow of Electrically Conducting Fluids Over a Flat Plate in the Presence of a Transverse Magnetic Field. By Vernon J. Rossow, NACA	489
1359.	Thin Airfoil Theory Based on Approximate Solution of the Transonic Flow Equation. By John R. Spreiter and Alberta Y. Alksne, NACA	509
1360.	Growth of Disturbances in a Flame-Generated Shear Region. By Perry L. Blackshear, Jr., NACA	546
1361.	Approximate Analysis of Effects of Large Deflections and Initial Twist on Torsional Stiffness of a Cantilever Plate Subjected to Thermal Stresses. By Richard R. Heldenfels and Louis F. Vosteen, NACA	593
1362.	Theoretical Combustion Performance of Several High-Energy Fuels for Ramjet Engines. By Leonard K. Tower, Roland Breitwieser, and Benson E. Gammon, NACA	605
1363.	Origin and Prevention of Crash Fires in Turbojet Aircraft. By I. Irving Pinkel, Solomon Weiss, G. Merritt Preston, and Gerard J. Pesman, NACA	623
1364.	Measurement of Static Pressure on Aircraft. By William Gracey, NACA	643
1365.	A Correlation of Results of a Flight Investigation With Results of an Analytical Study of Effects of Wing Flexibility on Wing Strains Due to Gusts. By C. C. Shufflebarger, Chester B. Payne, and George L. Cahen, NACA	669
1366.	The Mechanism of Thermal-Gradient Mass Transfer in the Sodium Hydroxide—Nickel System. By Charles E. May, NACA	683
1367.	Calculated and Measured Stresses in Simple Panels Subject to Intense Random Acoustic Loading Including the Near Noise Field of a Turbojet Engine. By Leslie W. Lassiter and Robert W. Hess, NACA	703
1368.	Systematic Two-Dimensional Cascade Tests of NACA 65-Series Compressor Blades at Low Speeds. By James C. Emery, L. Joseph Herrig, John R. Erwin, and A. Richard Felix, NACA	713
1369.	Blowing-Type Boundary-Layer Control as Applied to the Trailing-Edge Flaps of a 35° Swept-Wing Airplane. By Mark W. Kelly, Seth B. Anderson, and Robert C. Innis, NACA	799
1370.	Area-Suction Boundary-Layer Control as Applied to the Trailing-Edge Flaps of a 35° Swept-Wing Airplane. By Woodrow L. Cook, Seth B. Anderson, and George E. Cooper, NACA	823
1371.	Investigation of Some Wake Vortex Characteristics of an Inclined Ogive-Cylinder Body at Mach Number 2. By Leland H. Jorgensen and Edward W. Perkins, NACA	857

No.		Page
1372.	A Method of Computing the Transient Temperature of Thick Walls From Arbitrary Variation of Adiabatic-Wall Temperature and Heat-Transfer Coefficient. By P. R. Hill, NACA	877
1373.	Theoretical Analysis of Total-Pressure Loss and Airflow Distribution for Tubular Turbojet Combustors with Constant Annulus and Liner Cross-Sectional Areas. By Charles C. Graves and Jack S. Grobman, NACA	899
1374.	The Similarity Rules for Second-Order Subsonic and Supersonic Flow. By Milton D. Van Dyke, NACA	925
1375.	A Wind-Tunnel Investigation of the Aerodynamic Characteristics of a Full-Scale Supersonic-Type Three-Blade Propeller at Mach Numbers to 0.96. By Albert J. Evans and George Liner, NACA	933
1376.	Elliptic Cones Alone and With Wings at Supersonic Speeds. By Leland H. Jorgensen, NACA	975
1377.	Measurements of Free-Space Oscillating Pressures Near Propellers at Flight Mach Numbers to 0.72. By Max C. Kurbjun and Arthur W. Vogeley, NACA	999
1378.	A Method for Simulating the Atmospheric Entry of Long-Range Ballistic Missiles. By A. J. Eggers, Jr., NACA	1009
1379.	Compressible Laminar Boundary Layer Over a Yawed Infinite Cylinder With Heat Transfer and Arbitrary Prandtl Number. By Eli Reshotko and Ivan E. Beckwith, NACA	1016
1380.	An Analysis of Pressure Studies and Experimental and Theoretical Downwash and Sidewash Behind Five Pointed-Tip Wings at Supersonic Speeds. By William B. Boatright, NACA	1067
1381.	A Study of the Motion and Aerodynamic Heating of Ballistic Missiles Entering the Earth's Atmosphere at High Supersonic Speeds. By H. Julian Allen and A. J. Eggers, Jr., NACA	1125
1382.	A Comparative Analysis of the Performance of Long-Range Hypervelocity Vehicles. By Alfred J. Eggers, Jr., H. Julian Allen, and Stanford E. Neice, NACA	1141
1383.	Survey of Hydrogen Combustion Properties. By Isadore L. Drell and Frank E. Belles, NACA	1161
1384.	A Summary of Preliminary Investigations Into the Characteristics of Combustion Screech in Ducted Burners. By Lewis Laboratory Staff, NACA	1195
1385.	Drag Minimization for Wings and Bodies in Supersonic Flow. By Max. A. Heaslet and Franklyn B. Fuller, NACA	1213
1386.	Investigation of the Drag of Various Axially Symmetric Nose Shapes of Fineness Ratio 3 for Mach Numbers from 1.24 to 7.4. By Edward W. Perkins, Leland H. Jorgensen, and Simon C. Sommer, NACA	1231
1387.	Full-Scale Investigation of Several Jet-Engine Noise-Reduction Nozzles. By Willard D. Coles and Edmund E. Callaghan, NACA	1249
1388.	NACA Research on Slurry Fuels. By M. L. Pinns, W. T. Olson, H. C. Barnett, and R. Breitwieser, NACA	1273
1389.	Characteristics of the Langley 8-Foot Transonic Tunnel With Slotted Test Section. By Ray H. Wright, Virgil S. Ritchie, and Albin O. Pearson, NACA	1297
1390.	Incompressible Flutter Characteristics of Representative Aircraft Wings. By C. H. Wilts, California Institute of Technology	1385
1391.	Investigation of a Nonlinear Control System. By I. Flügge-Lotz, C. F. Taylor, and H. E. Lindberg, Stanford University	1423
1392.	Boron and Zirconium From Crucible Refractories in a Complex Heat-Resistant Alloy. By R. F. Decker, John P. Rowe, and J. W. Freeman, University of Michigan	1457

Letter of Transmittal

To the Congress of the United States:

In compliance with the provisions of the Act of March 3, 1915, as amended, which established the National Advisory Committee for Aeronautics, I transmit herewith the Forty-fourth and Final Annual Report of the Committee for the Fiscal Year 1958. This report covers the activities of the Committee through the close of business September 30, 1958, when it was superseded by the National Aeronautics and Space Administration.

The National Advisory Committee for Aeronautics is to be commended for its many contributions to the progress of aeronautical science in the United States and for the spirit of teamwork in aeronautics it has inspired among leaders in science, the military and industry. I wish also to acknowledge at this time the excellent work and dedication of the Committee's research staff who, over the years, have given unstintingly of their talents in a manner which reflects credit upon them and all other civil service personnel of the United States.

DWIGHT D. EISENHOWER.

THE WHITE HOUSE,
APRIL 27, 1959.

Letter of Submittal

NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS,
WASHINGTON, D.C., *September 30, 1958.*

DEAR MR. PRESIDENT:

In compliance with the act of Congress approved March 3, 1915, as amended (U.S.C. title 50, sec. 151), I submit herewith the Forty-fourth Annual Report of the National Advisory Committee for Aeronautics for 1958.

At the close of business on this date the National Advisory Committee for Aeronautics goes out of existence. Under the terms of the National Aeronautics and Space Act of 1958, the property, facilities, and personnel (other than the members of the Committee) are absorbed in the establishment of the new National Aeronautics and Space Administration. This is, therefore, the concluding Annual Report of the National Advisory Committee for Aeronautics.

Respectfully submitted.

JAMES H. DOOLITTLE,
Chairman.

THE PRESIDENT,
The White House, Washington, D.C.

Preceding Page Blank

National Advisory Committee for Aeronautics

Headquarters, 1512 H Street NW., Washington 25, D.C.

Created by Act of Congress approved March 3, 1915, for the supervision and direction of the scientific study of the problems of flight (U.S. Code, title 50, sec. 151). Its membership was increased from 12 to 15 by act approved March 2, 1929, and to 17 by act approved May 25, 1948. The members have been appointed by the President and serve as such without compensation.

JAMES H. DOOLITTLE, Sc. D., Vice President, Shell Oil Co., Chairman
LEONARD CARMICHAEL, Ph. D., Secretary, Smithsonian Institution, Vice Chairman

ALLEN V. ASTIN, Ph. D., Director, National Bureau of Standards.
PRESTON R. BASSETT, D. Sc.
DETLEV W. BRONK, Ph. D., President, Rockefeller Institute for Medical Research.
FREDERICK C. CRAWFORD, Sc. D., Chairman of the Board, Thompson Products, Inc.
WILLIAM V. DAVIS, Jr., Vice Admiral, U.S. Navy (detached May 22, 1958, as Deputy Chief of Naval Operations (Air) and NACA membership terminated).
PAUL D. FOOTE, Ph. D., Assistant Secretary of Defense (Research and Engineering).
WELLINGTON T. HINES, Rear Admiral, U.S. Navy, Deputy and Assistant Chief of the Bureau of Aeronautics.
JEROME C. HUNSAKER, Sc. D., Massachusetts Institute of Technology.
CHARLES J. MCCARTHY, S.B., Chairman of the Board, Chance Vought Aircraft, Inc.
DONALD L. PUTT, Lieutenant General (retired from U.S. Air Force June 30, 1958, from service as Deputy Chief of Staff, Development, and NACA membership terminated).
JAMES T. PYLE, A.B., Administrator of Civil Aeronautics.
FRANCIS W. REICHELDERFER, Sc. D., Chief, U.S. Weather Bureau.
EDWARD V. RICKENBACKER, Sc. D., Chairman of the Board, Eastern Air Lines, Inc.
LOUIS S. ROTHSCHILD, Ph. B., Under Secretary of Commerce for Transportation.
THOMAS D. WHITE, General, U.S. Air Force, Chief of Staff.

HUGH L. DRYDEN, Ph. D., *Director*
JOHN W. CROWLEY, Jr., B.S., *Associate Director for Research*

JOHN F. VICTORY, LL.D., *Executive Secretary*
EDWARD H. CHAMBERLIN, *Executive Officer*

HENRY J. E. REID, D. Eng., Director, Langley Aeronautical Laboratory, Langley Field, Va.
SMITH J. DEFRANCE, D. Eng., Director, Ames Aeronautical Laboratory, Moffett Field, Calif.
EDWARD R. SHARP, Sc. D., Director, Lewis Flight Propulsion Laboratory, Cleveland, Ohio
WALTER C. WILLIAMS, B.S., Chief, High-Speed Flight Station, Edwards, Calif.

FORTY-FOURTH ANNUAL REPORT
National Advisory Committee for Aeronautics

WASHINGTON, D.C., *September 30, 1958.*

To the Congress of the United States:

In accordance with act of Congress, approved March 3, 1915, as amended (U.S.C., title 50, sec. 151), which established the National Advisory Committee for Aeronautics, the Committee submits its Forty-fourth Annual Report for the fiscal year 1958. This is the Committee's final report to the Congress.

The National Aeronautics and Space Act of 1958 (Public Law 85–568) provides in section 301 that the NACA "shall cease to exist" and "all functions, powers, duties, and obligations, and all real and personal property, personnel (other than members of the Committee), funds, and records" of the NACA shall be transferred to the National Aeronautics and Space Administration. The aforesaid act provides that "this section shall take effect 90 days after the date of the enactment of this act, or on any earlier date on which the Administrator shall determine, and announce by proclamation published in the Federal Register, that the Administration has been organized and is prepared to discharge the duties and exercise the powers conferred upon it by this act." The Administrator, Hon. T. Keith Glennan, has advised the Committee of his intention to issue such proclamation, effective October 1, 1958.

During the 43 years that the NACA was charged with responsibility to "supervise and direct the scientific study of the problems of flight, with a view to their practical solution," its great strength, as reflected in the advances in aeronautics resulting from its researches, has been the high caliber of its scientists, engineers, and supporting personnel. The gratitude of the entire Nation is due these public servants.

There is another reason—subordinate only to that cited above—why the NACA was so successful in accomplishing the technological progress in aeronautics that enabled the United States to achieve and maintain superiority in the air. This was the support the Congress gave over the years, appropriating funds for construction of highly specialized laboratory facilities. These were provided for the study of new problems posed by the steady increases in aircraft performance that earlier work had made possible.

On following pages, there appear brief accounts of the history of the NACA, covering the first 40 years by Dr. J. C. Hunsaker, my predecessor as Chairman, and summarizing activities of the past 3 years, by the undersigned.

The extent of our penetration into space in the next few years will depend in large measure upon how effectively we use knowledge in hand, and upon how hard we work to reach the distant performance goals set for instrumented and man-carrying spacecraft. I know I can speak with confidence and without reservation on behalf of the 8,000 dedicated people of the NACA, who will serve as the nucleus of the National Aeronautics and Space Administration. They will continue to merit the confidence, and the support, of the President, the Congress, and the people of the United States as they perform their new and tremendously important work.

J. H. DOOLITTLE,
Chairman.

526597—60——2

Part I—TECHNICAL ACTIVITIES

THE NACA—WHAT IT IS AND HOW IT OPERATES

During the 43 years since the Congress founded it as an independent Federal agency, the National Advisory Committee for Aeronautics has sought to assess the current stage of development of aircraft, both civil and military; to anticipate the research needs of aeronautics; to build the scientific staff and unique research facilities required for these research needs; and to acquire the needed new knowledge as rapidly as the national interest requires.

By discharging its primary responsibility—scientific laboratory research in aeronautics—the NACA serves the needs of all departments of the Government. The President appoints the 17 unpaid members of the Committee, who report directly to him. They establish policy and plan the research to be carried out by the 7,900 scientists, engineers, and other persons who make up the staff of the agency.

The NACA research programs have both the all-inclusive, long-range objective of acquiring new scientific knowledge essential to assure United States leadership in aeronautics and space and the immediate goal of solving, as quickly as possible, the most pressing problems. In this way, they effectively support the Nation's current aircraft and missile construction program.

Most of the problems to be studied are assigned to the NACA's research centers. The Langley Aeronautical Laboratory in Virginia works on structural, general aerodynamic, and hydrodynamic problems. The Ames Aeronautical Laboratory in California concentrates on high-speed aerodynamics. The Lewis Flight Propulsion Laboratory in Ohio is a center for powerplant studies. At the High-Speed Flight Station in California special fully instrumented research aircraft probe transonic and supersonic problems in flight. The Pilotless Aircraft Research Station at Wallops Island, Va., is a branch of the Langley Laboratory where rocket-powered free-flight models are used to attack aerodynamic problems in the transonic, supersonic, and hypersonic speed ranges.

A major task of the NACA since its beginning in 1915 has been coordinating aeronautical research in the United States. Through the members of the Committee and its 27 technical subcommittees, the NACA links the military and civil government agencies concerned with flight. The aviation industry, allied industries, and scientific institutions are also represented.

Assisting the Committee in determining and coordinating research programs are 4 major and 23 subordinate technical committees with a total membership of nearly 500. Members are chosen because of technical ability, experience, and recognized leadership in a special field. They also serve without pay, in a personal and professional capacity. They furnish valuable assistance in considering problems related to their technological fields, review research in progress at NACA laboratories and in other establishments, recommend new research to be undertaken, and assist in coordinating research programs.

Members of the technical committees and subcommittees and of the Industry Consulting Committee are listed in Part II of this report, beginning on page 83.

Research coordination is also accomplished through frequent discussions by NACA scientists with the staffs of research organizations of the aircraft industry, educational and scientific institutions, and other aeronautical and space agencies. Through a west coast office the NACA maintains close liaison with aeronautical research and engineering staffs in that important aviation area.

The first report of aeronautical research published by the NACA covered a study conducted at the Massachusetts Institute of Technology under a research contract. Throughout its existence, NACA has utilized this means of obtaining the benefits of the special talents, unique facilities, and fresh points-of-view of scientists outside its own laboratories. The resulting independent thought and novel attacks upon research problems are a continuing stimulus to NACA scientists. They produce valuable data and theoretical analyses to complement internal NACA research. Fifty-two reports of sponsored research were published during the fiscal year 1958. During this period the following institutions participated in the program:

Polytechnic Institute of Brooklyn
California Institute of Technology
University of California
Georgia Institute of Technology
University of Illinois
Iowa State College
Johns Hopkins University
Lightning & Transients Research Institute
University of Maryland

Massachusetts Institute of Technology
University of Michigan
University of Minnesota
New York University
Ohio State University
Rensselaer Polytechnic Institute
Southwest Research Institute
Stanford University
Syracuse University
University of Washington

Proposals from such institutions are carefully weighed to assure best use of the limited funds available to the NACA for sponsoring research outside its own facilities. Published research reports of the useful results of this part of the NACA program are distributed as widely as other NACA publications.

Most of NACA's research information is distributed by means of its publications. Technical Notes and Reports are not classified for military security reasons and are available to the public in general. Translations of important foreign research reports appear as Technical Memorandums. The NACA also prepares research reports containing classified information. For reasons of national security, these receive carefully controlled circulation. When such information can be declassified, the research reports may be given wider distribution. Current NACA publications are announced in the NACA Research Abstracts.

Every year the NACA holds a number of technical conferences with representatives of the aviation industry, the universities, and the military services present. Attendance at these conferences is restricted because classified material is presented and the subject matter discussed at each conference is focused on a specific field of interest.

Forty Years of Aeronautical Research

By J. C. HUNSAKER
*Chairman, National Advisory Committee for Aeronautics**
Regent, Smithsonian Institution

FROM THE SMITHSONIAN REPORT
FOR 1955

Before the Wrights' airplane flew, all the elements of the airplane were known: wings, rudders, engine, and propeller. The Wrights showed how to combine a man's senses and reflexes with the controls of a flying machine to make the machine both controllable about its attitude of equilibrium and steerable as desired. The secret of flight was manual control, in a three-dimensional fluid medium, in accordance with visual signals (the pilot's view of the ground and observation of his attitude relative to it—fixed axes of references), and monitored by visual observation of the response to his control actions (feedback). The Wrights' airplane was, however, like the Wrights' bicycles, inherently unstable and was controllable only when it had sufficient forward speed. Controlled by the sight, brain, nerves, and muscles of man, the Wrights' unstable vehicle was the first practical flying machine in the history of the world!

The Wright airplane was quick to respond to control action because it had no righting tendency if disturbed. The pilot was expected to act at once to recover from any disturbance of equilibrium. There was no fixed tail to push it into a safe glide if the engine stopped.

The early pioneers of flight worked with gliders and with self-propelled models. They strove for inherent stability and conceived the ideal to be an inherently stable flying platform on which the pilot need do no more than steer. Pénaud's model gliders of the 1870's, with long tails, were stable; Lanchester developed prior to 1908 a theory of dynamical stability for his model "aerodromes"; Langley flew stable steam-powered models in 1896, and Bryan in 1903 published the dynamical equations of motion for a glider, and criteria for inherent stability. In all cases, stability was found to require a tail and slightly elevated wingtips.

As might be expected from complete and constant dependence on one man's sometimes defective judgments and reactions, the Wright airplane could be tricky and even dangerous, especially in rough air. Furthermore, the gasoline engines of the day were notoriously unreliable. As a result of what later came to be known as the stall, Wright airplanes too often dived into the ground out of control. The press blamed it on an "air pocket" or "hole in the air."

European airplane builders were prompt to copy the Wright's system of control but soon discovered the dangers of instability. They abandoned the Wright's form of structure but retained their system of controls on airplanes shaped more like successful gliders.

The world was astonished in 1909 when Louis Bleriot flew across the English Channel in his little monoplane. It had a long tail, tractor propeller, and wheel landing gear. It was, in fact, the prototype of the airplanes of the next 20 years.

After 1910, with the mounting tension of approaching war, aeronautical development in Britain, France, Germany, Austria, Russia, and Italy was intensively pushed. Scientists, engineers, and industrialists were encouraged by their governments to devote their skills and resources to the new art. European progress was rapid, and at times spectacular.

While development of the airplane in the United States was dependent largely upon the efforts of a host of amateur inventors, there was in Europe a quick recognition of the gains to be had from aeronautical laboratories staffed by competent engineers.

The French were among the first to utilize scientific techniques in aeronuatics. The army's aeronautical laboratory at Chalais-Meudon and Gustav Eiffel's private wind tunnel clarified some of the principles of powered flight. As early as 1904 Riabouchinski had an aeronautical laboratory in Koutchino, Russia, and the same year Ludwig Prandtl began his classic aerody-

*Elected annually and served as chairman, 1941–56.

namic research at Göttingen University, Germany. After 1908, German aeronautical work was rapidly expanded, first at Göttingen and later at the government establishment at Adlershof, near Berlin. Italy provided an aerodynamics laboratory for her Specialist Brigade of Engineers.

Great Britain was relatively late in undertaking a national program of aeronautical research. However, Great Britain could record a full century of experiment. In the first half of the nineteenth century, Sir George Cayley had made important contributions, and Stringfellow and Henson had succeeded, as early as 1848, in flying a steam-powered monoplane model a distance of 120 feet. In 1866 the Aeronautical Society of Great Britain was formed; it served to stimulate research and experiment by individuals, and to provide a forum for interchange of information. Wenham (the Society's first president) and Phillips were the first to devise and use wind tunnels.

After the public demonstration of practical human flight by Wilbur Wright on his 1908 visit to France and Bleriot's 1909 cross-channel flight, the British Prime Minister was moved to appoint an Advisory Committee for Aeronautics with the great physicist Lord Rayleigh as chairman.

During the same period the United States made no special effort. The Army Signal Corps bought a few airplanes to train pilots and the Navy set up a flying school equipped with Glenn Curtiss seaplanes. When World War I erupted in 1914 it was reported that France had 1,400 airplanes, Germany 1,000, Russia 800, Great Britain, 400, and the United States 23!

DRIVE FOR A NATIONAL LABORATORY

The backward position of the United States in the application of applied science to this new art was realized by a growing list of prominent Americans who believed the situation was not only a national disgrace, but a possible danger to our security. More Americans, including the leaders in Congress, were strong for neutrality, and felt that any special government concern with aeronautical development might imply belligerent intentions.

Capt. W. I. Chambers, USN, officer-in-charge of naval-aviation experiments, proposed in 1911 that a national aeronautical research laboratory be set up under the Smithsonian Institution. Along with objections by both the War and Navy Departments, the plan was referred to President Taft's Committee on Economy and Efficiency, from which it was never returned.

Two men who were more influential in the drive for a national aeronautical laboratory were Alexander Graham Bell and Charles Doolittle Walcott. The former, as a regent of the Smithsonian Institution, had been a supporter of Langley and had experimented with the lifting capabilities of kites. With Mrs. Bell he formed the Aerial Experiment Association in 1907 to support the airplane experiments of Glenn Curtiss, Lt. T. E. Selfridge, F. W. ("Casey") Baldwin, and J. A. D. McCurdy. Their efforts resulted in the development of the Curtiss biplanes and the use of ailerons to replace the Wright's wing warping for lateral control.

Dr. Walcott was no aeronautical scientist; his field was geology. But Dr. Walcott, as successor to Professor Langley as Secretary of the Smithsonian, was determined that the Institution should resume its position as a leader of aeronautical science in America. How better than to have the new aeronautical laboratory attached to the Smithsonian!

The establishment of a national aeronautical laboratory was pressed by members of the National Academy of Sciences, notably by Bell and Walcott. The Academy had been created by Congress during the Civil War and had the duty of giving advice to the Government, when asked. The Academy, as a body, was not asked for advice on this matter, but its members appear to have been influential in persuading President Taft to appoint on December 19, 1912, a 19-man commission to consider such a national laboratory and its scope, organization, and cost, and to make a recommendation to the Congress.

The President's Commission was headed by Dr. R. S. Woodward of the National Academy of Sciences and the Carnegie Institution of Washington and included Dr. Walcott. The Army, Navy, Weather Bureau, and Bureau of Standards were represented, as well as interested civilians. The Commission recommended that the laboratory be established in Washington and administered by the regents of the Smithsonian Institution. President Maclaurin of the Massachusetts Institute of Technology objected to the location at Washington, which the majority report favored as "conveniently accessible to statesmen of the National Government who may wish to witness aeroplane demonstrations."

Unfortunately, the President had appointed the Commission without "the advice and consent of the Senate." Authorizing legislation failed to get unanimous consent and the Commission's report was buried in the archives.

Probably as a result of his service with the President's Commission, President Maclaurin in May 1913 persuaded the Corporation of M.I.T. to authorize a graduate course in aeronautical engineering and a wind tunnel for aerodynamic research in the Department of Naval Architecture. He requested the Secretary of the Navy to detail an officer of the Construction Corps to take charge. The writer was so detailed for 3 years.

At about the same time, the Smithsonian regents decided to reopen Langley's old laboratory, with Dr. Al-

bert F. Zahm in charge. It was arranged by Walcott and Maclaurin to send Zahm and Hunsaker abroad, armed with personal introductions to scientific friends. Their objective was to visit the principal aeronautical research laboratories and, as far as possible, to learn how to operate the special facilities and equipment in use there with a view to duplicating them in this country.

Visits were made to the Royal Aircraft Factory, the National Physical Laboratory, and Cambridge University in England; to the St. Cyr, Chalais-Meudon, and Eiffel Laboratories in France; and to the Deutsche Versuchsanstalt für Luftfahrt and Göttingen University in Germany. In 1913, security restrictions did not apply to scientific and engineering work and the visitors were cordially received. In fact, the Massachusetts Institute of Technology later built its wind tunnel from drawings supplied by Sr. Richard Glazebrook of the NPL and the NPL aerodynamic balances duplicated by Sir Horace Darwin's Cambridge scientific instrument shops.

Dr. Zahm's report, published by the Smithsonian in 1914, made clear the width of the gap between European and American positions in aeronautical science. This report had an important influence on the decision of the Smithsonian regents in 1915 to memorialize the Congress once again on the subject of a national aeronautical laboratory.

Woodrow Wilson approved the Smithsonian plan of reopening Langley's laboratory with representatives of the War, Navy, Agriculture, and Commerce Departments serving on an Advisory Committee. However, the Comptroller ruled that, under an act of 1909, such an Advisory Committee could not serve without the authority of the Congress.

On December 10, 1914, the Chancellor of the Smithsonian, Chief Justice White, appointed Dr. Alexander Graham Bell; Senator William J. Stone of Missouri; Representative Ernest W. Roberts of Massachusetts, and John B. Henderson, Jr., regents; and Dr. Walcott, Secretary, to consider once again "questions relative to the Langley Aerodynamical Laboratory." On February 1, 1915, a "memorial on the need for a National Advisory Committee for Aeronautics" was delivered to the Speaker of the House. Pertinent sentences from the memorial follow:

> This country led in the early development of heavier-than-air machines. Today it is far behind. . . . A National Advisory Committee for Aeronautics cannot fail to be of inestimable service in the development of the art of aviation in America. Such a committee, to be effective, should be permanent and attract to its membership the most highly trained men in the art of aviation. . . . Through the agency of subcommittees, the main advisory committee could avail itself of the advice and suggestions of a large number of technical and practical men. . . . The aeronautical committee should advise in relation to the work of the Government in aeronautics and the coordination of the activities of governmental and private laboratories, in which questions concerned with the study of the problems of aeronautics can be experimentally investigated.

The Navy heartily endorsed the idea in a letter dated February 12 and signed by Franklin D. Roosevelt as Acting Secretary.

ESTABLISHMENT OF NACA

The joint resolution establishing the Advisory Committee and authorizing the President to appoint its 12 members was given final form in February. The people of the United States were at the time generally anxious to avoid involvement in what was then called the War in Europe. President Wilson is said to have felt that the establishment of a new aeronautical enterprise might reflect on American neutrality. Such reasoning may explain why the resolution was attached to the naval appropriation bill; perhaps a more likely reason was that in the rush to clear the legislative "logjam" by March 4, the date for adjournment of the Congress, Representative Roberts, Smithsonian regent, had found it simpler to effect its adoption by introducing the measure, as a rider to the naval appropriation bill, in the Committee on Naval Affairs, of which he was a member.

Following is the provision in the Naval Appropriations Act, approved March 3, 1915:

> An Advisory Committee for Aeronautics is hereby established, and the President is authorized to appoint not to exceed twelve members, to consist of two members from the War Department, from the office in charge of military aeronautics; two members from the Navy Department, from the office in charge of naval aeronautics; a representative each of the Smithsonian Institution, of the United States Weather Bureau, and of the United States Bureau of Standards; together with not more than five additional persons who shall be acquainted with the needs of aeronautical science, either civil or military, or skilled in aeronautical engineering or its allied sciences: *Provided*, That the members of the Advisory Committee for Aeronautics, as such, shall serve without compensation: *Provided further*, That it shall be the duty of the Advisory Committee for Aeronautics to supervise and direct *the scientific study of the problems of flight, with a view to their practical solution, and to determine the problems*[1] which should be experimentally attacked, *and to discuss their solution and their application to practical questions.* In the event of a laboratory or laboratories, either in whole or in part, being placed under the direction of the committee, the committee may direct and conduct research and experiment in aeronautics in such laboratory or laboratories: *And provided further*, That rules and regulations for the conduct of the work of the committee shall be formulated by the committee and approved by the President.
>
> That the sum of $5,000 a year, or so much thereof as may be necessary, for five years is hereby appropriated, out of any money in the Treasury not otherwise appropriated, to be immediately available, for experimental work and investigations undertaken by the committee, clerical expenses and supplies, and necessary expenses of members of the committee in going to, returning from, and while attending meetings of the committee:

[1] Italics in this and the following quotation supplied by the author for emphasis.

Provided, That an annual report to the Congress shall be submitted through the President, including an itemized statement of expenditures.

This language establishing the NACA closely followed that used by the British Prime Minister when he announced the formation of a similar committee to the House of Commons on May 5, 1909, in the following words:

It is no part of the general duty of the Advisory Committee for Aeronautics either to construct or to invent. Its function is not to initiate but to consider what is initiated elsewhere, and is referred to it by the executive offices of the Navy and Army construction departments. The problems which are likely to arise in this way for solution are numerous, and it will be the work of the committee to advise on these problems and to seek their solution by the application of both theoretical and experimental methods of research.

The work desired thus falls into three sections: (1) *The scientific study of the problems of flight, with a view to their practical solution.* (2) Research and experiment into these subjects in a properly equipped laboratory with a trained staff. (3) The construction and use of dirigibles and aeroplanes, having regard mainly to their employment in war.

The Advisory Committee are to deal with the first section, and also *to determine the problems* which the experimental branch should attack, *and discuss their solutions and their application to practical questions.* The second section represents the work referred to the laboratory (the National Physical Laboratory), while the duties concerned with the third section remain with the Admiralty and the War Office.

On April 2, 1915, President Woodrow Wilson appointed to the new Committee: Prof. Joseph S. Ames, of the Physics Department of Johns Hopkins University; Capt. Mark L. Bristol, USN, Director of Naval Aeronautics, Navy Department; Prof. William F. Durand, of the Engineering Department of Leland Stanford University; Prof. John F. Hayford of the Engineering Department of Northwestern University; Dr. Charles F. Marvin, Chief of the U.S. Weather Bureau; Hon. Byron R. Newton, Assistant Secretary of the Treasury; Prof. Michael I. Pupin of the Physics Department of Columbia University; Lt. Col. Samuel Reber, USA, Officer-in-Charge, Aviation Section of the Signal Corps, War Department; Naval Constructor Holden C. Richardson, USN, Department of Construction and Repair, Washington Navy Yard; Brig. Gen. George P. Scriven, USA, Chief Signal Officer, War Department; Dr. Samuel W. Stratton, Director, National Bureau of Standards; and Dr. Charles D. Walcott, Secretary, Smithsonian Institution.

Of the initial 12 members, 6 were members of the National Academy of Sciences (within the period of their NACA membership). It is of interest to note that for 40 years all chairmen of the NACA except the first, General Scriven, have been members of the National Academy. In 1955, there are 5 Academy members out of 17 members of the NACA. This statistic is of significance in view of the increasing impact on aeronautics of advances in many fields of science: for example, physiology and psychology of pilots, chemistry of combustion, physics of metals, physics of the atmosphere, acoustics, communications, electronics. The Committee is strengthened by the special knowledge of its individual members.

By direction of the President, the Secretary of War called the first meeting. The date was April 23, 1915; the place, his office. Conforming with the designation in the call for the first meeting, the word "National" was prefixed to the title "Advisory Committee for Aeronautics." General Scriven was elected temporary chairman, and Naval Constructor Richardson temporary secretary. With formulation of rules and regulations, subsequently approved by the President, the temporary chairman and secretary were elected for one year.

Perhaps the most important regulation adopted was for an executive committee, composed of 7 of the 12 members of the Advisory Committee. The full Committee was to meet only semiannually. The executive committee was set up to meet regularly throughout the year and was charged with the administration of the affairs of the Committee and "general supervision of all arrangements for research."

Dr. Walcott was the first chairman of the executive committee. The other members were Dr. Ames, Captain Bristol, Dr. Marvin, Dr. Pupin, Colonel Reber, and Dr. Stratton, with Naval Constructor Richardson, ex officio, as secretary. Improvised quarters in the Army's Aviation Section were used the first year.

In the beginning the executive committee was a working group; the NACA had no paid personnel. It was not until June 23 that the first employee was hired. He was John F. Victory; 41 years later he is continuing his faithful, effective service to the Committee. In 1917 he was named assistant secretary of the Committee; 10 years later he became secretary, and in 1945, executive secretary.

One of the first problems was to examine what aeronautical research was then in progress in the United States—both under Government auspices and by private organizations—and then to effect rational coordination to assure maximum value from the total effort. Congressman Roberts, reporting on the need for the NACA on February 19, 1915, had well stated the situation:

Besides these governmental agencies [he named the Bureau of Standards, the Weather Bureau and the War and Navy Departments] for the development of aviation, individuals in civil life have devoted time and expense in the scientific study and practical development of aeronautics. At the present time all of these agencies, both governmental and private, work independently without any coordination of activities.

Ten years later Dr. Ames gave a prime reason for "the great success of the Committee, because the Committee is a success," the coordination, on a rational scale,

of American aeronautical research. His comments were made before hearings of the President's Aircraft Board (often called the Morrow Board). He spoke as chairman of the executive committee, to which position he had been elected when Dr. Walcott became Committee chairman in 1919.

In part, Dr. Ames said:

> The organization has an Executive Committee which appoints a number of technical subcommittees whose function it is to coordinate the research work throughout the country. . . . The various problems which all the services of the Government and the people engaged in industry, so far as we know, have in mind are brought before these subcommittees. The importance of each problem is discussed, and a program is laid out. . . .
>
> Around our table meet . . . representatives from all the Government services involved. . . . We work for all the departments of the Government.
>
> Furthermore, there are discussions going on at our table between the Army and the Navy and all other people interested which otherwise would not take place. We are really a coordinating body and that function would be impossible if our organization were to be transferred to any executive department as such, because if our Committee were to be a part of any department it would necessarily follow that the aeronautical needs of that department would be primarily served. . . .
>
> We think, therefore, that in our independent existence we offer a wonderful opportunity for serving all the departments.

In 1915 one of the first projects undertaken by the executive committee was a survey of facilities available "for the carrying on of aeronautic investigations." It was determined that "a number of institutions have available mechanical laboratories and engineering courses capable of application to aeronautics, but only the Massachusetts Institute of Technology and the University of Michigan so far offer regular courses of instruction and experimentation." Note was made of the experiments with full-scale propellers mounted on a whirling table, being conducted at Worcester Polytechnic Institute.

"It appears that the interest of colleges is more one of curiosity than that of considering the problem as a true engineering one, requiring development of engineering resources and, therefore, as not yet of sufficient importance to engage their serious attention," the NACA commented in its first annual report. "Manufacturers are principally interested in the development of types which will meet Government requirements or popular demand, but which will not involve too radical or sudden changes from their assumed standard types."

The Committee recognized that "considerable work had already been accomplished with which the general public is not acquainted." The annual report said of this point: "This covers lines of development and investigation which if published would save money and effort on the part of individual investigators and inventors who are now duplicating investigations already made by others. . . . Some of this information is already embodied in reports which are only accessible to a few interested parties who know of its existence."

The Smithsonian Institution had published a bibliography of aeronautics, covering the period through the middle of 1909. Now the NACA undertook publication of later bibliographies compiled by Paul Brockett of the Smithsonian. The first such volume covered the period 1909–16; as soon as past years had been "caught up," the bibliography was published annually into the early thirties.

The Committee was fully aware that to fulfill its obligations would require not only a well-equipped, suitably staffed laboratory, but also a flight test center where engineers could determine "the forces acting on full-sized machines." It was felt, however, that "since the equipment of such a laboratory as could be laid down at this time might well prove unsuited to the needs of the early future, it is believed that such provision should be the result of gradual development."

In October 1916 the Committee recommended that the War Department (which alone had funds available) purchase land about 4 miles north of Hampton, Va., for use by the Army and Navy as an aircraft proving ground. Named Langley Field, this site became the home of NACA's first research center. The War Department used it for pilot training during World War I. Aircraft development work of both the Army and Navy was centered elsewhere.

Lacking its own facilities, the NACA took prompt steps to contract for research to be performed for it by others. The first annual report included seven reports, as follows:

No. 1. Report on behavior of aeroplanes in gusts, by the Massachusetts Institute of Technology.
- Part 1. Experimental analysis of inherent longitudinal stability for a typical biplane, by J. C. Hunsaker.
- Part 2. Theory of an aeroplane encountering gusts, by E. B. Wilson.

No. 2. Investigation of pitot tubes, by the United States Bureau of Standards.
- Part 1. The pitot tube and other anemometers for aeroplanes, by W. H. Herschel.
- Part 2. The theory of the pitot and venturi tubes, by E. Buckingham.

No. 3. Report on investigations of aviation wires and cables, their fastenings and terminal connections, by John A. Roebling's Sons Co.

No. 4. Preliminary report on the problem of the atmosphere in relation to aeronautics, by Prof. Charles F. Marvin.

No. 5. Relative worth of improvements on fabrics, by the Goodyear Tire & Rubber Co.

No. 6. Investigations of balloon and aeroplane fabrics, by the United States Rubber Co.
- Part 1. Balloon and aeroplane fabrics, by Willis A. Gibbons and Omar H. Smith.
- Part 2. Skin friction of various surfaces in air, by Willis A. Gibbons.

No. 7. Thermodynamic efficiency of present types of internal-combustion engines for aircraft, by Columbia University.
- Part 1. Review of the development of engines suitable for aeronautic service, by Charles E. Lucke.
- Part 2. Aero engines analyzed with reference to elements of process or function, by Charles E. Lucke.

"What has already been accomplished by the Committee has shown that although its members have devoted as much personal attention as practicable to its operations, yet in order to do all that should be done technical assistance should be provided which can be continuously employed," the Committee said in its first Annual Report.

For the fiscal year 1917 the NACA asked for and received $85,000. Of the funds available, $68,957.35 (all that was not spent otherwise) went toward construction of the new laboratory at Langley Field. Its total cost was estimated at $80,000, a figure that later was revised upward.

The war was over before the "Committee's field station" at Langley Field could be said to be in useful operation. The annual report for 1919 noted that the Committee's first wind tunnel, with a 5-foot test section, was completed but inoperative for lack of power. The Army's power plant at Langley Field was incomplete, with construction stopped for lack of money.

With the Army planning to keep its experimental work in aeronautics at McCook Field, Dayton, and with the Navy's experimental aviation work centered at Norfolk, the NACA in 1919 felt it had good reasons for moving its field station activities to Bolling Field, just across the Anacostia River from the Capital. It asked Congress to authorize the move:

> The Committee believes it uneconomical and unsatisfactory to remain at Langley Field. The same work can be carried on more efficiently, more promptly, and more economically at Bolling Field, where the work can be closely watched by all members of the Committee, and where the members of the engineering staff in charge of work can have ready access to the Committee, to large libraries, and other sources of information, constant communication with the Bureau of Standards, a more satisfactory market for labor and supplies and adequate power supply, and relief from the perplexing question of securing quarters at Langley Field or in Hampton or other nearby towns.

Congressional approval for the move to Bolling Field did not come. In April 1920, the Committee, perhaps with a collective sigh, took action that accepted as permanent the Langley Field site for the "field station." It sought Presidential approval of the name, "Langley Memorial Aeronautical Laboratory." President Wilson concurred, and dedicatory exercises were conducted on June 11. Attendance included guests, it was later reported, "of whom a number had flown to the field."

This date, June 11, 1920, may be considered the real beginning of NACA's own program of aeronautical research, conducted by its own staff in its own facilities. The previous year a start had been made in obtaining full-scale performance data from flight tests, but now the availability of a wind tunnel made possible systematic investigations of critical aerodynamic problems, such as: (1) Comparison between the stability of airplanes as determined from full-flight test and as determined from calculations based on wind-tunnel measurements; (2) comparison between the performance of full-scale airplanes and the calculations based on wind-tunnel experiments, and (3) airfoils, including control surfaces, with special attention to thick sections, plus combinations and modification of such sections.

THE COMMITTEE'S ADVISORY FUNCTIONS

This has been essentially a chronological account, first, of events preceding establishment of the NACA, and then its early steps to undertake its responsibilities as the nation's aeronautical research establishment. At this point it is in order to glance briefly at some early activities of the Committee which were consonant with the "Advisory" in its name.

In 1916 the executive committee invited engine manufacturers to attend a meeting on June 8 in Dr. Walcott's office at the Smithsonian Institution to discuss the problem of obtaining more powerful and more reliable engines and to bring about a better understanding between builders and users. Representatives of the military services were in attendance, and although it is to be doubted that many problems were solved, unquestionable good was done by bringing them into sharp focus. Another benefit from the meeting was an arrangement whereby the Society of Automotive Engineers became active in providing assistance in the solution of aircraft powerplant problems.

Also in 1916 the Committee examined the problem of the carriage of mail by air. The Post Office Department had failed in efforts to establish a contract airmail service in Alaska and from New Bedford to Nantucket Island. Airmail was then considered to be justified only over almost impossible terrain. "Conditions of both these routes were so severe as to deter responsible bidders from undertaking this service," the Committee decided. It felt, nonetheless, that because of the great progress made in aviation, the Post Office should set up one or more experimental routes, "with a view to determining the accuracy, frequency, and rapidity of transportation which may reasonably be expected under normal and favorable conditions, and therefrom to determine the desirability of extending this service wherever the conditions are such as to warrant its employment."

The above-stated opinion was transmitted to Congress in 1916 as a recommendation. In 1918, when $100,000 was appropriated for creation of an experimental airmail service, the NACA invited the attention of the Secretary of War to the following facts: "Practically all aircraft manufacturing facilities in the United States were being utilized by the War and Navy Departments, and all capable aviators were in the military or naval air services . . . [and] it was exceedingly desirable that Army aviators be regularly

and systematically trained in long-distance flying . . . [and that] it would appear to be to the advantage of the War Department and of the Government generally that military airplanes be used to render practical and effective service" in carrying mail between Washington, Philadelphia, and New York. In its 1918 annual report the NACA viewed with satisfaction the manner in which the experimental airmail service had been established along the lines recommended, and expressed the opinion it had already "been sufficiently well demonstrated since its inauguration to justify its extension generally."

In 1921, the Committee noted in a special report to the President that—

> There are several causes which are delaying the development of civil aviation, such as the lack of airways, landing fields, aerological service, and aircraft properly designed for commercial uses. The Air Mail Service stands out as a pioneer agency, overcoming these handicaps and blazing the way, so to speak, for the practical development of commercial aviation. As a permanent proposition, however, the Post Office Department, as its functions are now conceived, should no more operate directly a special airmail service than it should operate a special railroad mail service; but until such time as the necessary aids to commercial aviation have been established it will be next to impossible for any private corporation to operate under contract an airmail service in competition with the railroads.

In January 1917, the War and Navy Departments complained to the NACA about prohibitive prices for aircraft, said to be due to "the extra item of royalty added by each firm in anticipation of infringement suits by owners of alleged basic aeronautic patents who were then threatening all other airplane and seaplane manufacturers with such suits, and causing thereby a general demoralization of the entire industry."

The Committee held meetings with Government officials, owners of patents, and aircraft manufacturers. It then recommended organization of a Manufacturers Aircraft Association to effect the cross licensing of aeronautic patents and to make the use of all such patents available to any member firm at the relatively small cost of $200 per airplane. This happy solution was adopted, and resulted, in the Committee's opinion, in "the prevention of the virtual deadlock with danger of monopoly existing under the patent situation."

In many other ways the Committee gave advisory service on such varied matters as provision of insurance for aviators, naming of flying fields "in commemoration of individuals who had rendered conspicuous service," aerial mapping techniques, and selection of a site near Washington for a "landing field" to provide "accommodation of transient aviators."

A special subcommittee during World War I examined some 7,000 inventions and suggestions in the field of aeronautics. Of this work the NACA later said, "The great majority of the suggestions received are obviously of an impractical nature. Several, however, have seemed worthy of further consideration and have been referred to military or naval experts." In addition to this arduous task, the Committee served as arbitrator in the settlement of disputes involving technical questions between private parties and the military services.

Perhaps the most important of NACA's advisory services was the leadership which the Committee gave to the efforts for legislation necessary to the orderly development of civil aviation. With cessation of hostilities in 1918, the Committee promptly took up the basic question of what should be done about the civil use of aircraft. Although it would be nearly 8 years before the required Federal legislation was adopted (the Air Commerce Act of 1926), the recommendations made by the Committee in 1918 encompassed what was needed: "Federal legislation . . . governing the navigation of aircraft in the United States and including the licensing of pilots, inspection of machines, uses of landing fields, etc. . . . designed to . . . encourage the development of aviation . . . and at the same time to guide the development . . . along such lines as will render immediate and effective military service to the Nation in time of war."

On April 1, 1921, President Harding directed the Committee to meet with representatives of interested Government departments to determine what could be done to achieve Federal regulation of air navigation without legislative action, and what new legislation was needed. April 9, the recommendations were formulated. The Committee was brief: "Federal regulation of air navigation cannot be accomplished under existing laws. . . . It is recommended that a Bureau of Aeronautics be established in the Department of Commerce."

There were other NACA proposals in 1921: That the Post Office be authorized to extend its airmail routes across the continent, and that naval aviation activities be centered in a Bureau of Aeronautics within the Navy Department.

In its Annual Report for 1921, the NACA noted the principal reason for delay in passing the recommended legislation:

> The Committee is not unmindful of the legal sentiment that a constitutional amendment should first be adopted before such legislation is enacted, on the ground that effective regulation of air navigation as proposed would otherwise be unconstitutional as violating the rights of property and encroaching upon the rights of States. To postpone such legislation until a constitutional amendment can be proposed and ratified would have the effect of greatly retarding the development of commercial aviation, with no assurance that sufficient popular interest would ever be aroused to accomplish such an amendment. The Committee is of the opinion that the most effective course to be

followed for the development of aviation would be first to enact the legislation deemed necessary for the Federal regulation of air navigation and the encouragement of the development of civil aviation, and let the question of the constitutionality of such legislation be tested in due course. In the meantime, there would be development in civil and commercial aviation, and if eventually the legislation which made possible such development should be definitely determined to be unconstitutional there would then, in all probability, be sufficient public interest in the subject and popular demand to adopt an amendment to the Constitution.

Years of perseverance culminated, in April 1926, in a careful analysis by the Committee of fundamental differences of opinion respecting certain aspects of the basic legislation then before the Congress. The solutions then proposed by the NACA were accepted by the joint Senate-House conferees, and the Air Commerce Act became law on May 20, 1926.

"This act provides the legislative cornerstone for the development of commercial aviation in America," the Committee said. It "gives an important measure of stability to commercial aviation as a business proposition and in its direct effects will go far toward encouraging the development of civil and commercial aviation."

AERONAUTICAL RESEARCH

The Air Commerce Act made the Secretary of Commerce responsible for the regulation of civil aviation, and for its encouragement. At the same time, this action freed the NACA from an "advisory" burden it had carried during its first 10 years. From now on, the Committee could concentrate upon its chief responsibility—the conduct of aeronautical research.

During the first 10 years of the Committee's existence demands upon the time of NACA members were very heavy. From 1915 to 1919 the Committee had three chairmen: General Scriven, 1915; Dr. Durand, 1916–18, and Dr. John R. Freeman, 1919. Dr. Freeman was sent on a mission to China and was succeeded as chairman in 1919 by Dr. Walcott, who had served as chairman of the executive committee since its formation in 1915.

Dr. Walcott was succeeded as chairman of the executive committee by Dr. Ames, who effectively supported Dr. Walcott until the latter's death in 1927. At that time Dr. Ames became chairman to serve until his retirement in 1939. The fact that he was located in Baltimore, where he headed the physics department of Johns Hopkins University until he became president of the University in 1929, proved no handicap. Dr. Ames was in Washington as often and as long as Committee business required.

With the development of laboratory facilities at Langley, the NACA began building a competent engineering staff. The Langley Laboratory attracted young men with good training, who could grow to do work of increasing importance. The independence of the NACA was one of the attractions, as was also the opportunity for the young engineer to sign the published report of his own research. So was the availability of superior research and test equipment.

In 1919 the Committee invited Dr. George W. Lewis, professor of mechanical engineering at Swarthmore College, to become its executive officer. In this capacity, he was called upon to guide the research programs and to plan and build the research tools needed. In 1924 Dr. Lewis' title was changed to one that more closely described his responsibilities, director of aeronautical research. From then until 1945, when his health failed under the tremendous burdens he insisted upon carrying during World War II, George Lewis gave devoted and effective leadership to the staff of the Committee.

While the Committee was acquiring the equipment at Langley necessary for the research programs envisioned, use was made of facilities available elsewhere for certain investigations. Before the end of World War I, Dr. Durand was conducting most valuable research on air propellers at Leland Stanford University, and at MIT the availability of a wind tunnel and staff made possible fundamental aerodynamic research on stability and control and on the characteristics of wing sections.

The National Bureau of Standards worked on aeronautical problems at the request of the NACA and with its financial support. The Bureau developed apparatus for the study of combustion problems under simulated conditions of high altitude and later equipped itself with wind tunnels for fundamental research on turbulence and boundary-layer problems.

The aeronautical experimentation carried on at the Navy Yard in Washington and at McCook Field in Dayton was correlated with a comprehensive plan which the NACA formulated and which was kept up to date as military and industry needs changed. The pioneering work by Naval Constructor Richardson on seaplane hulls, and the later researches directed by Chief Constructor David W. Taylor, contributed significantly to the advancement of naval aviation. At McCook Field (later moved and enlarged to become Wright Field) the availability of a wind tunnel caused the NACA to detail one of its first technical employees, Dr. George de Bothezat (best known, perhaps, for his later work with helicopters) to Dayton to assist with aeronautical research there.

In 1920 the NACA's first wind tunnel was put to work. With relatively minor exceptions, this first major piece of equipment was patterned after one at the British National Physical Laboratory. The work that could be done with this tunnel was essentially no different from that which could be accomplished at the Navy Yard, McCook Field, MIT, or other locations where conventional wind tunnels were located.

In June 1921, the executive committee decided to build a new kind of wind tunnel. Utilizing compressed air,

it would allow for "scale effects" in aerodynamic model experiments. This tunnel represented the first bold step by the NACA to provide its research personnel with the novel, often complicated, and usually expensive equipment necessary to press forward the frontiers of aeronautical science. It was designed by Dr. Max Munk, formerly of Göttingen.

The value of the new tunnel was explained in 1922 by Dr. Ames:

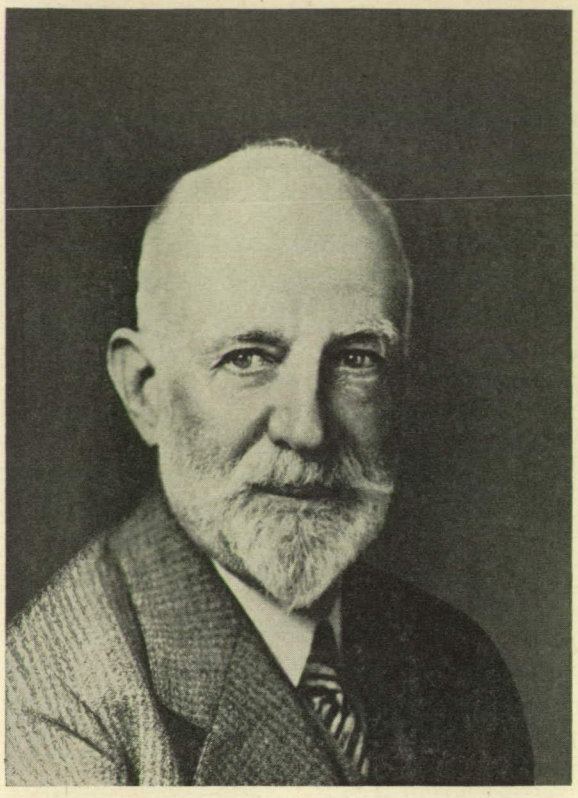
> When a new design of airplane . . . is made, it is customary to construct a model of it, one-twentieth the size or less, and to experiment upon this. The method now in universal use is to suspend the model from suitable balances in a stream of air . . . at a velocity of 60 mph. . . . The balances register the forces and moments acting on the model. From the results of such measurements one decides whether the original design is good or not. But is one justified in making such a decision? Why should the same laws apply to a little model inside the wind tunnel, as it is called, and to the actual airplane flying freely through the air? Evidently there is ground for grave uncertainty. The Committee has perfected a method for obviating this. It has been known from aerodynamic theory for some time that the change in scale, from airplane to its model, could be compensated by compressing the air from ordinary pressure to 20 or 25 atmospheres: as the structure moving through the air is reduced in size from 50 feet to 2 feet, the molecules of the air are brought, by comparison, closer and closer together until their distance apart is one twenty-fifth of what it was originally. The effect of scale is thus fully compensated and experiments upon a model in this compressed air have a real meaning. The Committee has constructed a large steel tank, 34 feet long and 15 feet in diameter, inside which is placed a wind tunnel with its balances, etc., and in which the air may be kept in a state of high compression. The information to be obtained from the apparatus will be the most important ever given airplane designers.

Experience with simple airplane models without propellers in the variable-density tunnel encouraged the NACA, in June 1925, to construct a wind tunnel large enough to test full-scale airplane propellers under conditions of flight. This was a costly decision, but the cost was repaid manyfold by improved airplane performance.

The propeller research tunnel was put into operation in 1927. It had a circular test section 20 feet in diameter and was powered by two Diesel engines rated at 1,000 hp. each. Its air speed was 110 mph. and, at the time, it was the largest wind tunnel in the world. Almost from the beginning of its use, the PRT provided information leading to design changes which resulted in dramatic improvements in airplane performance.

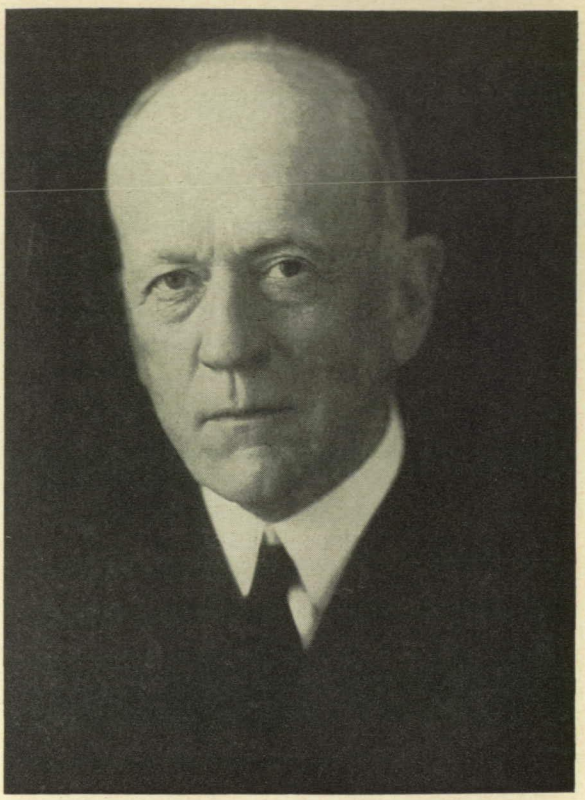
The first and most spectacular of these productive researches brought about the development of what became known as the NACA cowling for air-cooled radial engines. In its 1928 report, the Committee said that "by the application of the results of this study to a Curtiss AT-5A Army pursuit training plane, the maximum speed was increased from 118 to 137 mph. This is equivalent to providing approximately 83 additional horsepower without additional weight or cost of engine, fuel consumption, or weight of structure. This single contribution will repay the cost of the Propeller Research Tunnel many times."

The Collier Trophy, awarded annually "for the greatest achievement in aviation in America, the value of which has been thoroughly demonstrated by actual use during the preceding year," went to the NACA for the development of this form of cowling. President Hoover made the presentation on January 3, 1930 (for the year 1928), and after the reading of the citation Dr. Ames responded that "a scientist receives his reward from his own work in believing that he has added to human knowledge; but he is always gratified when his work is recognized as good by those competent to judge."



A second important benefit accruing from work in the PRT was more positive information about the best location of engine nacelles. The engines of the Ford Tri-motor, and similar aircraft of the twenties, were hung below the wing. As a consequence of research reported confidentially in 1930, multiengine aircraft designed thereafter had their engines faired into the leading edge of the wing with an important gain in speed.

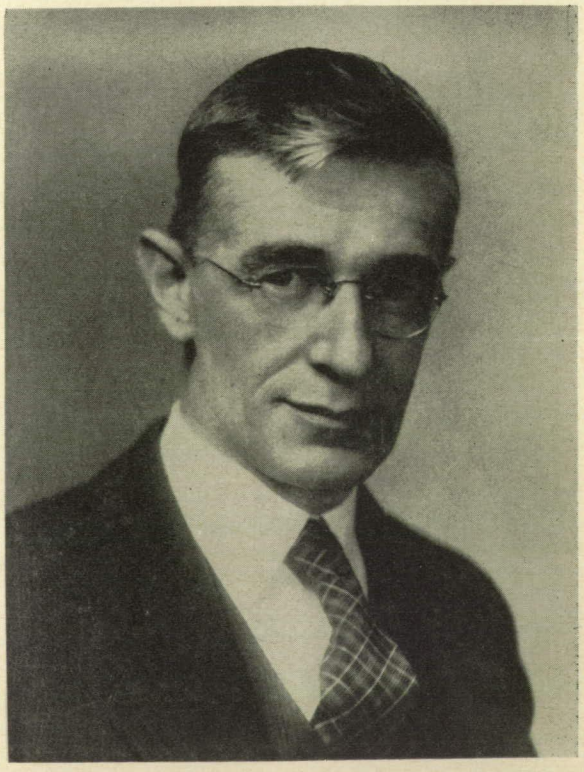
The systematic work accomplished in the PRT led to other practical design changes. For example, it was possible to obtain an accurate estimate of the drag caused by such apparently insignificant details as the location of a gasoline filler cap. Similarly, engineers studied the aerodynamic interference of wings and fuselage, and the use of fillets to reduce the interference was proposed. (In 1928 the NACA published its first Technical Note on this subject, by Melvin N. Gough.)



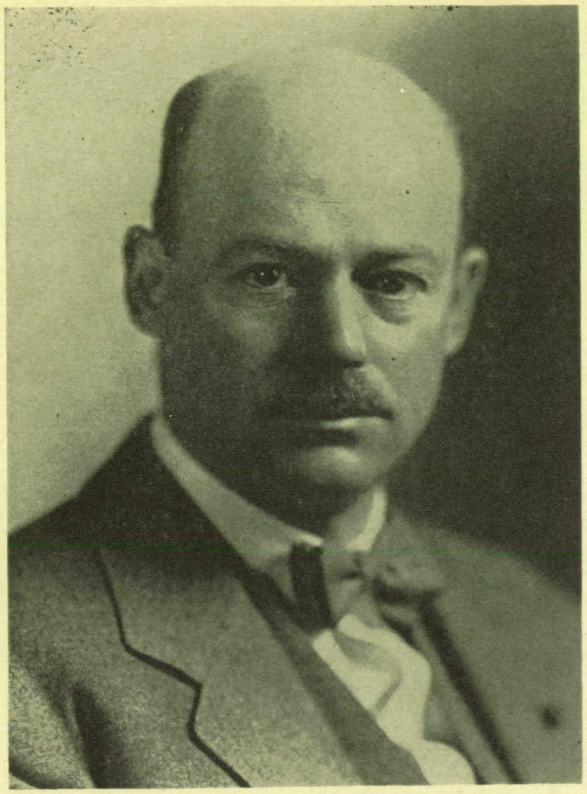
That the fixed landing gear represented a large amount of drag had long been appreciated, but it was not until the PRT became operative that the drag penalties of fixed landing gear could be determined precisely. The higher speeds made possible by use of the NACA cowling, the wing positioning of the engine nacelles, the filleting of wing-fuselage junctures, and other aerodynamic refinements now made attractive the investment of added cost and weight implicit in retractable landing gear.

In 1933, looking at the gains from the research at its Langley Laboratory, the Committee said: "No money estimate can be placed on the value of superior performance of aircraft in warfare . . . nor can a money estimate be placed on . . . improved safety. . . . The value in dollars and cents of improved efficiency in aircraft resulting from the Committee's work can, however, be fairly estimated. For example, the results of . . . researches completed by the Committee within the last few years, show that savings in money alone will be made possible in excess annually of the total appropriations for the Committee since its establishment in 1915."

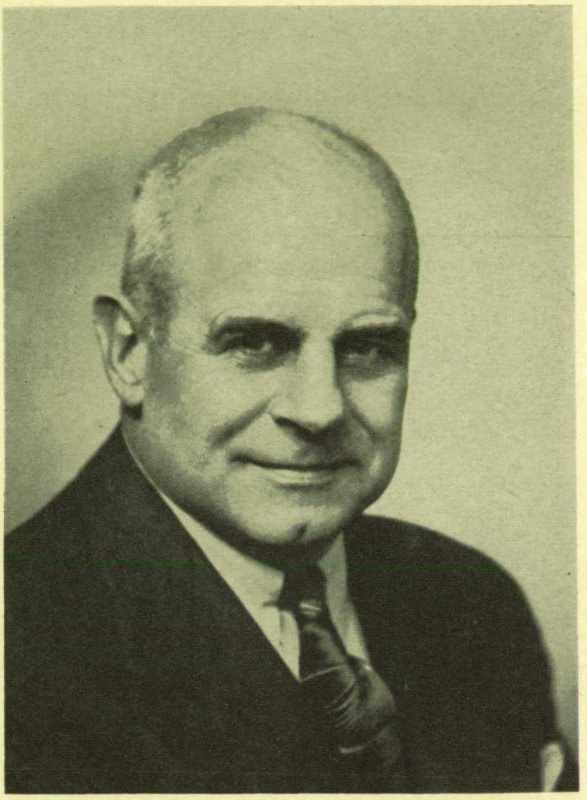
The economic depression that began with the stock-market crash of 1929 was not an unmixed evil for the NACA. Although there were strong pressures to re-



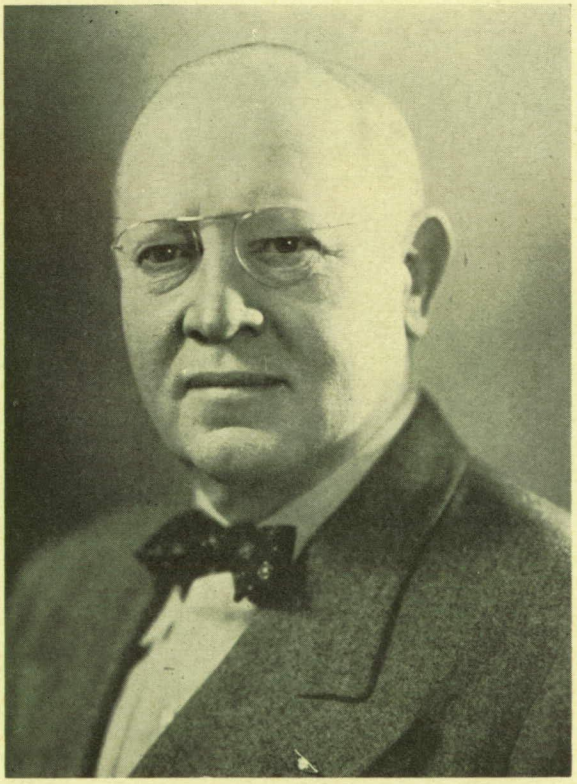
Dr. William F. Durand, member National Advisory Committee for Aeronautics 1915–33, 1941–45; Chairman, 1916–18.



Dr. Charles Doolittle Walcott, Secretary Smithsonian Institution 1907–27; member National Advisory Committee for Aeronautics 1915–27; Chairman, Executive Committee, 1915–19; Chairman, 1919–27.

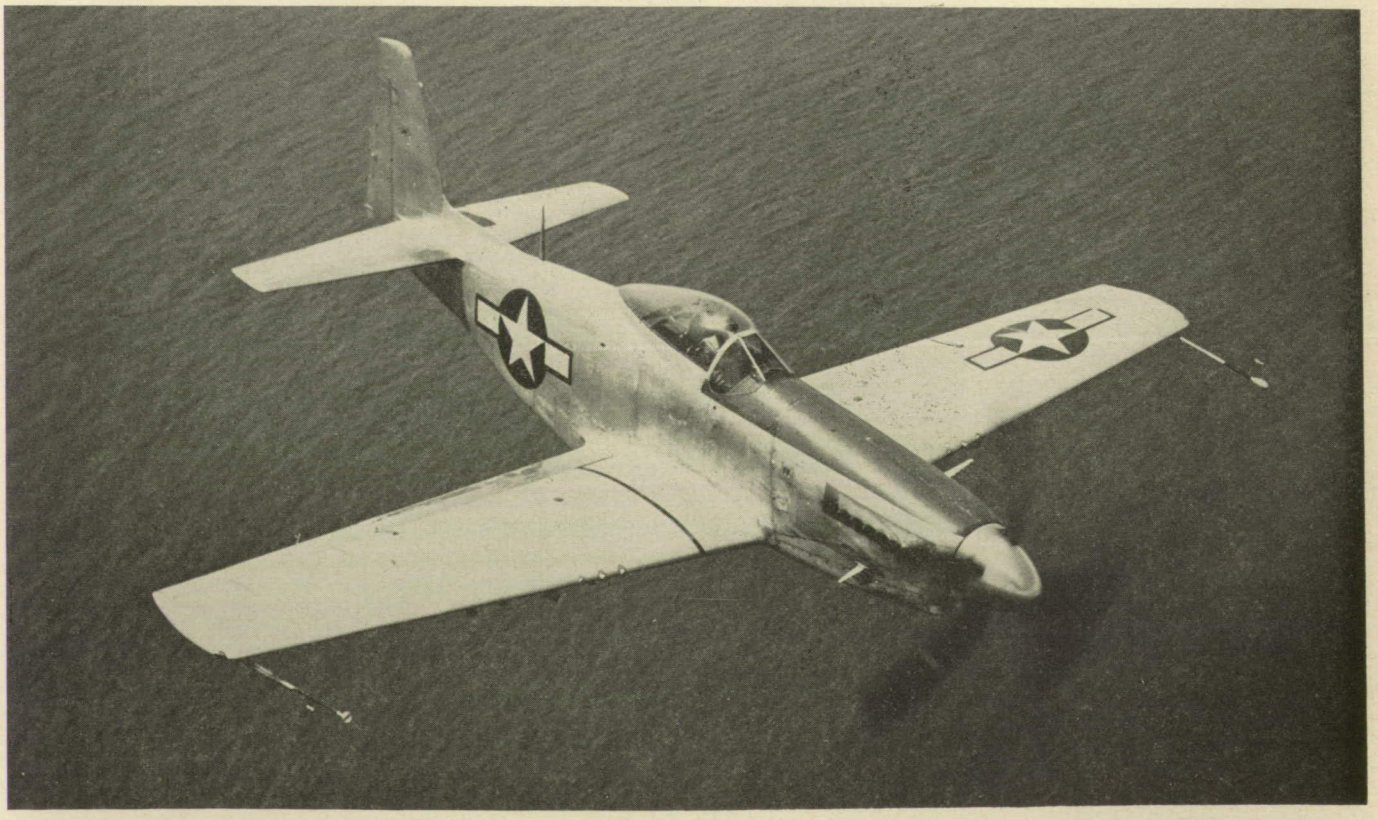


Dr. Joseph S. Ames, member National Advisory Committee for Aeronautics 1915–39; Executive Committee, 1919–37; Chairman, 1927–39.



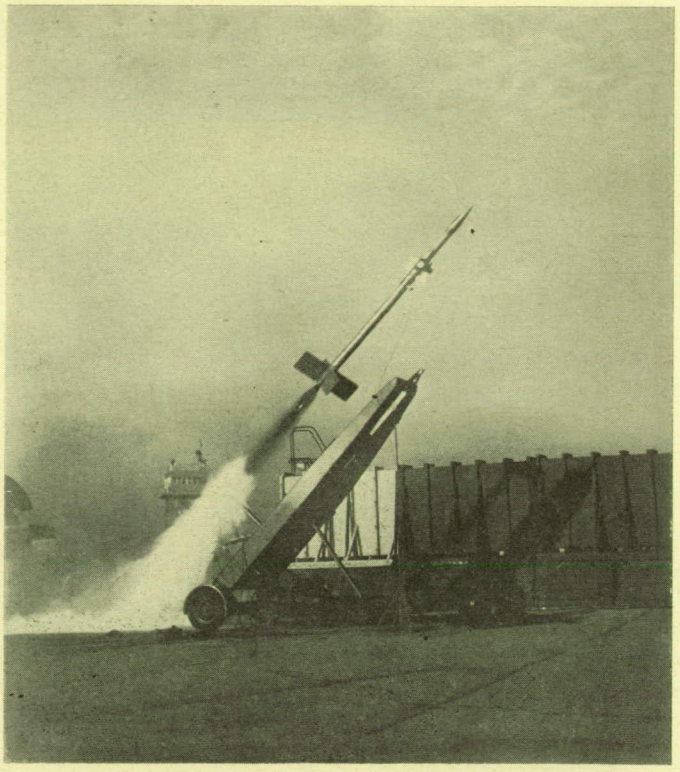
Dr. Vannevar Bush, member National Advisory Committee for Aeronautics 1938–48; Vice Chairman, 1938–39; Chairman, Executive Committee, 1938–41; Chairman, 1939–41.

Jerome C. Hunsaker, member National Advisory Committee for Aeronautics 1922–23, 1938–58; Chairman, 1941–56; Chairman, Executive Committee, 1941–56.

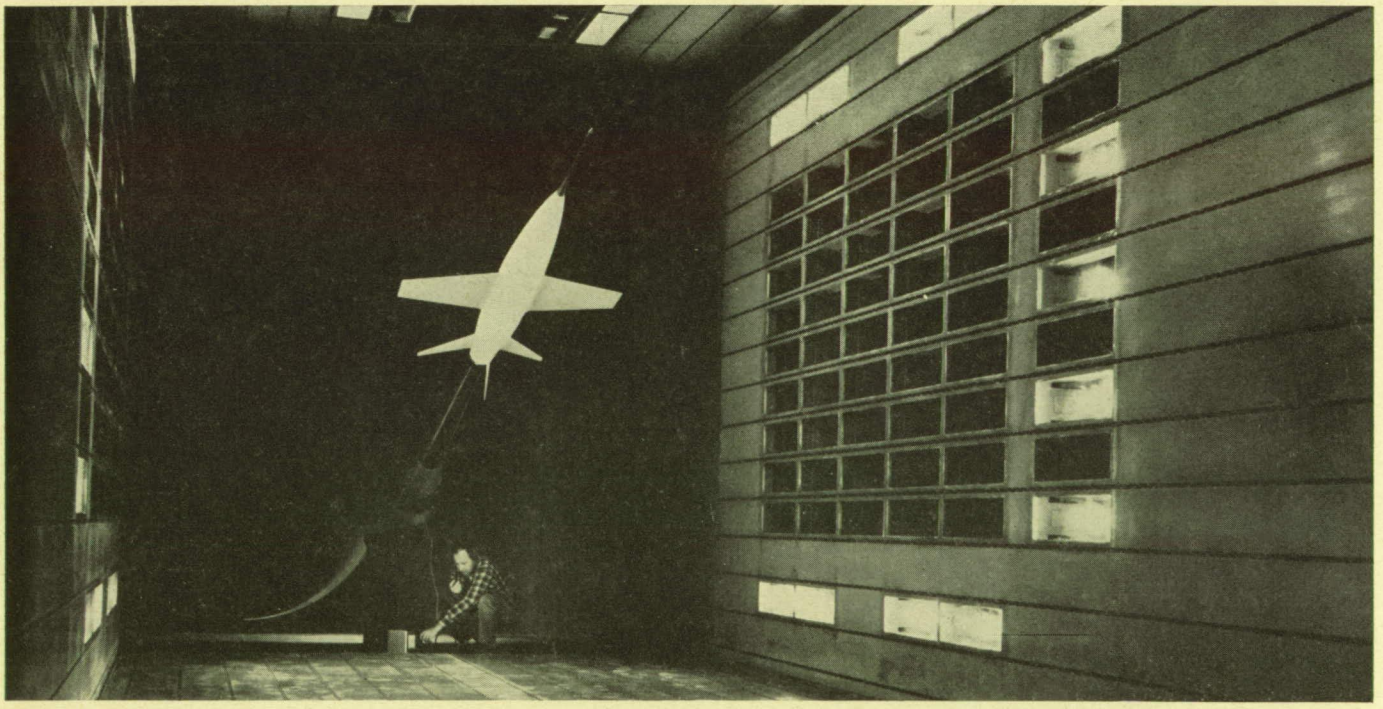


James H. Doolittle, member National Advisory Committee for Aeronautics 1948–58; Chairman, 1956–58; Chairman, Executive Committee, 1956–58.

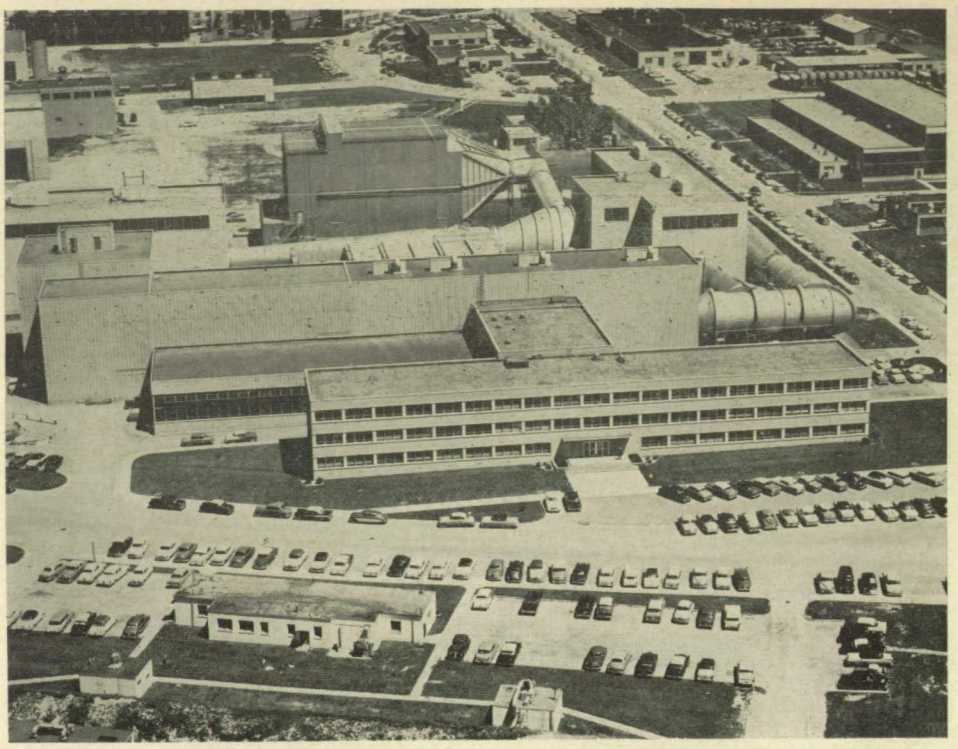
Dr. George W. Lewis, Director of Aeronautical Research, National Advisory Committee for Aeronautics, 1919–47.



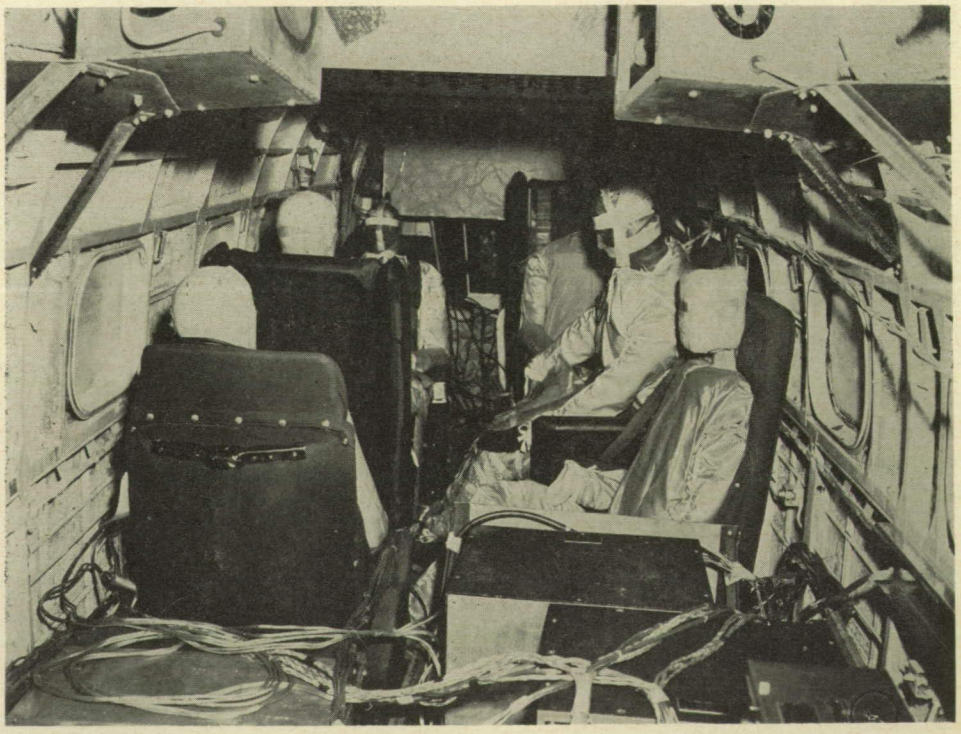
Application of NACA cowling on AT–5A Army pursuit training plane increased its speed from 118 to 137 m.p.h. This was equivalent to providing 83 additional horsepower.



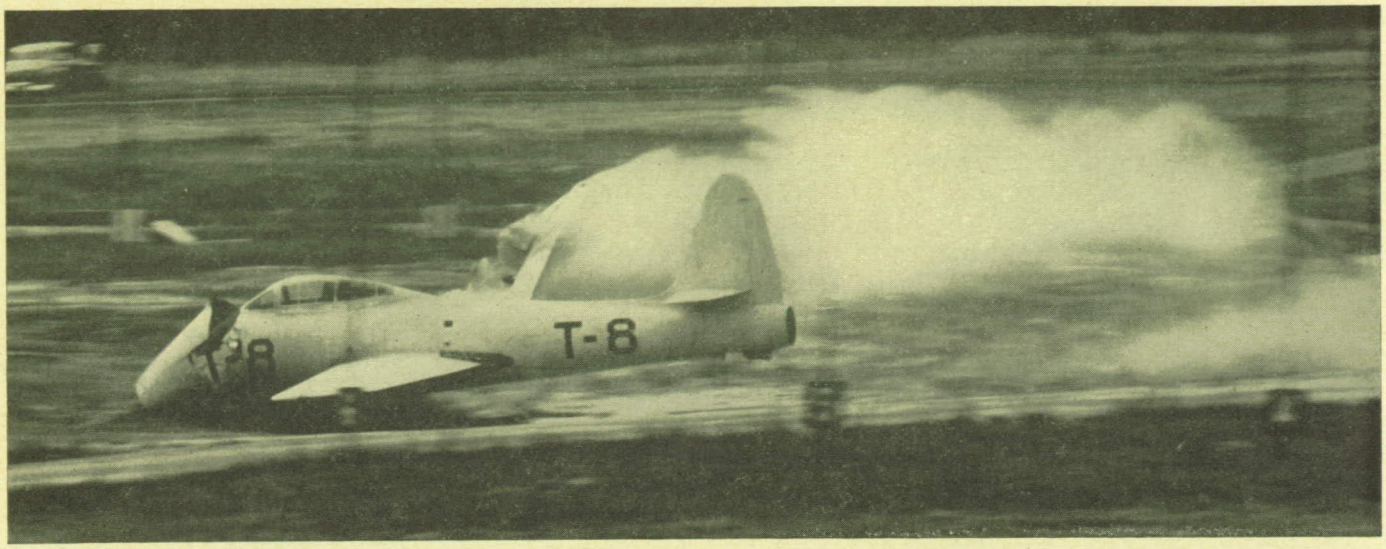
The NACA Langley Laboratory's low-drag wing was first used on the P–51 Mustang fighter, making it the fastest propeller-driven airplane of World War II.



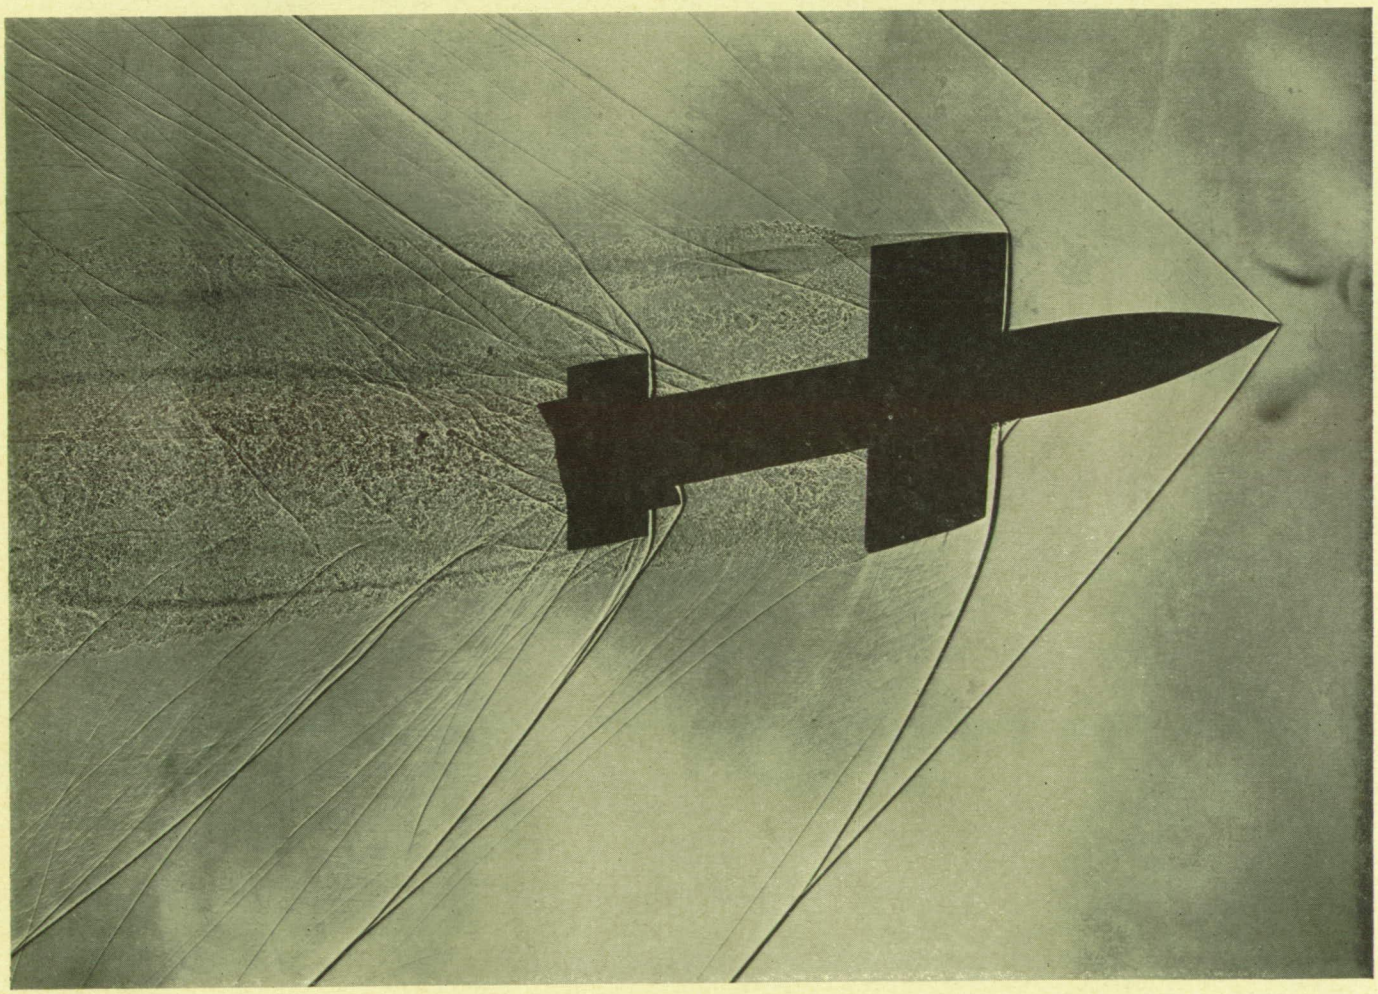
An engineer in NACA's towing tank at Langley Aeronautical Laboratory prepares a dynamic model equipped with hydro-skis for a test run.



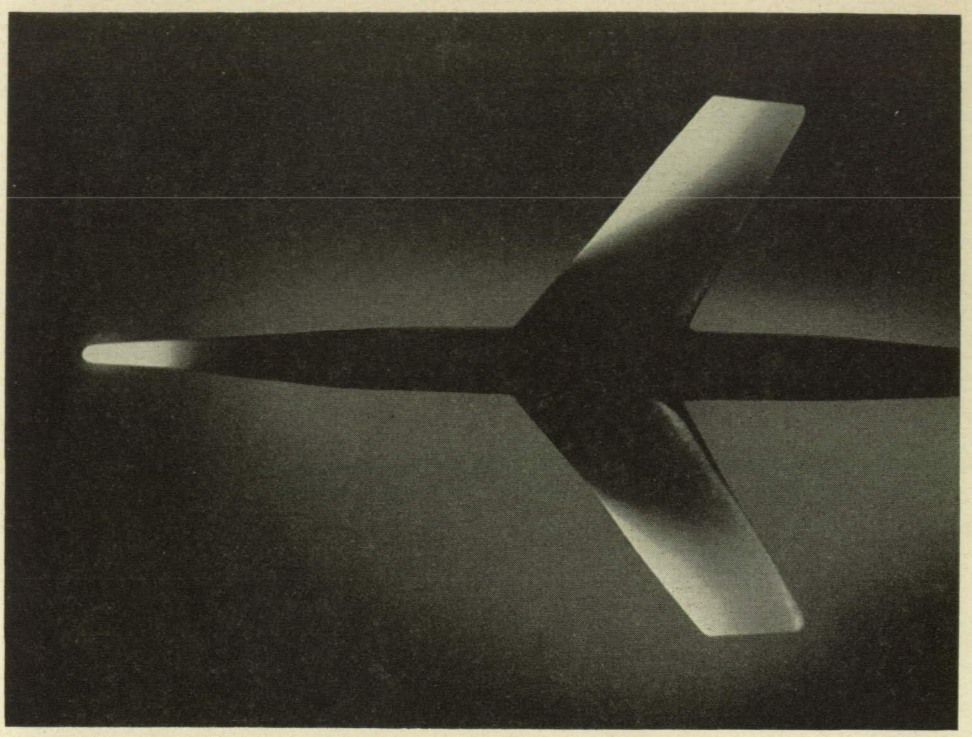
This rocket-powered model, one of a series tested by the NACA to investigate the flutter characteristics of low aspect ratio wings, shoots skyward toward the Atlantic Ocean from its launching ramp at the NACA Pilotless Aircraft Research Station, Wallops Island, Va.



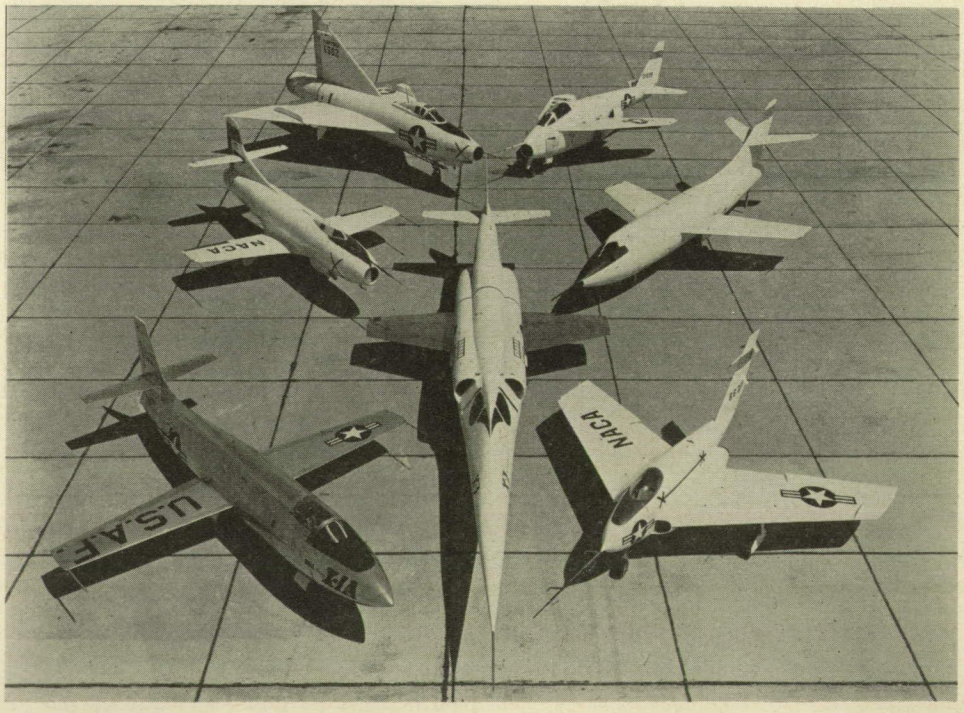
The 14-foot test section of the Ames Unitary Plan wind tunnel. It is capable of operating smoothly from subsonic speeds through the speed of sound to low supersonic values, a region where conventional wind tunnels are not usable, owing to choking. The perforated or slotted walls of the tunnel permit flow disturbances to pass through the open parts while retaining sufficient solid area to guide the air uniformly past the model. Two other test sections operate at speeds up to Mach No. 3.5.



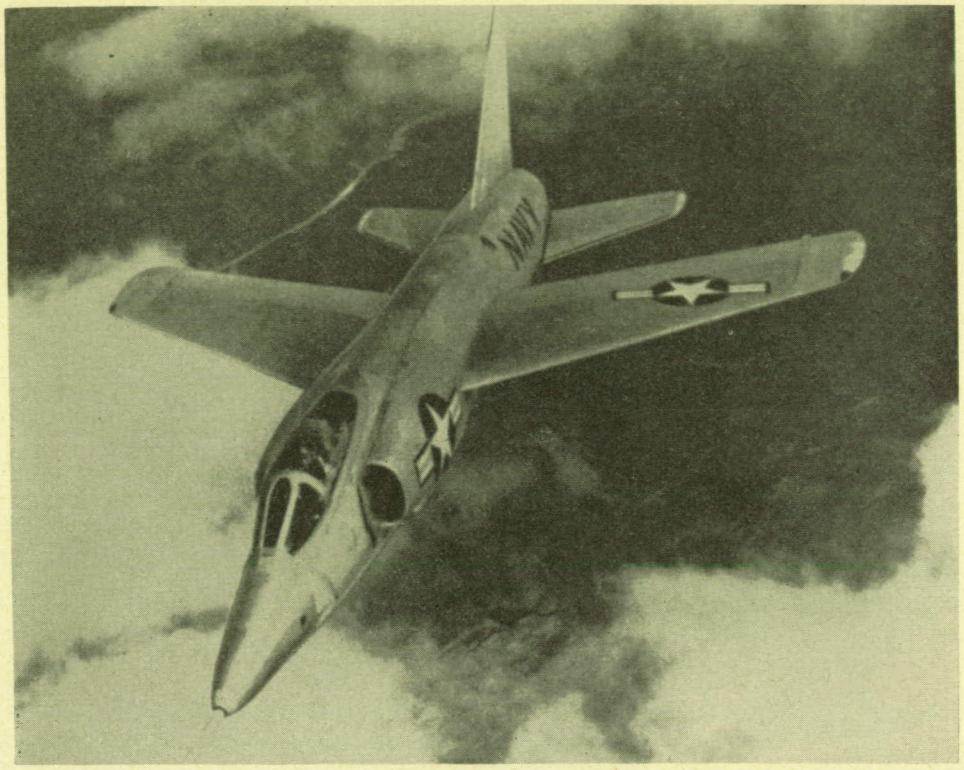
The NACA Lewis Laboratory's new 10-by-10-foot supersonic wind tunnel is used for research on aircraft power plants. This tunnel is designed for speeds of Mach Nos. 2 to 3.5.



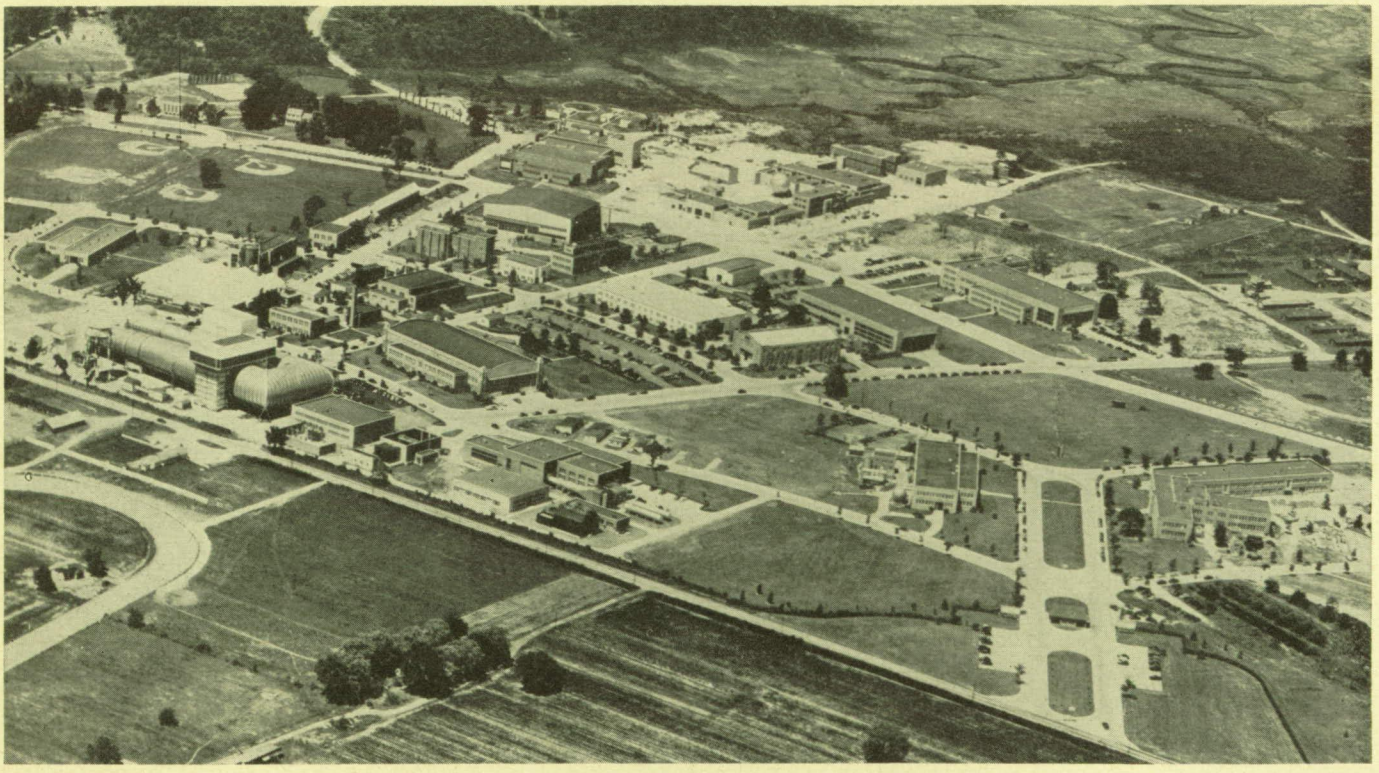
Six dummies, seated in various positions and in several types of seats, rode a service-weary Lodestar transport plane through a severe crash, one of a series staged by a research group of the NACA Lewis Flight Propulsion Laboratory. Objective of the crash program is to gather data on passenger and pilot survival problems in aircraft accidents.



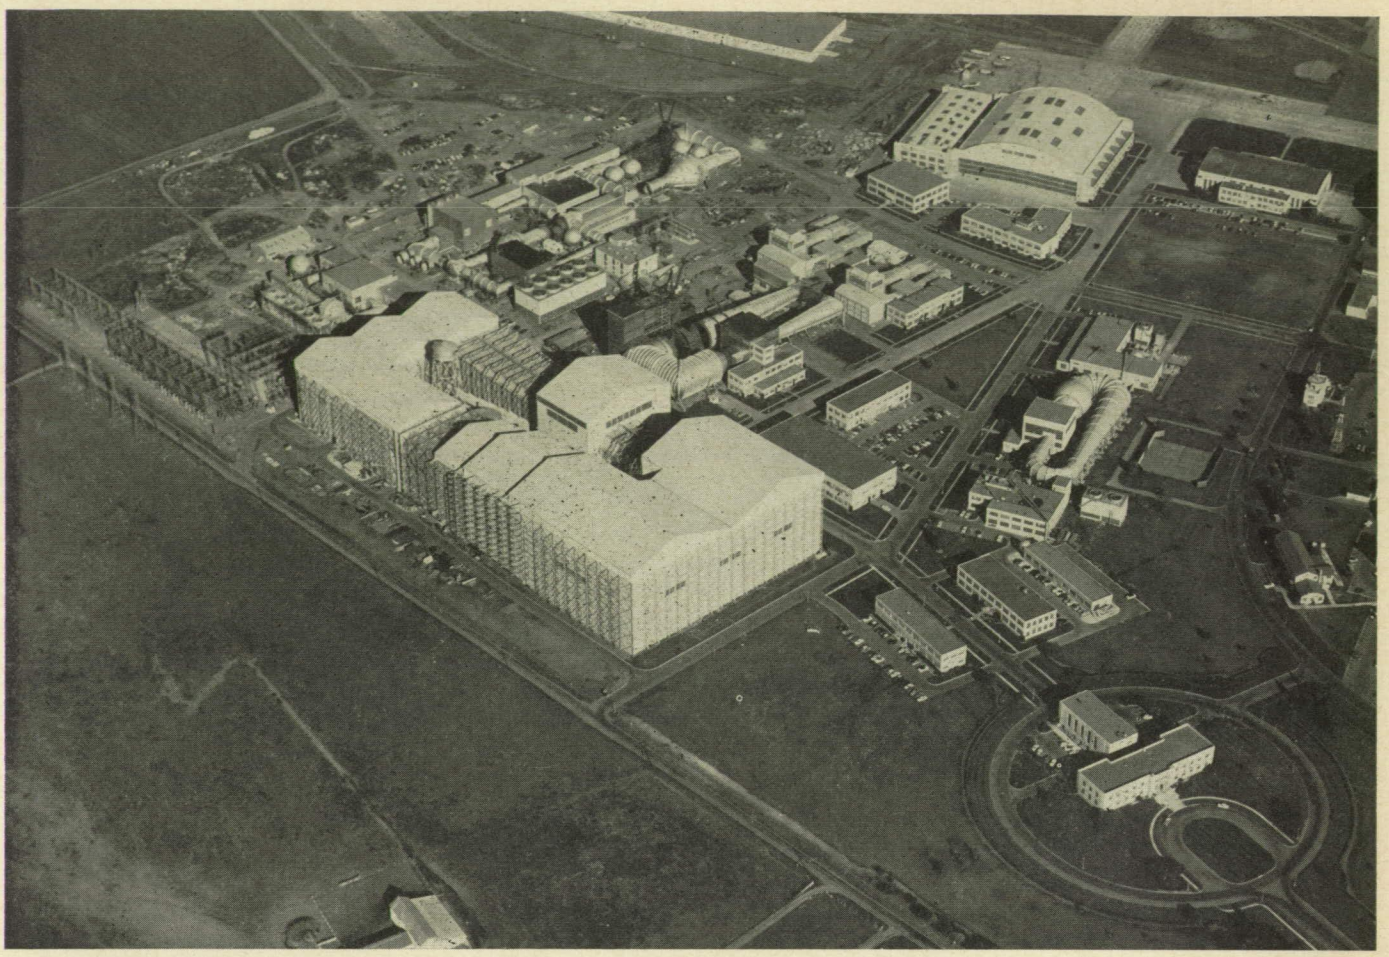
Damage was heavy but fire was prevented in this experimental crash because of a fire-inerting system devised by the NACA Lewis Flight Propulsion Laboratory. A series of crashes was staged with worn-out turbojet- and piston-powered aircraft to study problems of fire and human survival in crash accidents. The white cloud in the picture is jet fuel issuing from the ripped tank in the right wing.



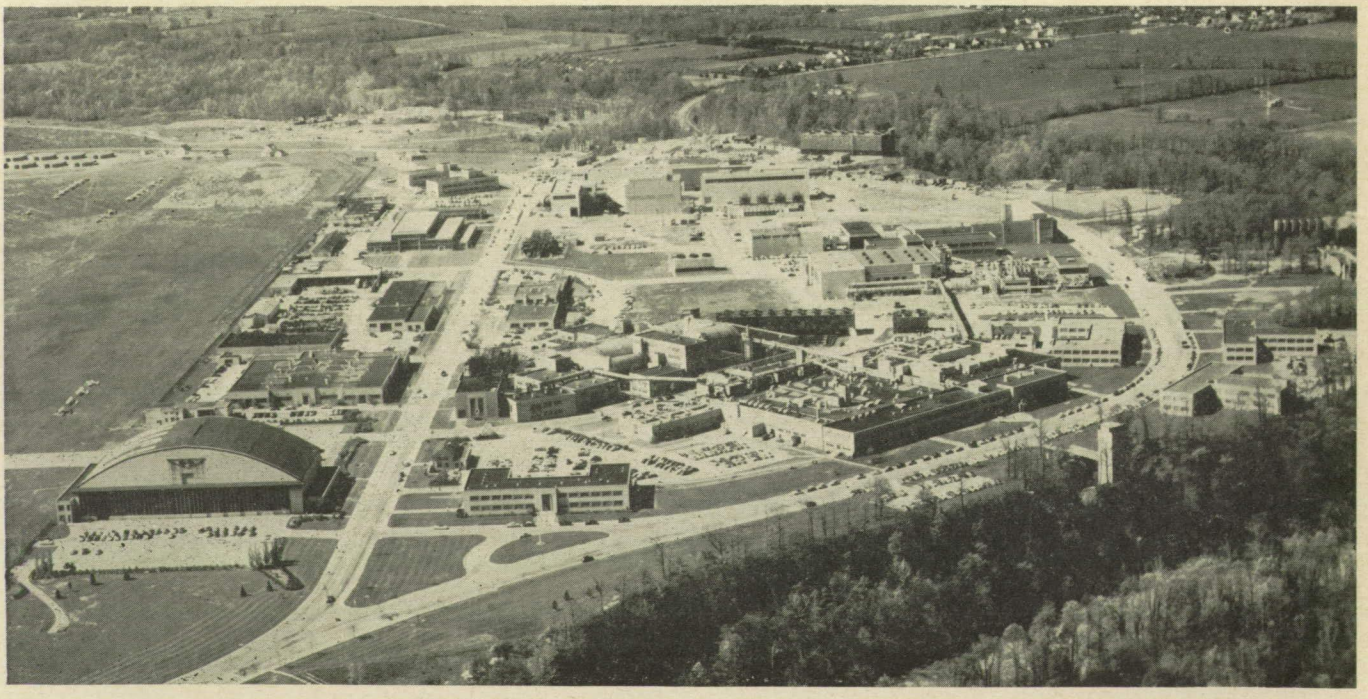
Caught in flight by shadowgraph technique, this free-flight research model shows the complicated pattern of shock waves and vortexes associated with high-speed flight. Vortexes are left in the wake of the model. The unsymmetrical shock-wave pattern shows that the model is turning. The model is 7 inches long and has just been fired from a 3-inch smooth-bore Naval gun into still air. Mach number at the instant of this photograph is 1.6.



Infrared photograph of a laboratory experiment simulating aerodynamic heating. At 2,000 miles per hour, sustained flight could produce temperatures up to 1,200° F. Much additional research is required to permit successful operation under such conditions.



Flying regularly at transonic and supersonic speeds, these research airplanes are exploring new fields for data needed to design the military and civil airplanes of the future. In the center is the Douglas X–3; at lower left, the Bell X–1A flown late in 1953 at a record 1,650 m.p.h. or 2.5 times the speed of sound. Continuing clockwise from the X–1A are the Douglas D–558–I "Skystreak"; Convair XF–92A; Bell X–5 with variable sweepback wings; Douglas D–558–II "Skyrocket," first piloted airplane to fly at twice the speed of sound; and the Northrop X–4. The National Advisory Committee for Aeronautics, the Air Force, the Navy, and the aircraft manufacturing industry are joined to design, build, and fly these and other advanced airplanes in a high-speed flight research program.



Grumman F11F–1. Use of the NACA-developed "area rule" concept for decreasing drag rise at transonic speeds gave this "Tiger" fighter plane supersonic performance. The "wasp-waisted" Navy carrier plane uses one-third less thrust than other airplanes of equivalent performance.

Ames Aeronautical Laboratory, Moffett Field, Calif.

Lewis Flight Propulsion Laboratory, Cleveland, Ohio.

duce operating expenditures, these were successfully resisted, in the main, by such impressive evidence of the money value of the Committee's work as that just cited. On the favorable side was the opportunity for the NACA to construct at depression costs new research equipment with funds already appropriated, and the availability of engineers, from whom many of its future leaders have developed.

The 30- by 60-foot, "full-scale" wind tunnel and the 2,000-foot towing tank (for study of hydrodynamic characteristics of water-based aircraft) were completed in 1931. The designer of the $900,000 "full-scale" wind tunnel (then the world's largest) was Smith J. DeFrance, who became director of the Committee's second research center, at Moffett Field, Calif., when it was established in 1941.

A somewhat later "depression baby" was the 500-mph., 8-foot wind tunnel. For some time after its completion in 1936, it was known, somewhat optimistically, as the "full-speed wind tunnel." Other novel research equipment constructed at Langley in these years included a free-spinning wind tunnel and a refrigerated wind tunnel (for study of icing problems).

In this depression period NACA engineers first disclosed the ability to use air more than once. Soon after the variable-density tunnel was rebuilt following a fire in 1927, it was suggested that some use should be made of the air released each time the tunnel was returned to atmospheric pressure. Why not discharge the pressurized air through an appropriate nozzle and thus obtain a really high-speed airstream? The result was a blowdown device, with a 12-inch test section in which aerodynamic phenomena could be studied at speeds almost that of sound (about 760 mph. at 60° F.).

Thus far, the discussion of research by the NACA has been largely concerned with aerodynamics where the greatest effort was made. Nevertheless there was fruitful work on powerplants, loads, and structures, which will be noted later. In retrospect, one marvels that so much could be accomplished. At the beginning of 1930, for example, the total employment at the Langley Laboratory was only 181.

By the mid-thirties, the work of the NACA had become internationally known and respected. Somewhat earlier the British journal Aircraft Engineering had commented about the Committee: "They were the first to establish, and indeed to visualize, a variable-density tunnel; they have led again with the construction of the 20-foot propeller research tunnel; and . . . [with] a 'full-scale' tunnel in which complete aeroplanes up to 35-foot span can be tested. The present-day American position in all branches of aeronautical knowledge can, without doubt, be attributed mainly to this far-seeing policy and expenditure on up-to-date laboratory equipment."

Somewhat wryly, A. J. Sutton Pippard of the University of London observed in 1953 "that many of our most capable design staffs prefer to base their technical work upon the results of the American NACA."

An important effort of the NACA was to make its research findings fully available for use. First, there were Reports, comprehensive presentations expected to have lasting value. Then there were Technical Notes, preliminary or narrower in scope. Technical Memorandums were reprints, or translations, from the aeronautical literature of other nations. Aircraft Circulars reported information about foreign aircraft and engines. In later years Research Memorandums were added; these were limited in distribution for reasons of military security or because they contained proprietary information.

Recognizing the importance of knowing what was available in the aeronautical literature of the world, Dr. Ames had been instrumental in the formation of an Office of Aeronautical Intelligence as an integral part of the Committee's program, and for years he served both as its director and as chairman of the NACA's subcommittee on publications and intelligence. Beginning soon after World War I and continuing (except for a break in World War II) until 1950, the Committee maintained a technical assistant in Europe. From 1921 the post was held by John Jay Ide, who faithfully and intelligently served the NACA both as European reporter and in a liaison capacity with foreign aeronautical research organizations. It was decided in 1950 to close the NACA's European office because the art and science of aeronautics had become too complex for reportage by a one-man bureau. International exchange of information is now handled by other means.

Beginning in 1926, the Committee sponsored an annual conference at the Langley Laboratory with representatives of the military services and the industry. In addition to the opportunity to see what the NACA was doing, guests had an occasion to criticize and to suggest new research on problems they felt were especially pressing. In the first years of the conference, "everyone" from the industry and the military services attended; even so, the guest list numbered little more than 200, and the journey to and from Langley, via Potomac River steamer, resulted in many unofficial but profitable sessions. After World War II, it became necessary to provide two types of meetings: (1) Technical conferences concerned with a specific subject, usually classified for security reasons, e.g., supersonic aerodynamics. (2) Inspections. Held annually, on a rotating basis at each laboratory, the NACA inspections seek to give the industry and military services a comprehensive view of technical progress. As many as 1,500 attend these meetings, which are not classified.

Also of importance from the standpoint of communication is a steady traffic of industry and military visitors

to NACA research centers. Much is accomplished by discussion of matters of specific concern to those involved. No less important are the visits by NACA technical personnel to specific industry plants.

Beginning in the mid-thirties, the NACA reported annually to the Congress and to the President that certain European nations were making a determined effort to achieve technical and quantitative supremacy in aeronautics. Each year the Committee's comments on this subject were stronger. In 1937, for example, Dr. Ames reported: "The greatly increased interest of the major powers in fostering aeronautical research and their determined efforts to excel in this rapidly expanding engineering science constitute a scientific challenge to America's present leadership." He explained:

> Up to 1932 the Committee had constructed at its laboratories at Langley Field . . . special equipment such as the variable-density tunnel, the propeller-research tunnel, the full-scale tunnel, and . . . a seaplane towing basin. They were at the time of construction the only such pieces of equipment in the world. The possession of such equipment was one of the chief factors in enabling the United States to become the recognized leader in the technical development of aircraft. Since 1932 this research equipment has been reproduced by foreign countries and in some cases special research equipment . . . abroad . . . is superior to the equipment existing at Langley Field.
>
> This condition has impressed the Committee with the advisability of providing additional facilities promptly as needed for the study of problems that are necessary to be solved, in order that American aircraft development, both military and commercial, will not fall behind.

EXPANSION OF FACILITIES

In 1938, the Committee reported that its laboratory employees at Langley Field were "working under high pressure." It warned that "the recent great expansion of research facilities by other nations will bring to an end the period of American leadership in the technical development of aircraft unless the United States also constructs additional research facilities." Dr. Ames, in October 1938, appointed a Special Committee on Future Research Facilities to make recommendations.

But even before the Special Committee met, the NACA was making a strong recommendation for special facilities for research on aircraft structures. "With the advance in size and speed of aircraft . . . the problems involved require the conduct of laboratory research on structures on an increasing scale," the Committee wrote Congress. "This is the greatest single need for additional research equipment and . . . in the interests of safety and of further progress in aeronautics, it should be provided at the earliest possible date."

On December 30, 1938, the Special Committee recommended immediate establishment of a second NACA research center, in California, to relieve what the late Maj. Gen. Oscar Westover (then Chief of the Army Air Corps and a member of the NACA) called "the congested bottleneck of Langley Field." Although the recommendations had been presented as emergency in character, it was not until midsummer—August 9, 1939—just before the start of World War II, that the second laboratory was authorized by Congress. Hardly a month later, September 14, ground was broken at Moffett Field, some 40 miles south of San Francisco, for what became the Ames Aeronautical Laboratory.

Earlier that year an expansion of Langley facilities was authorized by Congress. S. Paul Johnston (now managing head of the Institute of the Aeronautical Sciences) was named Coordinator of Research to assist Dr. Lewis. Further intensification of research effort obviously was needed in the face of war in Europe, and a second Special Committee, headed by Charles A. Lindbergh, was appointed. This group recommended, October 19, 1939, that a powerplant research center be established at once.

"There is a serious lack of engine research facilities in the United States," Lindbergh's committee stated. "The reason for foreign leadership in certain important types of military aircraft is due in part to the superiority of foreign liquid-cooled engines. At the present time, American facilities for research on aircraft powerplants are inadequate and cannot be compared with the facilities for research in other fields of aviation." It was June 26, 1940—after Belgium and Holland had been overrun—that congressional authorization for the new flight-propulsion laboratory was forthcoming.

A site was made available by the city of Cleveland adjacent to its municipal airport. Immediate steps were taken by Dr. Lewis to plan and construct a complex of laboratories equipped with facilities for the investigation of airplane engines, their parts and materials, fuels and lubricants, ignition and combustion, heat transfer and cooling, intake and exhaust aerodynamics, as well as for the fundamental physics, chemistry, and metallurgy of power generation. In addition, facilities were provided for flight testing in laboratory-instrumented airplanes—practical flying laboratories for propulsion research.

There is no doubt that this flight-propulsion center was a large step in advance of any comparable facility in the world. It has cost up to date about $110 million and now employs about 2,800 people.

After the death of Dr. Lewis in 1948, the Committee decided on the name "Lewis Flight Propulsion Laboratory," as a memorial to that great engineer's crowning achievement.

Here it may be proper to explain why the research effort on powerplants and on structures had been so much less than that devoted to aerodynamics. In the first place, it must be remembered that between World Wars I and II, the United States was an intensely peace-minded nation. In addition, the thousands of

miles of ocean to our east and west gave a feeling of safety from attack, a complacent sense of detachment. The Congress was unwilling to expend really large sums for national defense or on research to improve it.

Until the eve of Pearl Harbor, the annual expenditure by the United States to support aeronautical research was indeed modest. Even as late as the summer of 1939, the NACA's total complement was 523, including only 278 technical people.

The major effort by the NACA over the years had been deliberately concentrated on aerodynamic problems. Here, for a given expenditure, the possible gains to be achieved were very large, particularly in view of the relatively few engineers who could be assigned to the work.

Powerplant research and structural research are expensive, and require extensive facilities for full-scale investigations. Small models are of limited utility in powerplant research. Furthermore, powerplants and structures are the immediate concern of strong and highly competitive industrial firms. The Committee evidently felt that under its fiscal restrictions, it would do better to concentrate on basic aerodynamic problems and might, hopefully, leave research and development of powerplants and structures to the industry and the military services.

However, the Lindbergh committee in 1939 said that this past policy was wrong, and the NACA agreed. It appeared that leaving fundamental research to the industry meant, in effect, that such research would be indefinitely postponed.

A competitive engine firm must concentrate on what its customers want. The firm improves its engine with small changes based on experience. It seeks the minimum risk of interruption of production. The military services, its principal customers, conduct competitive trials based on standard performance specifications. After quantity orders are placed, no major changes are possible. The services, of course, welcome small changes based on experience, if the risk of trouble be slight. As a result, engine development tends to adhere to a definite pattern and progresses slowly.

An engine manufacturer must make a relatively heavy investment in plant and tooling for production of a particular engine. The manufacturer is naturally inclined to concentrate on improvements in this engine to prolong its commercial life. These improvements are essentially proprietary in character.

Similar remarks apply to the airplane industry. Every effort is made to improve a particular airplane to prolong its vogue in production. This development effort is restricted to conservative changes in a basic design acceptable to the customer.

In this country, the Navy standardized on air-cooled radial engines that met Navy requirements, while the Army insisted on 12-cylinder, liquid-cooled engines to power the fighters in their program.

However, there were important fundamental applications of science to engine design that needed investigation in 1940.

From the beginning, one of the principal technical committees of the NACA was concerned with powerplants. During World War I, a few research projects in the powerplant field were carried on under its auspices, notably in the altitude facility at the Bureau of Standards, where engines could be operated under conditions simulating those experienced by high-flying aircraft. A program of systematic tests was conducted there for the NACA, including supercharging with a Roots-type blower.

At Langley the small but expert powerplant staff made some important contributions, in addition to their cooperation with the wind-tunnel people in developing the remarkable NACA cowling for air-cooled engines. One recalls improved finning for air-cooled engine cylinders, methods to decrease the octane requirements of high-compression engines, and work on such fundamental matters as the behavior of fuels—how they ignite, how they burn, and how this burning corrodes critical parts of the engine. A principal tool in the study of these latter questions was high-speed photography, and cameras capable of taking pictures at the rate of 400,000 per second were developed by the NACA.

In the field of jet propulsion the NACA exhibited an early awareness of its possible advent but did little about it. In 1923, in Report No. 159, "Jet Propulsion for Airplanes," Edgar Buckingham of the Bureau of Standards, reported that: "The relative fuel consumption and weight of machinery for the jet decrease as the flying speed increases; but at 250 mph. the jet would still take about four times as much fuel per thrust horsepower-hour as the air screw, and the powerplant would be heavier and much more complicated. Propulsion by the reaction of a simple jet cannot compete, in any respect, with air screw propulsion at such flying speeds as are now in prospect." This conclusion was entirely rational on the basis of the technology at that time.

In the early thirties, the NACA was asked by a representative of the airframe industry to resurvey jet-propulsion prospects and, although airplane speeds by then had passed the 250-mph. mark which Buckingham considered a goal, the story was much the same. The inefficiency of the jet engine at the speeds contemplated ruled it out of consideration.

Near the end of the 1930's, some preliminary experimental work on jet propulsion was undertaken at the Langley Laboratory. These experiments indicated that jet engines would be so fuel thirsty as to limit their useful application to very high-speed, very

526597—60——3

short-range aircraft. American thinking, perhaps because of geography, was focused on long-range performance where fuel economy was paramount. This idea served to discourage any real jet-development effort in the United States until intelligence of British and German experiments reached us.

In March 1941, Dr. Durand was recalled from retirement to head a special NACA Committee on Jet Propulsion. The fact that he was in his 82d year was only a matter of calendar counting. The vigor with which he and his committee launched a belated development effort would have done credit to a man less than half his age. Later in 1941, Gen. H. H. Arnold secured from the British one of the earliest of the Whittle jet engines to aid the development program initiated by Dr. Durand. In this program, the Durand committee was handicapped by the fact that the country had just been plunged into a war for which it was ill prepared and the principal airplane-engine firms were overloaded. The decision came "from the summit" that we would fight with the weapons in hand. First priority was given their production in immense quantity. Consequently, the Durand committee had to arrange with nonaeronautical firms to undertake the development of turbojet engines for possible later use to power fighter airplanes.

Over some 20 years, aerodynamic and powerplant improvement, much of it based on application of research results, permitted the top speed of military airplanes and the cruising speed of commercial airplanes to be doubled; the air loads imposed on the faster airplanes were severely increased, especially in rough air and when maneuvering.

The loads research group at the Langley Laboratory consisted of but 20 men in 1939, but their contribution was considerable, notably the V–G recorder (V for velocity, G for gravity) by R. V. Rhode and H. J. E. Reid. It was devised to measure continuously the loads experienced by an airplane flying in rough air. This was but one of many novel instruments which NACA engineers have devised for precise measurements in flight.

The research problem directly related to loads deals with structures to carry the loads. Here again the manpower available at Langley prior to World War II was small; as late as October 1940, only 10 men were working on airplane structures. Their work was concerned, principally, with fundamental knowledge about structures from which a trustworthy theory could be developed for design application. Delicate experiments and mathematical analyses dealing with the behavior of thin-walled cylinders, stiffened panels, and other structural units produced useful conclusions that were used on our World War II aircraft.

On October 7, 1939, Dr. Ames resigned from the Committee because of failing health. His responsibilities as chairman of the Committee were given to Dr. Vannevar Bush, who had been serving both as vice chairman and as chairman of the executive committee.

Note has been made already of the manner in which Dr. Ames had provided leadership of the highest quality to the Committee for nearly a quarter-century. The letter President Roosevelt wrote upon the occasion of his retirement contained this statement:

> Our Republic would not be worthy of the devoted service you have rendered for over 24 years without compensation if it could not on this occasion pause to pay tribute where it is so justly due. . . . That the people generally have not known of your brilliant and patriotic service is because it has been overshadowed by your passion for accomplishment without publicity. But the fact remains, and I am happy to give you credit, that the remarkable progress for many years in the improvement of the performance, efficiency, and safety of American aircraft, both military and commercial, has been due largely to your own inspiring leadership in the development of new research facilities and in the orderly prosecution of comprehensive research programs.

The Committee resolution, tendered to Dr. Ames in Baltimore by a special delegation, said:

> When aeronautical science was struggling to discover its fundamentals, his was the vision that saw the need for novel research facilities and for organized and sustained prosecution of scientific laboratory research. His was the professional courage that led the Committee along scientific paths to important discoveries and contributions to progress that have placed the United States in the forefront of progressive nations in the development of aeronautics. His was the executive ability and far-sighted policy of public service that, without seeking credit for himself or for the Committee, developed a research organization that holds the confidence of the governmental and industrial agencies concerned, and commands the respect of the aeronautical world. Withal, Dr. Ames was an inspiring leader of men and a man beloved by all his colleagues because of his rare qualities.

In July 1941, the President appointed Dr. Bush director of the newly established Office of Scientific Research and Development, and he resigned as chairman of the NACA. The writer was elected chairman, an honor he has been privileged since to hold.

WORLD WAR II AND AFTER

The war years for the NACA were plagued by the necessity for rapid expansion of the civil service staff from hardly 500 in 1939 to more than 6,800. Trained engineering personnel were unavailable. Consequently, it was mandatory that professionals be spread ever thinner, while loom fixers, toymakers, mechanics, blacksmiths, and women schoolteachers were recruited for jobs they could do or for which quick instruction could be given.

Especially in the matter of skilled management of research programs, the NACA might have been expected to be sorely weak. And yet, somehow, with each expansion of effort, new leaders were found from within the permanent NACA staff. No sooner did Henry

J. E. Reid, director of the Langley Laboratory, see some of his best men on their way to build the new laboratory at Moffet Field—named in 1944 in honor of Dr. Ames—than the process of designating the leaders of the new engine laboratory—named in honor of Dr. Lewis in 1948—was begun. Smith J. DeFrance was named director of the Ames Aeronautical Laboratory, and later Edward R. Sharp became director of the Lewis Flight Propulsion Laboratory. Both of these men were senior members of the permanent staff at Langley.

NACA's war effort was of necessity devoted very largely to applied research, the business of finding "quick fixes" to make existing aircraft better performers, and production engines more powerful. Fortunately, a considerable backlog of design data was available for application to such subjects as low-drag wings, high-speed propellers, stability and control, and improved systems for cowling and cooling engines. Between December 1941 and December 1944, the Committee's research centers worked on 115 different airplane types. In July 1944, 78 different models were under simultaneous investigation.

Perhaps the best comment on the value of NACA's World War II work is to quote from a statement by the late Frank Knox, made in 1943 when he was Secretary of the Navy:

> New ideas are weapons of immense significance. The United States Navy was the first to develop aircraft capable of vertical dive bombing; this was made possible by the prosecution of a program of scientific research by the NACA. The Navy's famous fighters—the Corsair, Wildcat, and Hellcat—are possible only because they were based on fundamentals developed by the NACA. All of them use NACA wing sections, NACA cooling methods, NACA high-lift devices. The great sea victories that have broken Japan's expanding grip in the Pacific would not have been possible without the contributions of the NACA.

The end of World War II marked the end of the development of the airplane as conceived by Wilbur and Orville Wright. The power available in the newly developed turbojet and rocket engines for the first time brought within man's reach flight through and beyond the speed of sound.

In the years following World War II there were changes, too, in the membership of the Committee. In 1948, the death of Orville Wright closed 28 years of his membership on the NACA. Though he was but one among many strong men who had given of time and talent to the work of the Committee, his passing sharpened the realization that in the working years of one man's life—between December 17, 1903, and January 30, 1948—the speed of the airplane had been increased from hardly 30 mph. to almost 1,000 mph.

In 1948 the membership of the Committee was increased to 17. This permitted the inclusion of a representative from the Department of Defense, presently the Assistant Secretary (Research and Development). Since the war the Committee has included one Presidentially appointed member from the airframe, the engine, and the air-transport industries, thus insuring awareness of the needs of those major segments of American airpower.

In 1948 Dr. Lewis died. In 1945, his health broken by the war effort, he had been forced to withdraw from active participation in the work of the Committee. For almost 2 years, John W. Crowley, Jr., served as acting director of aeronautical research. With the Committee since 1921, Crowley had been chief of research at Langley for a number of years. He provided vitally needed leadership during a critical period.

To succeed Dr. Lewis, the Committee in 1947 chose the Associate Director of the National Bureau of Standards, Dr. Hugh L. Dryden. He was no stranger to the NACA. Trained in physics and mathematics by Dr. Ames at Johns Hopkins University, he had gone to the Bureau of Standards in 1917, where he soon earned an international reputation by his aerodynamic researches in turbulence and boundary layer. His new task at the NACA was extremely difficult, yet it was vital to the Nation that a "new look" at the postwar situation be taken, and new objectives defined in terms of supersonic jet-propelled vehicles potentially available for the worldwide exercise of air power and, eventually, for civil air transportation.

At the end of World War II, the most urgently sought goal was attainment of practical flight at supersonic speed. It was realized that success in this effort required new knowledge which could be obtained only with new tools and new techniques. Even before the end of the war efforts were made to acquire needed data. Efforts to develop useful transonic aerodynamic theory had failed and it was necessary to resort to direct experimentation at velocities passing through the speed of sound. The fact that the principal tool of aerodynamic research, the wind tunnel, was subject to "choking" phenomena near the speed of sound forbade its use for the critical experimentation. Entirely new techniques had to be devised. The NACA's attack was broadened to include all approaches which offered promise.

The earliest attempt used especially instrumented aerodynamic bodies dropped from a high altitude, but it was not until late in 1943 that advances in radar and radiotelemetering equipment made it possible to obtain reliable data by this method. Even then, the velocity of a free-falling body seldom went much beyond a Mach number of 1 ($M=1$ equals the speed of sound).

Other attempts sought to use the acceleration of airflow above a curved surface. Small model wings were mounted near the leading edge of the wing of an airplane. In this way, lift, drag, and other aerodynamic characteristics of the model were measured. The meth-

od was employed also to study stability and trim of airplane shapes in the transonic speed range. The same principle of accelerating airflow was tried with small models positioned over a "hump" in the test section of a subsonic wind tunnel, but scale effects complicated the interpretation of test results for use in design.

Use of rocket-propelled models fired from the ground followed the first work with free-falling bodies by about a year. As instrumentation has been improved, this technique has become a valuable tool for transonic research. By the addition of powerful booster rockets, models of this kind are being used to study aerodynamic problems at speeds ranging up to a Mach number of 10 and higher. The fact that very high speeds are reached at low altitude, where the air is dense, makes the aerodynamic data readily usable for plane and missile design. In 1945, the NACA established a Pilotless Aircraft Research Station at Wallops Island off the Virginia coast, to carry on this work. It is attached to the Langley Laboratory.

In 1943, the idea was advanced of using specially designed piloted airplanes to explore the transonic speed range. Propelled by powerful rocket engines and provided with elaborate data-recording equipment, the research airplane could be safely flown at high altitudes where the density of the air, and hence the loads imposed on the structure, would be low.

The spectacular accomplishments of the research airplanes—the supersonic flight of the Bell X–1, October 14, 1947; the twice-the-speed-of-sound flight of the Douglas D–558–II, November 20, 1953, and the even faster flights of the Bell X–1–A which followed soon after—have sometimes obscured the fact that these airplanes were tools for research. These flights are historic; all agreed as to the rightness of the Collier Trophy award to three men for the year 1947: John Stack, Langley Laboratory, for conception of the research airplane program; Lawrence D. Bell, for design and construction of the X–1; and Capt. Charles E. Yeager, USAF, for making the first supersonic flight.

But even more valuable than the dispelling of the myth about the sound barrier was the accumulation of information about the transonic speed region. The shape and the performance of tactical military aircraft which have been designed since reflect the use of data obtained by the research airplane program centered at the NACA's High-Speed Flight Station at Edwards Air Force Base, Calif.

Despite the success of this flight program, there remained the need for a technique whereby transonic experimentation could be carried on under the closely controlled conditions possible only in the laboratory. Actually, the data coming from the research airplanes accented this need, because they pointed up the fundamental problems of fluid mechanics that would have to be studied in great detail for the design of useful supersonic aircraft.

By late 1950, following intensive theoretical work, there was put into operation at the Langley Laboratory a new type of wind tunnel. Incorporating a "slotted throat" at the test section, it was free from choking near the speed of sound and truly could be described as a transonic wind tunnel. Again, the Collier Trophy was awarded to John Stack and his Langley associates for the conception, design, and construction of this most useful research tool.

One must appreciate the very great difference between airplane design in the past and today. In the past, the difference between the best design and the second best, assuming the same power, might be at most only a few miles an hour. Now the difference may be measured in hundreds of miles an hour. The art is being extended so rapidly that no longer is there a comfortable time margin between the acquisition of research data and its application.

Hardly had the first of the NACA's transonic wind tunnels gone into full operation, in 1951, when Richard T. Whitcomb, a young engineer at the Langley Laboratory, began the experimental verification of what has since become known as the "area rule." In essence, Whitcomb worked out a rational way to balance the lengthwise distribution of volume of fuselage and wings to produce an airplane form with minimum drag at high speeds. Seemingly slight modifications to the shape of the airplane fuselage greatly improved performance.

As soon as the new design principle was verified in preliminary form, it was made available in confidence to the designers of military airplanes and the new information was promptly applied.

In one instance, the prototype of a new fighter aircraft was unable on test to attain supersonic speeds. With the deceptively subtle modifications dictated by the "area rule," the airplane enjoyed a performance gain in speed of as much as 25 percent.

At the velocities contemplated for our future missiles and airplanes, temperatures measured in thousands of degrees Fahrenheit will be encountered owing to aerodynamic heating—friction. The consequent structural problems are little short of fantastic and, with presently available materials of construction, the solution is not in sight. More research is needed.

The performance possible from the harnessing of nuclear energy for airplane propulsion would be nonstop flight over virtually unlimited range. Again, one is faced with problems of enormous complexity and difficulty, but national security requires that research and development be carried forward with imagination and vigor.

Millions of passengers are now carried by air. Air transportation also expedites the delivery of great volumes of mail and goods. Airliners regularly span oceans and continents, and smaller utility planes serve remote regions in the Arctic and tropical jungles. There is promise of helicopter service between nearby cities, with no need for large outlying airports.

The safety record of civil aeronautics is remarkably good, but it is never good enough. We still read, from time to time, of disasters from collision, fire, storm, human error, and, rarely, from structural or mechanical failure of the airplane itself. The human pilot is aided by wonderful instruments and by radio, radar, gyros, etc., but we still depend on his judgment and skill. He must be better protected against noise and fatigue—subjects for research.

Air transportation is fast and can be faster. But greater flight speed is illusory if it requires too long a climb to reach the high altitude necessary for economy. Furthermore, higher speed airplanes tend to require longer runways and bigger airports. This could mean a new program of airport building at colossal expense, with the new airports even farther from the passengers' ultimate destination. Getting to and from the airport could consume more time than is saved by faster flight. Research continues on improving landing and takeoff characteristics of airliners.

It may be that airliners of the future will be designed to the limitations of the airports they are to serve, just as transatlantic steamers are designed to enter only a few major seaports, where the channel and piers have adequate depth of water.

Civil aeronautics can make its greatest contribution to trade and commerce under a favorable international climate of free interchange of people, goods, and ideas. Greater economy, efficiency, and safety are prerequisites for its full utilization. Research can show the way to advance toward these goals.

Through the years the NACA has been provided by Congress with the most modern research equipment at a total cost of approximately $300 million, and the present operating staff numbers about 7,600 persons, of whom over 2,000 have professional degrees. These resources, in the present hostile and threatening international climate, are directed for the most part toward research helpful to national security. Research to improve military aircraft is ultimately applied to civil aviation, when proved to be thoroughly practical by experience, but there are differences in emphasis, because safety, comfort, and economy are relatively more important in civil airplanes. The Committee has numerous investigations in progress which are directed toward the immediate problems of civil aviation, as for example the work on noise, icing, fire prevention, atmospheric turbulence, and reduction of landing speed.

A more favorable international climate would permit greater emphasis on civil aviation, but it is likely that for some time to come the national security will require a great effort to penetrate more rapidly into the vast region of the unexplored and unknown. The Committee feels its responsibility for guidance of the overall research effort in aeronautics, and it is hoped that through its work aeronautics may make the maximum possible contribution to human welfare.

The Following Years

1955–58

By James H. Doolittle
Chairman NACA, 1956–58

The latter years of the NACA were among its most productive. It was almost as if the talented scientists and engineers of the organization during the years of World War II when they were so intensively engaged in efforts to improve current airplanes, had been saving up bold, big ideas about how to accomplish dramatic improvements in aircraft performance. Once peace was restored, even though it was soon to prove an ephemeral thing, there was a steady flow from the people at the Langley, Ames, and Lewis Laboratories, of new information about the laws governing flight that the designers of the industry could incorporate quickly into their new aircraft. Much of what I shall describe in this brief summary belongs, really, to the 40-year period covered by Dr. J. C. Hunsaker's preceding account of the NACA. The principal reason he could not include this information was security. There is much more I should like to say about current work, but again, some of the story must await a future occasion.

One of the most important aspects of NACA research during the postwar years was the systematic study of such problems as aircraft and rocket fuels. Any high school or college chemistry student can look at the charts and determine that hydrogen has the highest energy content per pound and therefore should be a principal element in the ideal fuel, the one that will produce the most thrust per pound. The goal is to devise such an ideal fuel and methods of practical use in the face of such obstacles as toxicity, availability, cost, etc. Here, there is no easy quick path to accomplishment; hard work, sustained research over long periods, is the only sure way to success.

At the Lewis Laboratory, beginning with the closing days of the war, a program to develop "super fuels" was begun that, even in mid-1958, is still producing useful information. Progress, long-range progress, has been and continues to be made, despite a succession of inevitable disappointments. One promising lead after another had to be studied and discharged until it became known that the answers were to be found elsewhere. Finally, of course, this systematic effort pointed toward the "best answers."

For example, one way to obtain more powerful, more useful fuels was to burn such materials as aluminum or magnesium. The problems of compounding slurries of these metals had to be solved, but when solutions to these problems were found, the realization followed that this approach was not useful, for reasons that need not be dealt with here. Other solutions to the problem had to be sought. In passing, I should like to emphasize that in the business of learning how to fly faster, higher, and farther, it is sometimes very important to *learn what won't work*. With this essentially negative information in hand, it then becomes possible to work rapidly and surely toward goals that will pay off.

Even today, the subject of "exotic fuels" remains heavily classified. I may state, however, that basic produce the most thrust per pound. The goal is to dework by scientists and engineers at the Lewis Flight Propulsion Laboratory on fuels incorporating boron compounds has been so successful that large industrial plants have been built to produce these new fuels. They will be used to send our new bombers and interceptors to speeds approaching or exceeding 3 times that of sound (2,000 mph) over very long ranges.

Before turning to other aspects of NACA research, it is appropriate to mention the work being done to find ways and means of providing rocket motors having the greater thrust needed by the ballistic missiles of today and the spacecraft of tomorrow. These efforts include studies of such basic fuel components as hydrogen and fluorine. Slightly farther away on the time scale is the development of engines utilizing nuclear energy. Here, the NACA people have been in closest cooperation with their opposite numbers in the Atomic Energy Commission. Again it is too early to describe in detail the progress that has been made; we must be content to observe that substantial progress is being made. Also some time in the future will come exploitation of "electric propulsion," including such devices as ion jets and plasma jets. We must succeed in learning how to design and build these completely new engines by the

Preceding Page Blank

day, not too distant, when we shall be ready to launch voyages of discovery to Venus and Mars, and beyond. A good start has been made; there is much more to do.

In the area of aerodynamic loads and structures, the goal remains much the same as in the earliest days of NACA, to learn how to make our airplane structure, and more recently, our missile and spacecraft structures, strong enough to withstand the greater loads imposed by the greater speeds we are attaining, with, of course, the continuing stipulation that our structures contain not 1 ounce of unnecessary weight. The total structures problem is made the more difficult because our airplanes have attained speeds where aerodynamic heating—air friction—imposes new and more difficult requirements. We have to think in terms of materials that will maintain their high-strength characteristics at temperatures beyond the 1,000° F mark. We have to take into account problems of thermal stress that, by themselves, are complicated and hard to solve. And, all the time, we have to remember that weight must be kept to the absolute minimum. All this has made necessary the calculation, to the closest numbers possible, of the structural requirements that will just satisfy our needs.

Difficult as is this problem with respect to airplanes and guided missiles, it becomes even more challenging in the cases of ballistic missiles and space vehicles. The ballistic missile arches high into space on its way to the target. Most of its flight is at speeds measured in thousands of miles per hour. During reentry into the atmosphere it is subjected to heating problems many times more severe than those affecting the high-speed airplanes mentioned earlier. Spacecraft, as they return to earth, will experience not only very serious heating problems but difficult deceleration problems. The decelerational loads imposed on structure, instrumentation, and passengers must all be within tolerable limits. Spacecraft requirements also are so weight sensitive as to be enormously more difficult to meet than is the case with the airplane.

Research in this area has made necessary the design and construction of novel facilities in which the complex problem can be broken down into solvable parts, and studied under the precisely controlled conditions of the laboratory. The NACA has been a leader in this area, and its new facilities are already producing research information that is immediately useful.

One result of such research that has been especially valuable was development of the "waffle grid" concept of construction. Systematic studies demonstrated the value, both structurally and as a weight saver, of plates that were strengthened and lightened by cutting away metal, either mechanically or by chemical etching, on the inner surface. Today the design of virtually all ballistic missiles and spacecraft makes extensive use of the "waffle grid" concept, and its use is hardly less extensive in the newest airplane designs.

Not unrelated to the structural heating problem is the successful development of H. Julian Allen's "blunt nose" concept. Although Allen's concept, worked out at the Ames Aeronautical Laboratory, was essentially completed in 1952, it was not until 1957 that public disclosure became possible.

In essence, Allen's concept called for a complete reversal of the existing practice of designing ballistic missile warheads with a finely pointed, low drag shape. Instead, he proposed a blunt-nose shape which would create a very high-pressure drag during the reentry phase of flight, where aerodynamic heating was so critical. In this way, he reasoned, most of the heat would be dissipated in the region of the shock wave. To reduce this dramatic story to its barest essentials, Allen's work was verified in special, new laboratory apparatus, and today, every U.S. ballistic missile warhead is designed in accordance with his once radical precepts.

The X–15 is the most recent of research airplanes. It is a direct result of research studies by the NACA that were begun in 1952. The Air Force and Navy agreed on the need for such a project and on a plan of joint financing by contracting with North American Aviation for complete design and construction. The X–15 is intended to be used to provide for full-scale scientific investigations in flight of such space flight problems as weightlessness, reentry heating, and control at altitudes approaching 100 miles, where aerodynamic forces are no longer effective, and at speeds exceeding 3,600 miles per hour. The X–15, however, is definitely not a spacecraft. Rather, it is a vehicle that will permit studying problems that must be solved to enable space flight. It is a successor to the earlier research airplanes of the "X series," and, like them, is a joint venture, with the military services, the aircraft industry, and the NACA working smoothly as a team.

Here it may be pertinent to note that for the past dozen years the research programs of the NACA have been undergoing a gradual change in emphasis, away from airplane problems toward missile and space problems. To be sure, many of the problem areas were of interest and concern to designers of airplanes as well as of missiles and spacecraft. Nonetheless, the reorientation process has been positive and, in fact, accelerating. By the end of the fiscal year, June 30, 1958, approximately 50 percent of the NACA research effort was being devoted to problems affecting missiles and space vehicles.

But, as has been said so often and so forcefully, the military airplane is not yet facing extinction, and NACA research in recent years has contributed importantly to the continued worth of manned aircraft. The Convair B–58, America's first supersonic bomber, makes use of Whitcomb's area-rule principle, described

in Dr. Hunsaker's account, and of the conical camber concept developed at the Ames Laboratory. The North American B–70, often described in the newspapers as the "Mach 3 chemical bomber," has yet to fly. When it does, it will incorporate much in the way of NACA research information that still has high security classification and cannot be mentioned. In the lower speed ranges, Whitcomb's work is being applied to commercial turbojet transport design, in the case of the Convair 600.

Despite the seemingly insatiable demand for more speed, in both military and commercial categories, the NACA has been aware of the need for continued research in the areas of the "low and the slow." Aircraft with the capability to take off and land, either vertically or with short runs, continue to be of interest, and progress has been made in solving problems peculiar to this type. Similarly, the Nation's flight research agency has done important work on such special matters as aircraft noise and operating problems.

Perhaps the most accurate assessment of the effectiveness of the NACA organization—its 8,000 technical and supporting personnel, its $300 million of laboratories, and its comprehensive research programs—came on July 29, 1958, when President Eisenhower signed the National Aeronautics and Space Act of 1958 that created the National Aeronautics and Space Administration. That act provided that the new agency be built upon the NACA as its nucleus. In this way, the lawmakers made sure that the country gained a running start on its bold, exciting ventures in space exploration for "peaceful purposes for the benefit of all mankind."

AERODYNAMIC RESEARCH

With the rapid advent of satellite, ballistic missile, and other hypervelocity vehicle operation, the NACA has intensified its aerodynamic research of both a basic and applied nature on problems of hypervelocity flight. All such vehicles have severe aerodynamic problems during operation within the atmosphere. Studies bearing on advanced flight concepts, aerodynamic heating and stability of reentry and hypersonic boost-glide vehicles, automatic guidance and stability and control of antiballistic missiles have all been pursued vigorously. Likewise emphasis has been placed on equally important basic gas dynamics research dealing with such subjects as high-temperature gas flows, dissociation and ionization phenomena, air properties at high speeds and temperatures, and magnetogasdynamics principles. Experimental investigations have encompassed temperatures up to 15,000° F. in arc jets, 25,000° F. in shock tubes, and speeds of more than 16,000 miles per hour. Such studies are providing new knowledge imperative for the success of launching man into space, with his safe return to earth assured.

The need for improvements in the efficiency as well as the speed, stability, control, and flying qualities of aircraft and conventional missiles has continued to merit a major part of the NACA research effort. The information obtained is being applied rapidly in new aircraft and missile designs. Unfortunately, aircraft for more efficient operation at the higher speeds have aggravated landing and takeoff problems. An important part of the NACA's research effort is being directed toward improving the low-speed characteristics and establishing low-speed piloting techniques of both high-speed and VTOL/STOL-type aircraft.

As may be seen from the following pages, aerodynamic research encompasses a speed range from takeoff to satellite velocity.

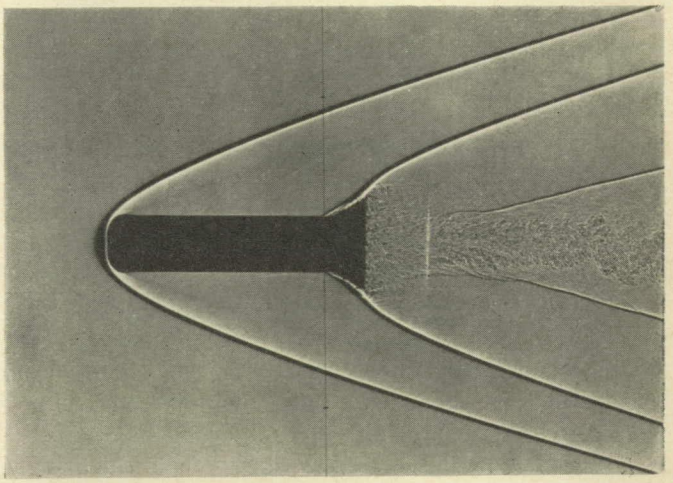
FLUID MECHANICS

Many problems in fluid mechanics, still very incompletely understood, are generated by ballistic missiles, hypersonic gliders, and satellites or space vehicles. Aerodynamic heating is a major factor in determining weight and propulsion requirements of these vehicles, and reduction in heating rates and heating loads pays large dividends. Thus, it is of the utmost urgency that methods of minimizing heat transfer and optimizing vehicle configurations be found. Progress has been made both along the lines of practical solutions to these problems and increased fundamental understanding of the underlying basic fluid flow and gas dynamic phenomena. In spite of the fact that at the high gas temperatures encountered in the flow about hypersonic vehicles, real-gas effects such as dissociation and ionization play an important role, much knowledge has been gained by considering air as a perfect gas. However, an important fact is that the ionized gas in the flow about a hypersonic vehicle permits electrical and magnetic fields to exert forces on the charged particles themselves, thus introducing the whole field of magnetogasdynamics. Activity has increased in this field of research having potential application to the reduction of heat transfer to the surfaces of hypersonic and space vehicles and in the generation of magnetohydrodynamic forces for vehicle lift, control, and propulsion. A brief description of some investigations in these and other areas follows.

526597—60——4

Boundary-Layer Transition and Skin Friction

Basic to the aerodynamic heating problem is an understanding of the boundary layer flow conditions inasmuch as turbulent flow produces significantly higher heating rates than laminar flow. Skin friction drag, especially important in airplane design, is likewise considerably lower for laminar than turbulent flow. Consequently, several important investigations of transition have been undertaken.



A study has been concluded concerned with the fundamental features of the transition process. Turbulence frequently begins in an unsteady fashion with an isolated burst of turbulence. Studies using a Mach-Zehnder interferometer were made of the shape, growth rates, and velocities of movement of such turbulent bursts at Mach numbers up to 7. Much progress has been made recently in wind-tunnel, flight and free-flight model tests in obtaining a better understanding of the effects of roughness on transition. Exploratory results first indicated that transition in most cases was caused by small roughnesses rather than inherent instability of the boundary layer. The limits, or conditions, in terms of basic boundary layer and roughness parameters, under which individual grains and bits of roughness will induce transition, have been clearly established for several basic shapes over an extended range of Reynolds and Mach numbers. Some of the roughness tests were made on blunt bodies. Both two-dimensional and three-dimensional roughness elements have been tested. If the roughness is below a certain critical height, it does not affect the skin friction drag perceptibly. Several investigations have been made for fully turbulent flow to study skin friction over a wide range of Mach and Reynolds numbers, boundary layer noise, and effects of high accelerations of a body on the flow.

It has been well established by tests in a number of facilities, including rocket model tests, that the effect of blunting the otherwise sharp leading edges of cones and flat plates is generally to move transition downstream. This effect has been explored up to Mach numbers of 10 and to very high Reynolds numbers. It has also been shown in recent years that moderate amounts of cooling tend to delay transition, although extreme cooling reverses this effect. Several research programs have yielded additional information on the phenomenon of "transition reversal due to overcooling" as may result when a body is heated rapidly on reentering the dense atmosphere. Perhaps the most important new result is that bluntness on some bodies may aggravate the reversal process, thus creating an interplay in the amount of nose or leading-edge bluntness to be incorporated from the opposing effects of reversal and theoretical transition delay due to bluntness.

Wing leading-edge sweep and shock interactions are known to promote early transition. Wind-tunnel and free-flight tests at Mach numbers up to 10 are continuing, including configurations appropriate for hypersonic boost-glide vehicles. One study has been directed at obtaining a better understanding of the flow mechanism at a sweptwing leading edge using an X-ray densitometer. Various flow visualization techniques have been developed for general transition experiments in both flight and wind-tunnel research.

Heat Transfer

Experimental studies of the aerodynamic heating of various shapes of blunt bodies applicable to reentering vehicles such as ballistic missile noses, hypersonic gliders, and satellites have been extended to higher temperatures, Reynolds numbers and to Mach numbers above 16 in some cases in flight, heated jets, wind tunnels, and shock tubes. Parallel theoretical work has firmy established analytical methods for calculating laminar heat transfer to basic blunt bodies, and both theory and experiments have shown the large reductions in heat transfer that can be obtained by making noses

Shadowgraph indicating heat-protecting shock wave generated at hypersonic speeds around gun-launched model of a blunt-nosed, flare-stabilized body.

flatter or less convex. One series of tests indicated a slightly curved surface to have the lowest maximum heat rates as well as the lowest total heating rates of a number of bodies tested. Extension of the nose-flattening concept to concave bodies has been shown to have further promise if the flow can be kept steady. Some aerodynamic heating investigations have also been made in a high temperature jet and in flight at Mach numbers up to 14 to determine the effects of erosion, roughness, and depressions as might be inflicted on body noses by meteorites and flak. Exploratory studies have been made of erosion by ion bombardment using an ion beam apparatus.

Afterbody heating can also be a serious problem on reentering bodies. A principal controlling variable is the local air pressure. At low supersonic speeds the air pressure on a boattail afterbody is lower than free-stream pressure. However, tests at Mach numbers up to 14 have revealed that the afterbody pressure increased systematically with increasing Mach number and was several times the free-stream pressure at the highest speed. Base heat transfer measurements have been made on flared cone cylinder models and on surfaces submerged in the wake of forebodies.

Although much of the above basic body heat transfer research is pertinent to supersonic aircraft, hypersonic boost-glide, and other hypervelocity winged vehicles, considerable additional research has been accomplished on other heating problems of such vehicles. The wings of such vehicles are critical from a heating standpoint and most configurations have regions of flow interaction aggravating heating. Investigations have been made of the beneficial effect of wing leading-edge sweep in alleviating the heating. Some of the investigations have been of a fundamental nature using yawed cylinders at speeds up to 6,500 feet per second to assist in developing new compressibility theories. In other tests, complete model configurations with different amounts of leading-edge sweep have been investigated in hot jets, hypersonic wind tunnels, and flight at Mach numbers up to 14.5. In one basic investigation of the heat transfer at the body-wing juncture of hypersonic aircraft, a small heating increase was shown as compared to a flat plate reference value; in other cases large effects have been noted. Intensive studies of heat transfer to basic configurations are now underway in a number of facilities where juncture effects, together with leading-edge blunting, transition, and shock impingement effects are simultaneously assessed. New "thin skinned" model construction techniques have been developed to permit thermocouple installation for heat transfer measurements on more complicated configurations.

In many heat transfer investigations considerably more emphasis is now being placed on studying the important effects of angle of attack or yaw and pressure gradient. In one rocket model experiment rolling, the model was observed to have only a secondary effect on heat transfer. Analyses have been made of the heat transfer to a high Mach number ramjet engine and to subsonic and supersonic diffusers. It has been observed in wind-tunnel tests that a protuberance increases local heat transfer rates on the side of a model by large amounts.

Some research has been concerned with the flow of heat through separated boundary layers. Theory has predicted that the heat transfer through a separated laminar boundary layer is roughly half of that through an attached layer. On the other hand, theory suggested a greater heat transfer through a separated turbulent boundary layer than through an attached layer. Preliminary experiments have indicated that the theoretical prediction is correct for the laminar case but incorrect for the turbulent case, so that flow separation may have promise for reducing heat transfer in both laminar and turbulent flow.

Cooling

Many types of advanced reentry vehicles will more than likely utilize some form of reenforced cooling in critical areas to overcome the heating problem. A number of investigations are presently underway dealing with transpiration, film, internal and ablation cooling. The transpiration cooling process has been generally investigated in hot jets and wind tunnels with flat-plate models and with conical and flat-faced nose shapes as well as a porous cylindrical leading edge using helium primarily as a coolant. The effectiveness of helium transpiration cooling for body noses is also being investigated in flight. Film cooling by upstream injection of gaseous and liquid coolants is likewise being investigated in the same manner with various shaped bodies having conical, hemispherical, flat faced, inverse hemispherical, and other blunt noses.

One cooling technique for reentry vehicles receiving attention is underskin cooling by natural convection of liquids. Both theoretical and experimental programs are underway to determine the feasibility of such heat sinks. Models of double-walled structures are being used to investigate the effectiveness of convection cooling derived from the circulation of gases and liquids within the walls. The effects of vehicle rotation on the internal flow is also being evaluated.

Considerable effort has recently been expended in investigating the basic theoretical principles of ablation cooling. As a part of this work exploratory measurements have been made of the effective heats of ablation of a large number of materials and combinations of new materials in air jets at moderate to high heating rates. The ablation program includes flight tests of several models at Mach numbers above 14. Considerable effort has been expended in the development of suitable ablation rate sensors for flight application.

Air Properties at Elevated Temperatures

Flight at extreme hypersonic velocities and the accompanying high temperatures make it necessary ultimately to consider air as a real gas and not a perfect one. Thermodynamic and transport properties of air in the disturbed flow fields about hypervelocity vehicles can deviate widely from ideal gas values due to dissociation and ionization. As temperature increases, air becomes subject first to molecular vibration, then to dissociation of the oxygen molecules to form atomic

oxygen and then to a similar dissociation of nitrogen molecules. An analytical study has been completed of the effect of oxygen vibration and dissociation in one-dimensional channel flow. The effects of the rates of the chemical and physical reactions were found to be appreciable. Theories for rates of reaction were found to be in serious disagreement indicating the need for experiments. A study has been made of the influence of the equilibrium chemical reaction in the air on expansion flows past corners termed Prandtl-Meyer flows. This type of flow has wide application in analyzing pressures on wings and bodies. The influence of the gas reactions was found to be subject to an exact analysis and the changes in flow properties were considerable.

Theoretical studies of air at extremely high temperatures have yielded approximate analytical expressions having considerable value in engineering applications in giving thermodynamic and transport properties of air that agree closely with those obtained by lengthy iteration methods.

Magnetogasdynamics

Ionization of air at high temperatures offers the possibility that airflow and hence heat transfer can be altered by application of magnetic fields about a body. The electrical conductivity of the high temperature gas at the nose of blunt bodies is appreciable during critical reentry conditions. Also, the conductivity may be increased by seeding the flow with easily ionizable materials such as the alkali metals. Such ideas have been theoretically explored and methods have been developed for permitting estimates of magnetohydrodynamic effects on heat transfer and skin friction to be made for cases hitherto unsolved.

Magnetogasdynamics opens a vitally important possibility of the generation and acceleration in the laboratory of high-velocity plasma flows that truly simulate hypersonic flight conditions. Considerable theoretical and experimental work is being accomplished on key problems, including electron diffusion, stability of plasma flows, boundary-layer flows in magnetic fields, rates of recombination of ions, and methods of ionization and electron emission. Arc jets and low-pressure seeded flows have been developed as ion sources.

There are indications that the conducting gas layer about a hypersonic vehicle may create a serious problem with regard to radio or telemeter transmission. Theoretical work has been carried out suggesting the use of magnetic fields to improve transmission. Radio transmission experiments are in progress using a cyanogen-oxygen flame seeded with potassium to simulate an ionized sheath about a body.

Body and Airfoil Flow Fields

An understanding of the basic flow fields around bodies and wings is fundamental to many design aspects of aircraft, missiles, and spacecraft. Several investigations of such nature have been completed or are in progress at all NACA laboratories throughout the speed spectrum. These include airfoil pressure distribution measurements, refinements in means of determining and reducing wave drag through area and moment-of-area rule principles, generalized theoretical studies of drag due to lift, generalized theoretical and experimental studies of body and wing-body flow fields at Mach numbers up to 10, and improvement of nose probe devices for measuring flow field characteristics.

Research Facilities and Techniques

An important part of the NACA's effort in basic fluid mechanics is continually devoted to exploring new techniques and apparatus in order that advanced facilities can be provided for research in the expanding frontiers of flight. Along these lines considerable progress has been made in the use of helium for high Mach number flows in wind tunnels. Advances have been made in tunnel-wall correction techniques. Work has continued in improving shock tubes to provide higher Mach numbers and stronger shocks. New shock tube and ultraviolet absorption techniques are being employed for studying air dissociation and recombination rates. Arc-powered wind tunnels and jets are likewise being developed to push the limits of their potentialities. Continued effort is being expended in improving the performance and utility of rocket free-flight test vehicles.

The combustion of cyanogen and oxygen yields CO and N_2 at a very high temperature suggesting a number of possible test uses which are being explored, for example, (1) heat transfer and ablation without chemical reaction, (2) chemical reaction effects and ablation by addition of contaminants to the hot flow, and (3) magnetohydrodynamics tests by seeding the flow with an alkali metal to obtain higher electrical conductivity. A low-velocity burner has been seeded with potassium and a supersonic jet is under construction.

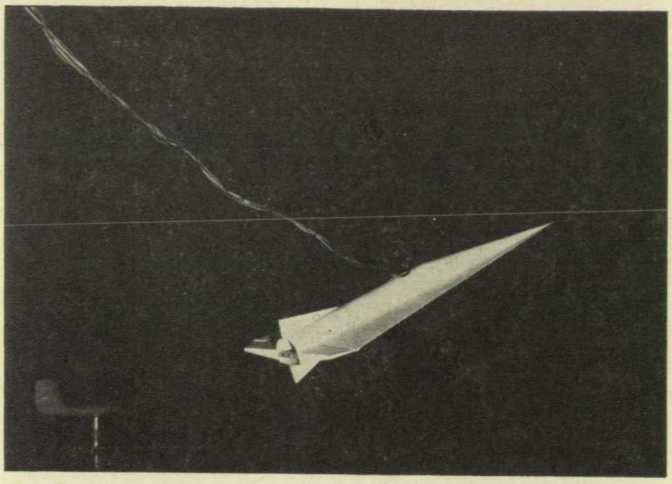
A free-piston compressor has been put into operation in conjunction with a M=11.2 nozzle. The feasibility of using the thermal decomposition of nitrous oxide in the compressor has been demonstrated successfully. Nitrous oxide decomposes with the release of heat into nitrogen and oxygen in proportions closely simulating air. Whereas for air the theoretical final temperature for a typical case is 6,000° F., the nitrous oxide decomposition products raise the temperature to about 13,500° F. The compressor walls considerably lower these temperatures; nevertheless, indirect measurements have in-

dicated temperatures greater than 5,000° F. using nitrous oxide.

HIGH-SPEED PERFORMANCE

All flight vehicles, whether an airplane, a missile, or a space vehicle that is to be recovered, must fly through the earth's atmosphere. Many aerodynamic problems must be overcome to accomplish this flight objective whether the vehicle is controlled by a human pilot or artificially. The aerodynamic characteristics of reentry vehicles are of such importance that the penalty for improper aerodynamic design is destruction. The NACA has conducted analytical and experimental studies to supply the information required for the solution of problems of atmospheric reentry. At the same time, work has continued on other problems of flight within the atmosphere. A very brief description of some of this work is contained in the following paragraphs.

Ballistic Missile, Satellite, and Spacecraft Configurations



Broad analyses have been made of the heat transfer, atmosphere entry deceleration, and propulsion problems of vehicles for satellite, lunar, and interplanetary missions. Simplified equations have been developed by which a wide range of flight trajectories can be studied and important parameters varied so that designers can readily visualize trends, such as the effect of entry angle, speed, drag, and lift. The analyses included numerical calculation of the trajectories for round trips to the moon and the near planets using ranges of thrust-to-weight ratio and specific impulse typical of chemical rockets, nuclear rockets, and electric propulsion systems.

Proposals for manned satellites have been based on several design concepts such as high-drag blunt ballistic configurations, low-drag winged configurations, and combinations of the two utilizing small wings or body shaping to produce lift with high drag. The blunt wingless vehicles depend on a concept developed at the Ames Laboratory for the dissipation of heat due to aerodynamic heating. This is the concept that is used for the nose cones of present ballistic missiles. The winged vehicle utilizes lift to hold itself in the upper regions of the atmosphere while its speed is gradually reduced by drag forces; its heat is dissipated largely by radiation. The winged vehicle, being a glider after it enters the atmosphere, possesses the potential for some degree of control, thus providing a pilot with a choice of landing area. Ballistic high-drag vehicles would land by parachute, and a pilot would have virtually no control over the landing point once the vehicle entered the atmosphere. The low-lift, high-drag vehicle with small wings would also land by parachute, although some aerodynamic control can be provided to permit a pilot to make limited correction for errors in reentry angle or speed.

Studies of the many problems associated with these three types of vehicles are continuing. Research on reentry vehicles has been devoted to both blunt, nonlifting bodies of revolution applicable to ballistic missiles as well as reentering satellites and to body shapes which utilize lift in attempts to alleviate deceleration and aerodynamic heating problems. The high decelerations that are imposed on an occupant during reentry create a serious problem. Basic studies on methods of controlling decelerations and heat transfer of satellite vehicles and of predicting with reasonable accuracy the range covered during the return of the vehicle into the earth's atmosphere have been initiated. In one analytical study of the entry of a general class of high-drag vehicles having low-aspect-ratio wings, the deceleration, heating, and range were controlled by programing the angle of attack as a function of several measurable quantities such as initial flight-path angle and wing loading. Another theoretical and experimental study has been made of the stability and heat transfer to basic bodies of revolution shaped for minimum heat-transfer rates and suitable for ballistic missile or satellite use. The aerodynamic and heat-transfer characteristics of bodies employing lift during atmospheric entry are being studied, and a shape has been found which appears promising for manned satellites from the standpoint of aerodynamic heating, reentry deceleration, stability, and control. Some experimental investigations of the longitudinal characteristics of blunt, wingless reentry configurations at a Mach number of 7 have indicated that simple fins or flaps can provide satisfactory trim characteristics.

Another advanced flight concept that possesses aerodynamic problems akin to those of the winged satellite vehicle is the boost-glide vehicle, so named because of its mode of operation, which consists of rocket boost to its cruising speed and altitude and a powerless glide to its destination. Experimental and analytical studies have indicated the feasibility of the boost-glide flight concept and work has been conducted in the NACA Laboratories to provide solutions for many of the design problems.

Three main problems are the achievement of required lift-drag ratios, alleviation of the severe aerodynamic heating, and provision of satisfactory stability. Experimental and theoretical work is being conducted at all NACA Laboratories on the performance and stability of a number of boost-glide configurations. Wind-tunnel and rocket-model tests are being conducted to study the effects of body and wing planform geometry on the lift-drag characteristics at supersonic and hypersonic speeds. Aerodynamic heating, stability, and con-

Model of a hypersonic boost glide vehicle being flight tested in a wind tunnel to determine low speed dynamic stability characteristics during landing approach. Controls of the hydrogen-peroxide powered model are electrically activated by "pilots" outside tunnel through slack wires shown.

trol are also being studied over the anticipated operational Mach number and angle-of-attack range.

In addition to the reentry and glide phase of flight for these advanced flight concepts, there is the problem of launching the vehicles to the required speeds and altitudes. Some studies have been completed and others are continuing to provide information on booster vehicle staging, separation, aerodynamic loads, and stability.

Airplane Configurations

Although the program of research into space has been intensified, effort also has continued to improve the efficiency of flight within the atmosphere to the point where supersonic flight of fighter and research airplanes has become routine. Aerodynamic efficiency is improved by shaping the airframe to generate the required lift with the least possible drag. Propulsive efficiency requires that the air-breathing engine together with its intake and exhaust systems yield the greatest possible thrust for the lowest consumption of fuel. Structural efficiency seeks the lightest weight at greatest strength.

High-speed wind tunnels have been used advantageously to exploit the potential drag reductions suggested by supersonic wing theory. The benefits of sweepback have been systematically analyzed and new studies have revealed methods of accomplishing an elliptical distribution of lift over the wing surface which, in theory, would result in minimum drag due to lift. The advantages of cambering and twisting wings have been well established, and several supersonic airplanes now in operational use or in development incorporate these principles. However, the full potential of this approach as predicted by theory has not been realized in experiments and work is continuing on this problem. Friction drag is a major portion of the drag of supersonic and hypersonic aircraft as well as the source of aerodynamic heating. Research in this area has been pursued actively at all NACA research facilities.

New studies of interference pressure fields show promise in supersonic design application. By properly shaping an airplane the pressure fields resulting from interference between various airplane components can be made to react favorably to improve flight efficiency and stability. The study of the basic components of a vehicle and how these components can be combined is essential to understanding the problems and providing design information. Through the study of wings, bodies, and wing-body combinations, the feasibility of the advanced concepts and aircraft configurations described above has been established. Many of these fundamental studies have been conducted and are continuing. Considerable work has also been conducted on cockpit canopies with regard to shape and location on the fuselage. Improper design of the cockpit canopy can be a source of severe drag penalties.

Inlet problems, too, are of great importance in supersonic aircraft. Aside from the requirement of efficient inlets, it is necessary that the inlets be located so as to produce the lowest overall airplane drag. Research results have indicated that inlets can be located to alleviate interference adversely affecting flight efficiency.

In addition to the aerodynamic interference between the major components of aircraft, the interference of such elements as external stores, missiles, and nacelles can be important and have been studied. With regard to missile interference effects, the aircraft flow field can affect the missile-launching characteristics to the extent in some severe cases that the missile could collide with and destroy the parent aircraft. Considerable work has been done on the launching problem for both externally and internally carried stores and missiles.

INTERNAL FLOW

The performance characteristics of supersonic airplanes and missiles with air-breathing engines are strongly influenced by the overall efficiency of the engine induction and exhaust systems. The pressure recovery of these systems must be high to obtain both a maximum thrust for a given weight and a low rate of fuel consumption. The components must be shortened wherever possible to reduce weight. The overall drag must be kept small and the propulsion system must be capable of satisfactory operation at off-design conditions. During the past year considerable research has been conducted to determine methods for improving the performance of aircraft and missile internal flow systems. At Mach numbers up to 3, the research has been of a detailed nature, whereas at higher speeds the research is of a more exploratory nature to determine the problems which must be solved.

Inlets

Considerable research effort has been expended during the past year on inlet designs suitable for operation at high supersonic speeds. These tests have included all-internal contraction, external-internal contraction, and all-external contraction inlets. Methods investigated for improving performance over the operating range have consisted of boundary-layer control, variable geometry, airflow bypass, and location of the inlet in favorable airplane pressure fields. In addition, methods have been developed for maintaining high performance during angle-of-attack operation.

Several programs have been conducted in the area of inlet dynamics and the experimental results of an inlet-engine configuration have been correlated with a simple theory. Two inlet control systems were also evaluated and found to be effective in maintaining high inlet performance with varying flight and engine operating conditions.

A theoretical study has been concerned with the calculation of the external pressures on inlet cowls and the internal pressures in internal compression inlets designed to have isentropic compression. Comparison of a number of theories for computing the external pressure on inlet cowls has been made to assess their accuracy. Analytical studies have also been made to determine the effect of surface temperature on the properties of the boundary layer handled by an inlet scoop system. These results permit a prediction of boundary-layer-removal-system performance at high speeds.

Exploratory studies have been conducted on a variety of inlets designed for flight at hypersonic Mach numbers. These investigations permit a comparison of the performance of the basic types of inlets operating in this flight regime and indicate many of the design parameters which must be considered before efficient hypersonic flight can be obtained. Since flight at hypersonic speeds will require blunted inlet leading edges to reduce heat transfer and to facilitate cooling, an investigation was conducted at Mach 3 to determine the effects of such blunting on off-design performance.

Inlet designs for a number of specific engines and airplanes have been investigated and methods for obtaining improved performance from these designs have been found. Flight measurements with several military aircraft have also been made and the actual inlet operating characteristics determined.

Ducts and Diffusers

During the past year subsonic diffuser research has been concentrated on a study of the effects on pressure recovery and flow distortion of a diffuser operating with or without a normal shock near the throat. Boundary-layer shock interaction effects have been studied and the effects of boundary-layer control in a short diffuser are being determined.

A basic investigation of the characteristics of a turbulent boundary layer in a continuous adverse pressure gradient is also in progress to determine a method for minimizing boundary-layer effects in supersonic inlets.

Jet Exits

Several studies at transonic speeds have been made of the effects of jet exits on base and afterbody drag characteristics. A comprehensive investigation of clustered, multiple exits was included in this program, and the performance of several jet-exit configurations was determined. In addition, a family of divergent ejector nozzles was investigated to determine the off-design thrust levels that could be maintained, and a series of convergent-divergent exhaust nozzles were investigated to determine the separation characteristics at low-pressure ratios.

The interaction of the rocket nozzle flow and the external airstream in the base region of several ballistic missile configurations has received continued attention. Conditions for base burning and the general level of base temperature to be expected were determined for a number of configuration variables as well as for the basic prototypes.

Investigation of a method of varying the effective flow area of a convergent exhaust nozzle by aerodynamic means was conducted on an unheated-flow duct rig. Effective control was obtained and analytical expressions relating the performance with significant design and operating variables were developed.

Several model jet deflectors were investigated to determine the effects of design variables on their performance and operating characteristics. Transonic tests of the effects of a target-type thrust reverser have been conducted, while swiveled nozzles, auxiliary nozzles, and mechanical and aerodynamic deflectors which were designed to be adaptable to a wide variety of turbojet exhaust systems have been investigated in quiescent air. Analytical expressions relating the performance of each type deflector with significant design variables were also determined.

AERODYNAMIC STABILITY AND CONTROL

Stability

During the past year continued study has been made of factors affecting airplane pitchup—a longitudinal instability discomforting to the pilot and often dangerous. Detailed experimental studies were made to investigate methods for eliminating or alleviating the pitchup tendency; information was obtained on the effects of such modifications as changing the location of the horizontal tail and wing, of modifying the wing shape, and of adding auxiliary horizontal tails.

The problem of providing adequate but not excessive longitudinal stability over the complete speed range for high-performance airplanes has also received additional attention; this problem is of concern inasmuch as a very stable airplane will not only be difficult to maneuver but the large control deflections required for trim and maneuvering will result, especially at high speeds, in large loads, and high trim drag. Extensive wind-tunnel studies have been made to determine the static aerodynamic characteristics of canard configurations which have been found to have some advantages over conventional, tail-rearward designs. Analytical studies have been made to study the flight characteristics of a canard airplane having various amounts of longitudinal stability, and to investigate the need for automatic pitch-damping devices.

The loss of directional stability with increasing speed and angle of attack, characteristic of most supersonic airplanes, continues to be a design problem. Experimental model studies have been conducted which indicate the important influence of such factors as vertical tail and ventral fin size; wing planform, dihedral, and location; and fuselage nose length and cross-sectional shape. Guided by the results of such tests, theoretical methods have been developed which enable accurate design estimates of the directional stability characteristics of airplane configurations.

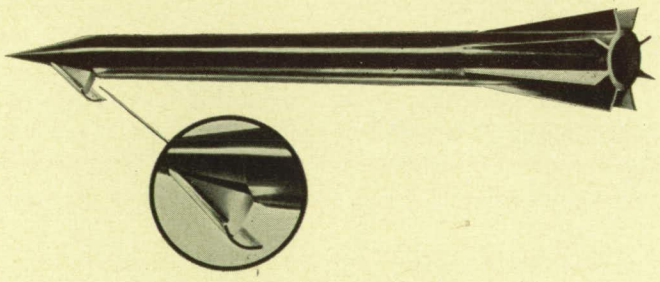
Accurate prediction of the dynamic stability characteristics of high-performance airplanes has also become of increasing importance to designers. Inasmuch as questions concerning dynamic stability can usually be resolved from a study of the rotary derivatives of a particular aircraft, increased attention has been given to obtaining information on these derivatives for a variety of configurations over a large angle-of-attack range. With these and other stability derivatives used as inputs into ground simulators, studies have been made of the ability of a pilot to control various airplane configurations under different flight conditions. Particular emphasis has been given to approximating the flight characteristics of the X–15 research airplane as fully as possible before its actual high-speed, high-altitude flights are initiated.

Although much of the information obtained in studies of conventional aircraft provide stability and control information applicable to very high-speed airplane and recoverable-satellite vehicles now being considered, additional and higher speed studies are required to determine the effect of the basic differences in such configurations on the aerodynamic characteristics. Extensive studies have been made on several hypersonic boost-glide designs to determine their stability and control characteristics over large speed ranges. Some of the models have been studies in free flight, simulating their characteristics in the low-speed, approach-to-landing flight condition, and providing information on the adequacy of the controls as well as on the possible need for artificial damping devices at these speeds. Analytical studies of the flight characteristics of such vehicles have also been made.

Experimental and analytical investigations to determine the stability and motion characteristics of configurations having lower lift-drag ratios considered more suitable for manned satellite or spacecraft during flight back into the earth's atmosphere have been initiated; the effects of fuselage nose blunting, stabilizing fins and flares, afterbody shape, and various types of controls have been studied experimentally. In addition to high-speed wind-tunnel studies to determine the basic stability and control characteristics of these configurations, low-speed information required to predict landing characteristics have been obtained. Analytical studies have been carried out with specific reference to the dynamic stability of a hypothetical manned vehicle which enters the atmosphere on a "skip-type" braking trajectory, executing an upward turn to eject itself from the atmosphere or to a less dense atmosphere to reenter at reduced speed. A general solution describing the dynamic stability and oscillatory characteristics of such vehicles following any trajectory has been developed.

The current importance of producing an effective long-range ballistic missile and of developing methods for combating them has resulted in an expansion of stability and control research in these areas. Experimental static and rotary derivative data have been obtained on a variety of configurations suitable for the warhead stage of the ballistic missile as well as for the previously mentioned studies of spacecraft entering the atmosphere. The effects of configuration changes, such as body-nose bluntness and afterbody shape, have been extensively investigated. These data, together with other calculated information, have been used in analytical studies to estimate the trajectory, stability, and aerodynamic heating during terminal descent.

Considerable effort has been devoted to the investigation of the supersonic aerodynamic characteristics of a series of missile models having configurations suitable for the interception of ballistic missile warheads. Various means of providing stability and control on tail-aft, canard, and flared-body models have been studied. Studies have also continued of the characteristics of more conventional, lower performance air-to-air, ground-to-air, ground-to-ground, and air-to-ground missiles.



Controls

The increasing variety of airplane and missile configurations being designed has necessitated a broader knowledge of the characteristics of conventional controls and consideration of new concepts of control.

Wind-tunnel investigations have been made of such controls as flap and spoiler-slot deflectors, differentially deflected (rolling) tails, jet spoilers, and lateral blowing jets to determine the effects of various wing geometric parameters on the control characteristics. The effectiveness of the canard control surface, previously mentioned as being an attractive means of providing longitudinal trim for high-performance aircraft, has also been extensively studied.

Research has increased on jet-reaction controls having application to flight at very low speeds or high altitudes where aerodynamic controls have reduced effectiveness. One investigation has been made of the performance of a number of reaction control devices having possible application to the landing of VTOL aircraft and space vehicles. Analog studies have also been conducted to determine the effectiveness of reaction-jet controls similar to those to be used in flight tests of the X–15 research airplane.

Aerodynamic control systems intended for low aspect-ratio winged missiles have been studied over a range of supersonic Mach numbers; the relative effectiveness of tail, canard, swivel nose, and all-moving wing controls was determined. Other studies have been completed of the effectiveness of body-flap controls for air-launched, wingless missile configurations; such missiles require a minimum of stowage space and hence a minimum compromise of the drag characteristics of the missile-carrying aircraft. Body-flap controls have also been studied on missile configurations considered suitable for hypersonic antimissile use. In addition, basic studies have been made of vehicle control requirements for programing decelerations and heat transfer of vehicles reentering the atmosphere.

Model of a wingless air-to-air missile utilizing a retractable body flap as a lift-producing control device.

Flying Qualities

The flying qualities of airplanes designed to have very low or even negative static longitudinal stability at supersonic speed (in order to provide low trim drag and therefore increased range) have been studied recently. The limit of negative stability that can be tolerated, the effect of artificial pitch damping, and other factors affecting controllability were investigated from the standpoint of pilot opinion and measured performance using a pilot-controlled analog simulator.

Several projects to determine the acceptability of a side-located controller that requires an up-and-down hand motion pivoting at the wrist for longitudinal control and a lateral hand or forearm motion for lateral control have been undertaken. With this type of controller it is easier to restrain the pilot's arm so that high-acceleration levels will not introduce unwanted controller motions. Use of this type of controller also clears the center cockpit area which may then be used to good advantage for navigational instrument displays. Another fundamental flight research project was undertaken to determine the nature of such factors as pilot reaction time delay and response time in correcting airplane motions. Results of this research will aid in designing control systems to take best advantage of pilot capabilities. The results are also of value in determining the validity of other human-response tests conducted with ground simulators.

Investigation of the spin characteristics of models of many specific current and proposed military airplanes has continued utilizing the free-spinning tunnel. In some cases force data on the complete model or the fuselage nose alone have been required before proper interpretation of model spin-tunnel data could be made in terms of recovery characteristics for the corresponding airplane. The results show that recovery from the spin of some of the current-type fighters is so difficult that it would be very desirable to avoid entering fully developed spins. This can best be accomplished by determining the most expeditious way of recovery from the incipient phase of the spin. Preliminary tests have therefore been made to study methods of effecting such recovery on a scale model representing a current fighter airplane. A recently developed helicopter-launched, radio-controlled model technique has been utilized.

Flying quality research studies during the last year have also given additional consideration to the factors affecting pilot selection of landing-approach speed, Dutch-roll damping, and lateral-control requirements of several current fighter-type airplanes.

AUTOMATIC CONTROL

Missiles

Studies of missile stabilization and control have considered improved means of simplifying and analyzing complex automatic control and guidance devices. Although this program was initiated with reference to air-to-air attack missiles, the results have application to other classes of missiles, including ballistic and antiballistic, as well as to automatically controlled and guided airplanes. Some of these studies are discussed now.

Changes that occur in missile response characteristics to control deflections for varying flight conditions have led to complicated methods of adjusting automatic con-

trol parameters. In studying a number of simplifying techniques, consideration has been given to a control actuator whose torque output is proportional to the input of the control system. Results indicate that such actuators can simplify the control system and result in acceptable target-miss distances.

A study has been made to determine the relative importance of factors that place limitations on the minimum obtainable miss distance for a missile navigation system in which the missile follows a radar beam that is tracking the target. The factors considered were the natural motions, and steady-state acceleration capabilities of the missile, target evasive maneuvers, and radar angular scintillation noise. Simple correlation equations expressing minimum miss distance in terms of these factors were obtained. Possibilities for system improvements were indicated. Also studied were the effects on the average target-miss distance of limiting the allowable acceleration of a beam-rider missile. Contrary to intuitive thinking, the study showed that miss distance decreased as the ratio of the limiting to the design acceleration increased when the guidance system was designed for best performance at a given acceleration.

The determination of optimum radar-noise filtering characteristics to be used in weapon system design is generally a long and tedious process. Studies of these complex equations have been successful in determining simplifications and approximations to enable sufficiently accurate explicit solutions. From these results it has been possible to answer in a quantitative manner important questions regarding the effect of the target maneuver on the effectiveness of the guidance system.

Other work on improving missile systems indicated the need for enlarging the scope of filter theory to include nonlinear considerations. This is due to the trend of potential targets to fly at higher speeds and altitudes where the maneuverability advantage of the defensive missile is lost. Under these circumstances present theory is inadequate because the problem becomes a nonlinear one. A study was undertaken to generalize previous theory by exploiting the intentional use of nonlinearities as a means of minimizing miss distances.

Present theory dealing with noise contamination is restricted to systems whose design constants do not vary with time of flight. However, many systems have time-varying constants. Studies have been carried out to enlarge the scope of the theory so as to be applicable to these systems. Factors considered were target evasive maneuver, radar glint noise, missile maneuverability, and the inherent time-varying character of the missile maneuvers. The results of this and the preceding filter studies are applicable to many aircraft interception systems.

The problem of storing air-to-air missiles on parent airplanes has led to the consideration of wingless or very low aspect ratio missiles. These missiles rely on body-lift capabilities for maneuvering which require large pitch and yaw angles. The effects of these large angles on the performance of a navigation system was investigated analytically. It was shown that a problem requiring careful attention is space stabilization of the radar antenna against body motions.

Guidance and control requirements for antiballistic missiles have been investigated, considering both aerodynamic and reaction controls. Two types of interception were considered; one in which the relative-approach speed is small compared with the target speed, and the other where the relative-approach speeds are extremely large as would be associated with head-on interception. As part of this study, roll stabilization of hypersonic vehicles was investigated. Considered were the effects of large fuel expenditures and large dynamic pressure variations.

Aircraft and Spacecraft

Flight control studies of current high-performance airplanes and advanced airplane-design concepts have included ways and means of providing automatically stability and control characteristics acceptable to the human pilot for specific tasks such as landing and target tracking, and completely automatic flight-control where improved mission performance dictates.

Slow airplane response to various control commands such as roll, yaw, and throttle adversely affects the pilot's ability to control an airplane in landing approaches. Flight studies conducted in smooth and rough air with an airplane modified to provide artificial variation of roll and yaw damping have provided boundaries defining acceptable levels of damping and control response. Flight studies have also shown automatic throttle control to be a promising way of allowing reduced speeds in landing-approach maneuvers.

In many high-performance airplanes it is possible for the pilot to exceed inadvertently the design loads in accelerated and/or high angle-of-attack maneuvers. Analytical and ground simulator studies of an elevator-motion braking device actuated by normal acceleration, pitching acceleration, and pitching velocity signals were extended to flight. The flight studies indicate that inadvertent accelerations will be limited to tolerable levels.

Other studies have resulted in the development of a method of predicting the relative severity of pitchup and the effects of aerodynamic modifications and stability augmentation devices on several supersonic airplanes with pitchup problems. An automatic pitchup control system incorporating an angle-of-attack sensing device to retrim the horizontal stabilizer as the "pitchup region" is approached and entered has alleviated the pitchup considerably on a test airplane.

To increase the utilization of computer systems carried on aircraft, it has been thought that some functions need not be carried as continuous processes but could be handled intermittently on a time-sharing basis. Studies of yaw and pitch stabilization have led to the belief that discontinuous control systems could reduce complexity and system power requirements of airplane automatic control systems. A study has been made of the application of sampled-data theory to an airplane with an altitude control system. A better understanding of switching criteria has been obtained and should lead to useful design techniques.

On future airplane designs it may be necessary to tolerate marginal levels of static and/or dynamic stability for reasons of performance improvement and to obtain desired characteristics by stability augmentation. The problem of marginal flight control characteristics when the primary stability augmentation system fails has been studied to determine whether the pilot can cope with the emergency or whether secondary systems must be provided.

An airplane which can have its longitudinal dynamic response and control system characteristics varied has been utilized in a study of control system dynamics. Similar studies have been made on a ground-based simulator. Insight has been gained regarding the desired dynamics of longitudinal control systems for airplanes varying from transport types to those proposed for atmospheric entry vehicles.

Studies of airplane control systems where the pilot controls the airplane through commands to an automatic pilot were extended to take into consideration flight in rough air and flight at negative static stability margins as may be encountered at subsonic speeds by hypersonic designs. The systems involving angular-rate command and normal-acceleration command appear to be able to cope with small degrees of longitudinal instability.

The use of information derived from airborne radar equipment tracking a target at the end of a runway to assist in making an automatically controlled approach has been studied analytically. Such systems would eliminate the need for auxiliary ground equipment as employed in present landing control systems and make use of radar equipment already carried on many airplanes for other purposes. A usable airplane control scheme has been devised.

Flight and analytical research has continued on tracking control problems of current and projected interceptor airplanes. Studies included consideration of computer and radar display parameters for manual-mode tracking and study of factors that affect flight path stability and aiming accuracy in attacks with an automatically controlled interceptor, including consideration of system changes to improve performance against maneuvering targets. Studies were also made of the effects of high closing rates with consideration of the effects of interceptor maneuverability on guidance systems designed for interception in collision course attacks, and of an automatically controlled interceptor using bank-angle-error for lateral-control commands.

Piloting problems in exit and entry of manned flight from the atmosphere of the earth expose the pilot to an acceleration environment beyond his past experience. A joint NACA-contractor-military service program in support of the X–15 airplane program was conducted in a centrifuge to determine the effects of typical exit and entry acceleration time histories on pilots' ability to control the airplane. Specific factors considered were airplane stability augmentation and flight data presentation to the pilot. Other studies with hypersonic airplane type configurations have involved the use of a ground-based flight simulator to investigate damping requirements with regard to longitudinal, lateral-directional, and roll modes of motion.

Prediction of the dynamic behavior of large vehicles representative of ballistic missiles, hypersonic aircraft, or spacecraft during boost is complicated by the characteristic lightweight, flexible structure, and the large variable internal mass. In order to understand the stability and control problems of this class of vehicle, studies were undertaken considering autopilot and thrust control response, aerodynamic forces, fuel sloshing, and structural elasticity. These studies have given some insight to the problem of automatically stabilizing complete high-performance vehicle systems. Also the effects of reaction controls on the automatic stability control and orientation of these types of vehicles have been studied in the flight regimes where low air density makes conventional aerodynamic controls ineffective.

The flight dynamics of vehicles reentering the earth's atmosphere must be such that the vehicle does not exceed limiting attitude angles associated with aerodynamic heating and/or other structural considerations. Studies have been conducted to determine the degree of inherent aerodynamic or artificial stability required for typical bodies. Studies have also been made of the possible utilization of a man aboard a satellite for piloting purposes. Considered were flight-data instrumentation as well as vehicle stabilization and control requirements.

Preliminary considerations indicate that certain types of satellites will require accurate placement in orbit and accurate control of attitude. In a generalized investigation of satellite stabilization and control, consideration was given to such matters as the earth's force fields, internal power requirements and sources, control and sensing devices, and initial placement of the

Electronic Simulator Explores Piloting Problems

Cockpit in left background which is free to rotate in pitch and roll, coupled with electronic equipment in foreground, constitutes one of a number of flight simulators which enable study of piloting and control problems of high speed flight. In view of the safety and economy of simulators their use is becoming widespread.

satellite in the design orbit. The matter of attitude control was given special consideration. Control systems considered include hydrogen peroxide jets, inertia wheels, and permanent magnets that react with the magnetic field of the earth.

LOW-SPEED AERODYNAMICS

VTOL and STOL Aircraft

Emphasis in the field of VTOL and STOL aircraft has shifted somewhat from basic configuration studies to the broader problem of performance and stability of complete configurations. Dynamic models of two propeller-driven, tilt-wing experimental aircraft have been tested to determine the behavior of the aircraft during the transition from hovering to forward flight. Jet-powered models of the tilting-engine and tilting-wing-and-engine types have also been flown. Full-scale wind-tunnel tests of an unloaded rotor-type convertiplane have been made to investigate the vibration characteristics of the wing-pylon-rotor combination. In addition to free-flight model and wind-tunnel tests of VTOL and STOL aircraft, the NACA is becoming engaged in flight tests of test-bed VTOL/STOL aircraft to investigate handling qualities as well as stability and control characteristics.

Interest continues in a wide variety of VTOL/STOL applications involving both propellers and jet power plants. Recent investigations of a deflected slip-stream model showed that improved hovering efficiency is obtained when the number of propellers along the wing-span is increased, even when some overlapping of the propellers becomes necessary. The large amount of information now available on deflected slipstreams has been used as the basis for a semiempirical procedure for predicting lift and drag in transition of this type of vehicle.

Shrouded-propeller applications in the form of a stand-on aircraft and multiple-fan "flying jeeps" are also being investigated in model flight tests. These include investigation of the stability and control characteristics of two- and four-propeller arrangements in both shrouded and unshrouded configurations. A supporting program involves force tests of the same models. Initial flight tests with the two-propeller model showed that it required roll stabilization in hovering flight. As forward speed increased, increasing amounts of roll stabilization were required. The flight tests also showed that a greater angle of inclination was required to achieve a given forward speed than was anticipated.

Jet Flaps

Research on providing greater lift in order to improve the landing and takeoff performance of airplanes is continuing, with a significant portion of the effort directed toward the augmentation of lift by means of the jet-flap principle. Although some attention is still being given to refinement of methods of providing lift by suitable location of the jet exhaust on the wing profile and to the effect of flap span, increased emphasis is being placed on studies of the stability and control characteristics of complete configurations and on noise suppression possibilities of the various arrangements. In addition to low-speed wind-tunnel studies, free-flying models are being used to study the dynamic stability and control characteristics of jet-flap arrangements flying at high-lift coefficients. In these studies various methods of providing longitudinal trim and control are being used including downward-directed fuselage nose jets, jet-augmented flaps on canard surfaces, and various tail sizes and locations. Models of conventional jet-transport-type configurations with jet flaps have been flown at lift coefficients up to 12, using a nose jet for trimming.

Two other jet-flap areas receiving attention are cruise performance and the large loss of lift in ground effect. Research on the ground proximity problem is continuing in static wind-tunnel studies and is being extended to include takeoffs and landings with flying models. High-speed cruise performance studies have shown that the lift can be increased by blowing downward through closely spaced holes along and near the trailing edge.

Propellers

Among the several means of achieving VTOL operation of airplanes is the tilting propeller concept. Propeller data (performance and stress) are rather lim-

ited at high angles of attack. To attack the problem of obtaining full-scale propeller data under conditions typical of VTOL operation, a 3,000-horsepower tilting dynamometer has been put in operation, enabling the determination of isolated propeller characteristics under full-scale VTOL conditions in a wind tunnel. This includes operation at angles of attack up to 90°, corresponding to hovering and low-speed forward flight, and also at 180° corresponding to descending flight. The characteristics measured include not only conventional propeller coefficients but also levels of blade stresses encountered during the unconventional operating conditions. The first propeller type studied had flapping blades designed with the intention of alleviating the 1–P stresses encountered during high angle-of-attack operation and to permit a lighter propeller, although at the expense of a more complicated hub. In descent conditions the propeller had flapping instability introducing unacceptably large stresses.

Increasing interest in shrouded propellers for VTOL aircraft has prompted questions concerning their operation at zero forward speed and low forward speeds at high angles of attack. Performance, efficiency, and general design information is being gathered on a series of shrouded propellers from zero forward speed to high subsonic forward speeds, and from angles of attack from 0° to 90°. In addition, a systematic investigation has been started to determine the low-speed and hovering characteristics of shrouded propellers operating in the presence of wings and in the chord plane of wings.

An investigation of the aerodynamic characteristics of propellers designed for transonic forward speeds is essentially complete, utilizing a propeller research airplane. Three propellers were tested in conjunction with several spinners. Two propellers were designed for a forward Mach number of 0.95 and the third for a Mach number of 0.82. The first was a true supersonic propeller; the second a modified supersonic propeller; and the third, a transonic propeller. Efficiencies as high as 80 percent were measured at a forward Mach number 0.95 with the supersonic propellers. Minimum thickness-ratio distribution was determined to be the most important parameter in the design of propellers for transonic forward speed. Although all the propellers were noisy, the investigation indicated that supersonic propellers provide an attractive means of propulsion for long-range airplanes in which economy of operation, flexibility, and high static thrust are important.

SEAPLANES

Hydrodynamic research of both a basic and applied nature is progressing toward improving hydroski and hydrofoil development as well as seaplane configuration development having improved supersonic performance. At the same time a substantial amount of research has been initiated on underwater-launched missiles and on the water recovery or landing of manned spacecraft and hypersonic boost-glide vehicles.

Hydroskis

Fundamental research on hydroskis in the submerged and planing regimes has continued with the derivation of a unified method for calculating the lift of a rectangular flat plate in both regimes. Experimental investigations are likewise continuing on the effects of upper surface camber on a submerged surface and of longitudinal convexity on the bottom of a planing surface. Studies have been made of the characteristics of a submerged hydroski having a shape easily adaptable to practical construction methods, suitable means of reducing the spray of such elements during emergence and planing, and the influence of mutual wakes in multiple hydroski installations. Applications of the ski concept have been investigated on models of fighter aircraft, guided missiles as a recovery device, and hull-type seaplanes as a load-alleviating device.

Superactivating Hydrofoils

The new concept of using supercavitating hydrofoil sections on water-based aircraft elements to combat the adverse effects of high water speeds has been vigorously pursued both theoretically and experimentally. Analytical methods for dealing with ventilated as well as supercavitated flows, effects of aspect ratio, depth of submersion, and development of optimum sections have been derived and verified by model tests. Design charts to facilitate routine use of the theory have been devised. The physical process of ventilation is becoming better understood by the use of new methods to visualize the complex flows associated with this phenomenon. Attention is being given to practical application by investigation of structurally sound, surface-piercing arrangements such as highly tapered monoplanes, biplanes, and cascades with end plates. A specific application of two supercavitating hydrofoil systems is being investigated with a model of a full-scale test-bed airplane. The ability to accept highly cavitated flows at high water speeds gained in the research on hydrofoils has also led to investigation of supercavitating principles applied to underwater missiles.

Hull-Type Seaplanes

Research on hydrodynamic configurations and evaluations of advanced water-based aircraft concepts or preliminary design configurations has remained a substantial part of the hydrodynamic effort. With increasing interest in hydro-ski and hydrofoil solutions, the continued usefulness and versatility of the flying-boat hull have not been neglected. Experimental investigations have been continued in this area over a wide range

of requirements from the very low landing speeds associated with antisubmarine warfare seaplanes to the very high landing speeds associated with supersonic attack aircraft. The configurations of interest have included those of large transonic transport aircraft, bomber aircraft, and small supersonic interceptor aircraft. In one series of tests of supersonic attack bomber-type configurations, attention has centered on means of obtaining spray clearance for air-breathing engine intakes and various hydrodynamic features for water takeoffs and landings. An investigation to determine the comparative rough-water capabilities of hulls, skis, and hydrofoils for such aircraft is also in progress.

Recovery of Spacecraft and Hypersonic Glide Vehicles

New horizons in the evolution of water-based aircraft have appeared in the form of manned hypersonic boost-glide vehicles and spacecraft which must be safely "ditched" or recovered after flight outside the atmosphere. Hydrodynamic investigations have accordingly been initiated of the water landing characteristics of typical satellite vehicles, including both high-drag winged and wingless reentry types. It is anticipated that through further research, the decelerations associated with water entry in favorable areas on the earth can be kept within reasonable human and structural tolerances.

Hydrodynamic Facilities

Investigation of the use of a small high-speed water jet to obtain fundamental hydrodynamic data has been completed. It was concluded that the use of a simple slotted boundary for such a jet reduced the boundary corrections on planing lift to a point where direct agreement with towing tank data could be obtained at high speeds for a wide range of test conditions. An improved towing carriage for the Langley high-speed hydrodynamic facility is being provided to increase the range of water speeds available by conventional tank procedures.

ROTARY WING AIRCRAFT

Performance

The extension of basic rotor theory in accordance with anticipated state-of-the-art changes has been a continuing process. Current efforts relate primarily to clarification of rotor force and blade-flapping phenomena for the severe flight conditions brought about by the considerable increases in installed power which are evident in new designs. This work utilizes published numerical procedures, in conjunction with electronic computers and full-scale experimental setups.

Limitations of helicopter speed due to retreating blade stall have been largely based on pilot reactions to roughness caused by the blade stall. A technique has been developed whereby the beginning of this blade stall can be detected readily under high forward-speed conditions. This is accomplished by monitoring blade-pitching moments and power input so that blade stall can occur to a measurable but not catastrophic degree. As a consequence, it has been possible to establish the allowable increase in forward speed for a rotor of a tandem helicopter resulting from a change in blade section from a symmetrical to a cambered section. A 20- to 25-percent increase in forward speed at the same weight or a 15-percent increase in gross weight appears possible.

Investigations are in progress to determine the static aerodynamic characteristics of helicopter rotors operating at tip speeds up to 900 fps. The effects of centrifugal forces on the rotor-blade boundary layer, tip flow field, and varying stall or compressibility areas over the rotor in forward flight are also being studied. Rotors having a wide range of blade-thickness ratios, thickness form, and leading-edge radius have been tested. These investigations have resulted in successful attempts to "synthesize" airfoil data from rotating rotor tests. Such data are expected to provide greater accuracy in the calculation of the forward flight characteristics of rotors operating at high tip speeds.

Vibration

As helicopters have become larger and more flexible, the magnitude of the vibrations associated with them has increased. The use of the helicopter for longer military missions and the increasing use of helicopters in civil applications have made the present vibration levels an increasingly serious matter. The designer is frequently unable to predict vibration sources and to provide methods of alleviation.

As a result of the increasing importance of this problem, a flight investigation was made to measure the vibration encountered by a specially equipped tandem helicopter. The first phase of the project involved the development of a method for measuring rotor blade, fuselage-coupled frequencies in flight. The technique involved the use of a mechanical shaker mounted in the helicopter. The results indicated that the method developed would provide a satisfactory means for flight testing of prototype helicopters for coupled frequency effects.

The project was extended to include the measurement of relative aerodynamic inputs for several flight conditions, of vibration effects due to blade out-of-track, and flight vibration mode shapes, through use of magnetic tape data recording. Vibration was only slightly increased when the blade out-of-track was less than 1 inch. However, as the out-of-track increased to slightly over 2 inches, the vibration became nearly intolerable. These efforts have not resulted in a state of knowledge

which will permit satisfactory prediction and reduction of helicopter vibrations; however, use of the research technique holds promise for the attainment of this goal.

Stability and Control

Stability and control studies utilizing a variable-stability helicopter have succeeded in determining the degree of improvement attainable by increased damping and control power during instrument-flight landing approaches.

Low airspeed flights, including efforts to hover over a ground reference, have been conducted under simulated instrument conditions with a single-rotor helicopter having electronic autopilot-type components which permit alteration of the apparent (to the pilot) stability and control characteristics of the helicopter. By means of these components, systematic variations in such parameters as control power, damping in roll, yaw and pitch, stick force gradient and stabilization about each axis can be evaluated singly or in combination. The results confirm earlier work showing that improvements in handling qualities result with increases in damping. Also there is a large range of damping values within which desirable control powers are independent of the damping. However, as the damping is increased, the allowable maximum control power tends to increase.

A device that supplies signals to the pilot's instruments to indicate helicopter position and rate of change of position with respect to a ground reference, as well as helicopter altitude over the ground, has been constructed. The purpose of the device is to permit hovering on instruments so that handling qualities in hovering may be investigated. An additional device is also being constructed which will provide position and rate signals to the pilot in the form of stick forces.

Current efforts to assist in modernization of military flying qualities specifications for helicopters serve to emphasize both the value of the damping and control-power work completed and the need for more information; for example, how to apply the results established for helicopters of typical size to size extremes which can range from 250 to 100,000 pounds gross weight. As one step in learning possible effects of size, and also the effects of gross changes in the ratio of rotor inertia to aircraft inertia, brief tests have recently been completed with a tip-jet-driven helicopter of far smaller size but of higher relative rotor inertia than any previously tested. Certain beneficial effects related to high rotor inertia were readily apparent and led to additional comparative tests with more typical designs. Correlation of these results with those obtained with other larger helicopters is continuing.

POWERPLANTS

During the past year, the NACA increased its effort on studies of those powerplants believed to have potential as space propulsion systems and secondary power sources. The first results were presented at the NACA 1957 Flight Propulsion Conference, given at Cleveland in November 1957, 1 month after Sputnik I. This classified conference encompassed analyses of space missions, chemical propulsion systems, nuclear propulsion systems, electrical propulsion systems, auxiliary power systems, and propellants.

The conference also presented an NACA survey and assessment of air-breathing engines required for a "next generation" of airborne vehicles. Data, technology, research requirements and potential, with reference to turbojet and ramjet engines for flight from Mach 4 to Mach 18 were discussed.

SPACE PROPULSION

Analyses of satellite space vehicle problems and interplanetary space missions have been made. These analyses, while based on present knowledge and therefore very preliminary, have led to certain broad conclusions concerning the relative merits of various propulsion and auxiliary power systems and have helped to delineate the many areas of propulsion research that will be of increasing importance for space applications.

Auxiliary Electric Power

Systems using solar energy (solar batteries and solar turboelectric systems) involve the least weight for power requirements up to a few kilowatts, provided almost-continuous operation in the sun is possible. If only half time is spent in the sun, a number of systems are competitive, including radioisotope hydrogen-oxygen cells and radioisotope turboelectric systems. The nuclear turboelectric system without shielding is also competitive in this range of power, but shielding requirements, particularly for manned vehicles, may rule it out. Chemical batteries are competitive weightwise only for durations of operations of the order of a few days. The required voltage must also be considered in selecting auxiliary power systems. (Figs. 1 and 2.)

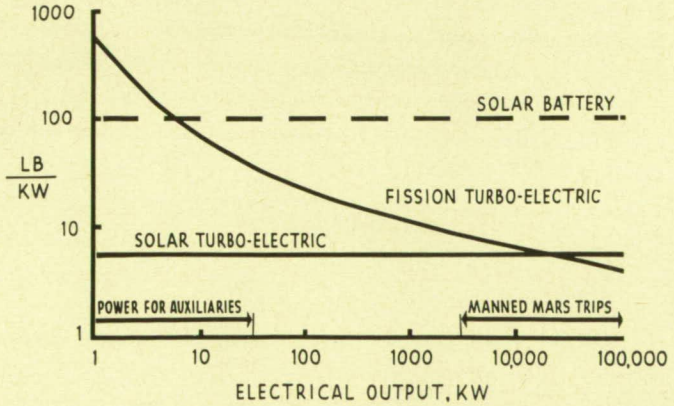


Figure 1.—Weights for kilowatts of electrical power.

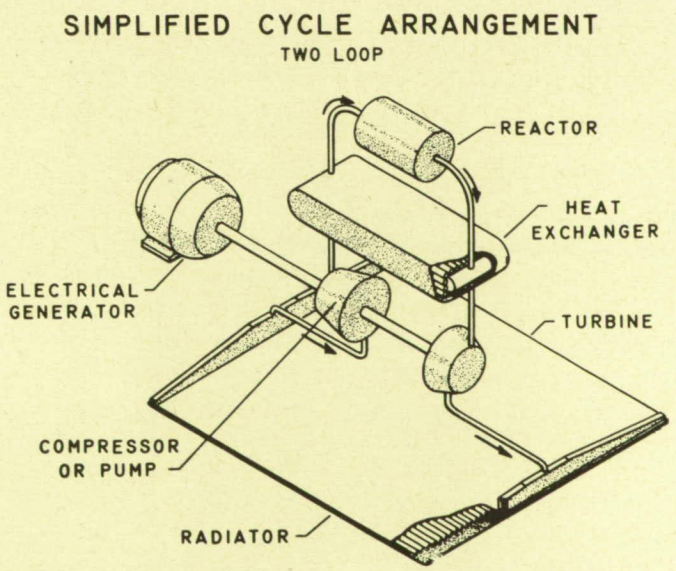
Satellite Sustainers and Orbit Control

For periods of operation of the order of 100 to 200 days or less, a low-thrust chemical rocket can provide the required propulsive energy without excessive weight penalty relative to electric systems. Particularly, if rapid orbit changes are required, the chemical rocket seems to be the only feasible propulsion system. For very long durations, or for permanent satellites, electric propulsion systems using solar energy or nuclear energy require less initial weight or resupply weight than chemical rockets.

Lunar and Mars Journeys

Many missions involving trips to the Moon and Mars can be accomplished without excessive weight penalty with high performance chemical rockets. These missions include one-way instrumented journeys to the Moon and Mars, and manned trips to the Moon. Electric propulsion systems seem undesirable for the Moon trip because of the long times required for the journey compared with those required for high-thrust rockets. For manned trips to Mars, however, electric propulsion



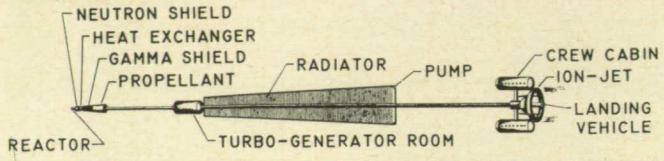


Figure 2.—Auxiliary power from nuclear turbo-electric system.

Preceding Page Blank

systems require only moderately more time for the complete journey than the chemical rocket, and their advantage in initial weight becomes greater and greater as the size of the expedition increases. Of the electric systems considered, the nuclear turboelectric, the solar turboelectric, and possibly the fusion-powered systems are capable of supplying the required electric power with sufficiently low weight. Of the thrust generators considered, the ion-electric accelerator appears to be most promising on the basis of current technology. (Fig. 3.)

PAYLOAD FOR 8 MAN CREW	LB	LENGTH	600 FT

LANDING VEHICLE	40,000	THRUST	32.2 LB
TOTAL	178,000	POWER	11 MW

EXPLORATION TIME AT MARS, 329 DAYS
TOTAL ROUND TRIP TIME, 1100 DAYS

Figure 3.—**Electric spacecraft for round trip to Mars.**

The low-pressure, high-specific-impulse nuclear rocket is competitive with electric systems for large-scale Mars expeditions and has the advantage of higher thrust-weight ratio. It has the disadvantages that much higher temperatures are required than in the electric systems and that hydrogen must be used to attain the required high specific impulse. The latter requirement may impose severe storage difficulties for long-duration journeys.

Another advantage of the electric system over both the nuclear and chemical rockets is the resupply advantage. Since the electric system has the higher specific impulse, its propellant replacement weight is much less than that of the chemical and nuclear rockets.

PROPELLANTS

A continuing need exists for accurate and up-to-date theoretical performance data for a large number of rocket propellant combinations. A program for automatic computing equipment to permit calculation of the theoretical performance of any rocket or ramjet propellant has been set up. Calculations of the theoretical performance of many propellant combinations are kept up to date by a continual revision of the thermodynamic data necessary as various research organizations determine that data. (Fig. 4.)

Although the emphasis on rockets has grown considerably, work has continued on fuels for air-breathing engines, especially on the problems of applying the boron-hydride fuels.

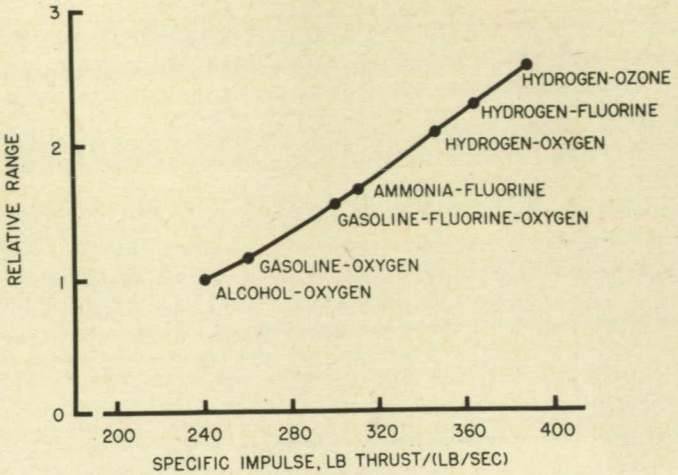

Figure 4.—**High energy fuels increase range.**

COMBUSTION

Combustion research has been directed toward studies of the vigorous combustion of high-energy fuel systems and rocket propellant combinations.

The value of gas analysis as a diagnostic tool for turbojet combustor research was demonstrated. It appears that the technique may also be of advantage in rocket research. In the turbojet combustor, estimates were made of local, rather than overall, fuel-air ratios, efficiencies, and heat release rates.

With the trend toward higher combustion temperatures that are associated with high-flight Mach numbers in air-breathing systems and with the use of rocket engines, studies of the physical chemistry of the burned gases are becoming more important. The rates of reaction and recombination in the burned gases are of special importance and are being studied. The effects of chemical reaction on heat transfer from combustion and other high-temperature gases are also under investigation.

Rocket combustion is a complex phenomenon involving many simultaneous physical and chemical processes. The rates of individual processes have been studied in order to predict overall performance in terms of the slowest rates. Detailed calculations of the evaporation rates of various rocket propellants have shown great promise for computing rocket performance, and a method relating the performance to the quantity of liquid propellant vaporized has been devised. The relation indicates that incomplete vaporization is responsible for combustor inefficiency.

COMPRESSORS

Over the past 15 years the results of research on compressors for turbojet engines have been reported in numerous publications. In the majority of instances, each of these reports presents only an incremental bit of information which taken by itself may appear to

have only limited value. Taken altogether and properly correlated, however, this information represents significant advances in the design of axial flow compressors. The NACA, therefore, has compiled and assimilated into one report, virtually all of the advanced axial flow compressor technology.

During the past year, primary emphasis in compressor research has been on high-performance transonic and supersonic compressors for supersonic aircraft gas turbine engines.

A method was developed for the prediction of the off-design performance of axial-flow compressors. This method is consistent with a framework of equations and blade-element performance correlations commonly used in compressor design, and represents an attempt to provide a more general off-design performance prediction procedure than "stage-stacking" techniques which use assumed stage performance data. The performance of a rotating blade row was predicted, using this method, and compared with the experimental performance characteristics. At rotor-tip speeds that resulted in low relative inlet Mach numbers, computed performance was in good agreement with the experimental data. For high speeds, where the basic cascade data are not so applicable, a narrower satisfactory operating range was predicted than was obtained experimentally. It is believed that the discrepancies can be reduced by improvement of the estimation of high Mach number effects on blade-element performance.

PUMPS

A major part of the turbomachinery research effort has been directed at the problems of liquid pumps for rocket engine application. The objectives of this research are to increase operating limits of pumps, to reduce size and weight, and to provide pumps capable of operating with high-energy propellants. Initial research in this area involved the application of compressor design techniques to rocket pumps. The major problems were considered to fall into two categories: (1) cavitation, and (2) allowable loading (or velocity gradients) on pump blading. Fundamental research on the phenomenon of cavitation has been started, with emphasis on cryogenic fluids. In the category of blade-loading research, programs have been started on both centrifugal and axial-flow pumps, to establish blade-loading limits.

A study of flow-starting transients in a rocket was completed. A configuration consisting of a tank, suction line, constant speed pump (with bypass), variable flow-control valve, injector, and rocket chamber was analyzed theoretically. From this study, it was found that the time history of the main flow control has a decisive effect on the inlet pump head.

As part of the research program on pumping of cryogenics, a study was made of the conditions existing in a closed cryogenic container that typified a rocket propellant tank. This study showed that surface temperature controlled the pressure in a closed cryogenic container and verified the existence of temperature gradients in the liquid.

TURBINES

One phase of the turbine research program considered fundamental aspects of turbine design and performance. These studies are applicable to turbines for air-breathing engines as well as to turbodrives for rocket engines. As the culmination of some of this basic turbine research, an analysis (with substantiating experimental data) was made to establish turbine efficiency in terms of basic turbine design parameters for a range of turbine work and speed requirements and for various types of turbines.

A large part of the turbine research effort was directed at problems of turbodrives for rocket applications. These applications are characterized by very high work per pound of working fluid. The basic objectives of the research are to obtain high turbine efficiency, to reduce turbine size and weight, and to evolve turbines capable of operating in the working gases of rocket engines using advanced high-energy propellants. The initial phases of this turbodrive research included certain basic studies intended to establish research needs in the field. Analyses are being made to establish the effects of turbine-inlet temperature and turbine exhaust-gas thrust recovery on missile performance. A method was developed for determining turbine design characteristics for rocket turbodrive applications. A facility is being built to determine the effect on turbine performance of using cryogenic gases as the working fluid.

TURBINE COOLING

Turbine-coooling research was directed toward the study of air-cooled turbine blades that will be capable of operating at gas-temperature levels of 500° F. or more above those temperatures currently being employed in aircraft gas-turbine engines.

Research, using full-scale turbojet engines as test vehicles, was continued on shell-supported blades and strut-supported blades. The shell-supported blades offer very good heat-transfer characteristics and a relatively lightweight blade. Strut-supported blades offer very good heat-transfer characteristics but are heavier than shell-supported blades. Blades with porous shells for transpiration cooling were also investigated; such blades will theoretically cool more efficiently than other types of blades, but control of porosity and the obtaining of sufficient strength in the porous material are major problems. (Fig. 5.)

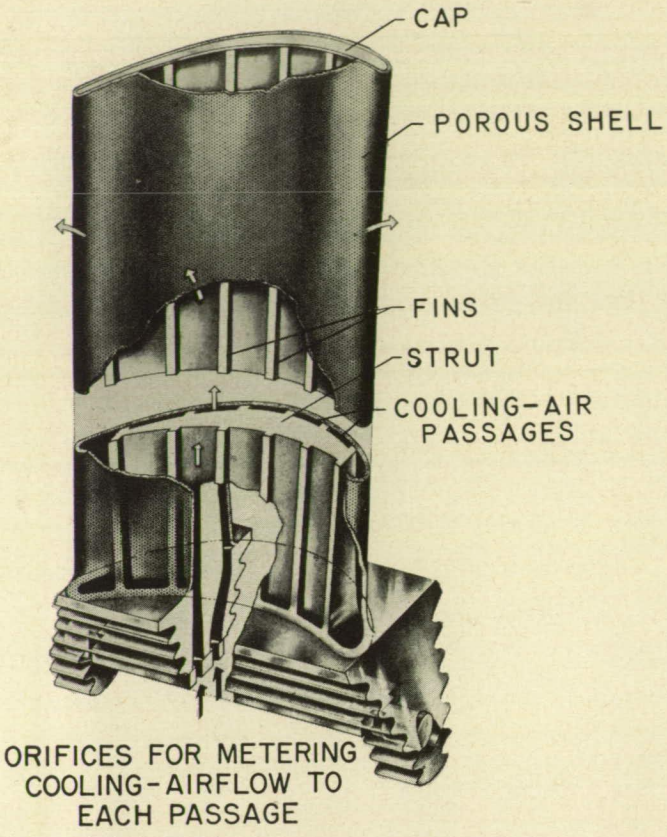

Figure 5.—**Transpiration cooled blade.**

Special studies of the cooling problems in the leading-edge regions of cooled turbine blades were inaugurated by investigating the cooling of small airfoils in a tunnel capable of operating at gas temperatures up to 3,000° F.

A special engine incorporating an air-cooled turbine stator and rotor for making full-scale engine investigations under actual high-temperature operating conditions is being prepared for operation. In order to provide turbine blades for this engine, it was necessary first to investigate a number of problems such as brazing techniques, effect of brazing on material strength, attachment of blade shell to blade base, and heat treatment, that are associated with air-cooled turbine blades. These problems have now been resolved, and a set of cooled blades for the engine has been fabricated and is now being instrumented prior to installation in the engine for research purposes.

An analysis of heat transfer and flow in boundary layers with variable fluid properties in the entrance region of smooth tubes and flat plates was completed. Also completed was an analysis on the effect of variable fluid properties on free convection, and an analytical and experimental study of laminar heat transfer in a vertical circular tube under combined forced and free convection. A new method for measuring residual stresses in disks was devised and analytically confirmed.

ENGINE CONTROLS

Emphasis on control research has been directed toward rocket engines, together with initial explorations of nuclear rocket and other space propulsion systems. Research is underway on rocket fuel systems with respect to such items as the dynamic characteristics of long hydraulic lines, dynamics of centrifugal pumps, combustion chamber pressure control, and propellant mixture ratio control. A study of the requirements of rocket engines and reaction devices for control of the trajectory of missiles has been initiated.

A major effort is being expended in an attempt to correlate analytical expressions for the dynamics of rocket components and for rates of propellant vaporization with experimentally observed liquid propellant rocket motor instability. The ultimate goal in this work is to permit accurate prediction of rocket instability and to determine design criteria for rocket scaling and for development of variable thrust rocket motors.

An analysis of control requirements for nuclear turbojet propulsion systems was initiated. System components were analyzed, reactor kinetics were simulated on an analog computer, and nuclear reactivity was determined.

The dynamic response of supersonic diffusers to disturbances in downstream conditions was analyzed. The analysis included the shock motion in the diffuser as a function of downstream pressure disturbances, and the response of subsonic diffuser pressures to disturbances in fuel flow for ramjet engines. The analysis relates the various dynamics to the particular operating conditions and to the physical dimensions of the system considered, and thereby makes possible control design prior to physical testing of the system.

Turbojet engine performance was investigated experimentally with several configurations of interacting multiple loop controls to determine the mode of control required for obtaining optimum rotor speed and turbine discharge temperature transient response characteristics during (1) thrust increase and (2) afterburner ignition, with manipulation of engine fuel flow and exhaust nozzle area. Good engine transient performance, near the design point, was obtained with a control system in which engine speed was controlled by exhaust nozzle area and the turbine-discharge temperature was controlled by manipulation of the engine fuel flow.

POWERPLANT MATERIALS

High Temperature Alloys

Despite the extensive test work done in the past which has established good correlations between stress-rupture data in the laboratory and service life in engines, several questions have remained unanswered. One concerns the

effect of "overtemperature" operation on the life of turbine blades. Since the stress-rupture life of the material may be shortened by overtemperature in a stress-rupture test, does it follow that engine life is affected by overtemperature operation? Does reheat treating the blades help?

To answer these questions, a recent study was made of S–816 (a cobalt-base alloy) blades overtemperatured in J–47 engines. An example of one of the conditions of overtemperature encountered was engine overspeed by 4 percent, with tailpipe temperature about 200° F. over normal, for an unknown period of time. These blades were removed from service and tested in a laboratory J–47 engine under repeated cycles of 15 minutes rated and 5 minutes idle speeds. Stress-rupture tests and metallographic examinations were made in an attempt to correlate properties and microstructure with engine results.

It was found that overtemperatured buckets did not fracture in service in abnormally short operating times. Cracking, particularly on the leading edge, was the principle mode of failure of buckets. Although cracks developed after short operating times, they did not propagate to fracture during several hundred hours of operation. The overtemperatured buckets failed in stress-rupture tests in shorter periods of time than buckets directly from stock and also failed in shorter periods of time than the overtemperatured buckets which had been subsequently heat treated. In fact, full reheat treatment of overtemperatured buckets, using the standard heat treatment, increased the resistance of the blades to leading edge cracking and also improved the stress-rupture life of the material. Such buckets performed both in the engine and in stress-rupture tests equivalently to new standard buckets.

A laboratory investigation of overheating indicates the complexity of the high-temperature alloy studies. In this investigation, periodic overheats were conducted at temperatures to 2,000° F. both with no stress and with stress present. (No engine tests were performed.) The alloy studied was a nickel-base alloy, M–252. It was found that periodic 2-minute overheats to 1,900° or 2,000° F. very substantially increased the rupture time of M–252 alloy at 1,500° F., provided no stress was present during overheat. Such overheating was damaging only if a sufficient high stress were present to use up a significant proportion of total rupture life. However, when M–252 alloy is repeatedly overheated to 1,650° and 1,800° F. in the absence of stress, the rupture life at 1,500° F. is reduced. In the presence of stress, however, the damage is less than anticipated. Consequently, if stress is present it must be quite high to do any significant damage.

Physics of Solids

The aim of the physics of solids research is to provide basic knowledge to aid in the development of materials for use at very high temperatures and in chemically active atmospheres. Among the problems under study are the chemical reaction of materials in certain environments which may be affected by nuclear reactor design, aerodynamic heating, and flight in the upper atmosphere.

Platinum has long been known as an inert metal; in fact, it has been the standard crucible material used in chemical analysis because of its resistance to oxidation and direct flames and its resistance to attack by rather active chemicals. Previous studies of the rates of oxidation of platinum at temperatures to 1,400° C. in molecular oxygen have indicated a very low oxidation rate. However, recent studies conducted at these temperatures and at pressures below 0.1 millimeter of mercury have indicated a very marked increase in oxidation rate at low pressures. These results appear contradictory when one considers the pressure of a gas is a measure of the concentration of the gas. However, the studies have been conclusive and indicate that previously observed rates under relatively static conditions may be in error when dynamic conditions, namely free motion of the gases, is present. At pressures above 0.1 millimeter of mercury, oxidation is strongly inhibited by back reflection from the gas.

LUBRICATION AND WEAR

Bearing Research

In recent years the statistical design of experiments has found favor as a device for planning experimental research. Many factors which affect the course and results of an experiment can be varied simultaneously and their effects separately and concurrently analyzed. However, with phenomena such as the fatigue failure of bearings, which are so complex and have so many factors contributing to or alleviating failure, statistical design has not been successful. Therefore, it has been necessary to return to the classical experimental method of studying one variable at a time in order to make any progress in the study of bearing failure.

Tests are performed on a rolling contact fatigue spin rig where balls are rolled around the inside of a cylinder by the action of compressed-air jets. Previous studies of the rig had indicated similar patterns of failure and fatigue lives on the balls in comparison with those obtained in actual bearings. In addition, the number of test variables is reduced.

One research area which appears very promising is the study of the metallographic structure of balls and races as a clue to variable bearing life. Balls and races

are made of steel which has been forged or rolled so that it has a definite crystal orientation. This orientation shows up on etching a cross section and is usually referred to as fiber. It has been found recently that if the fibers are not oriented parallel to the axis of the cylinder (which corresponds to the outer race of a bearing), the fatigue life of the cylinder is drastically reduced.

In this investigation, cylinders were prepared in three groups from forged stock. In the first group, the cylinders had their axes parallel to the fibers of the steel stock. In another group the fiber was arranged so that it was from 0° to 45° to the axis of the cylinder, and in a third group the axis of the cylinder was at 0° to 90° from the fiber of the material. When comparing the data obtained on these cylinders, it was evident that by using material whose fiber was parallel to the surface of the cylinder, a large increase in life of the cylinders was obtained. For example, in this series of tests only 10 percent of the cylinders with surfaces parallel to the fiber of the material had failed by 5 million cycles. By 60 million stress cycles, 80 percent of the cylinders had failed. However, with cylinders oriented from 81° to 90° to the fiber, 10 percent of the failures has been obtained by 1¼ million stress cycles and 80 percent by 3 million stress cycles. We thus see a profound effect of fiber orientation both on the first failures and on all failures. The study of the relation of failure to fiber orientation in balls is considerably more complex since fiber orientation can be determined only after the balls have been tested. However, the striking relationship of fiber orientation to ball failure is also illustrated by a polar projection of failure incidences versus fiber orientation. (Fig. 6.)

NUCLEAR PROPULSION

The NACA nuclear research program has been directed toward solving the problems associated with the application of nuclear power to the propulsion of aircraft and rockets. Analytical studies have been and are being carried out on nuclear aircraft propulsion systems, nuclear booster-rocket systems, nuclear heat-transfer, interplanetary propulsion systems, and nuclear electric-generating systems for space-travel application. These studies have been specifically directed toward defining the research problems that must be solved in order to achieve the potential indicated for these various systems.

The construction of reactor facilities to be used in conducting experimental nuclear research studies is continuing. The construction of the low-power, solution-type research reactor located at Lewis has been completed. Work is continuing on the Plum Brook

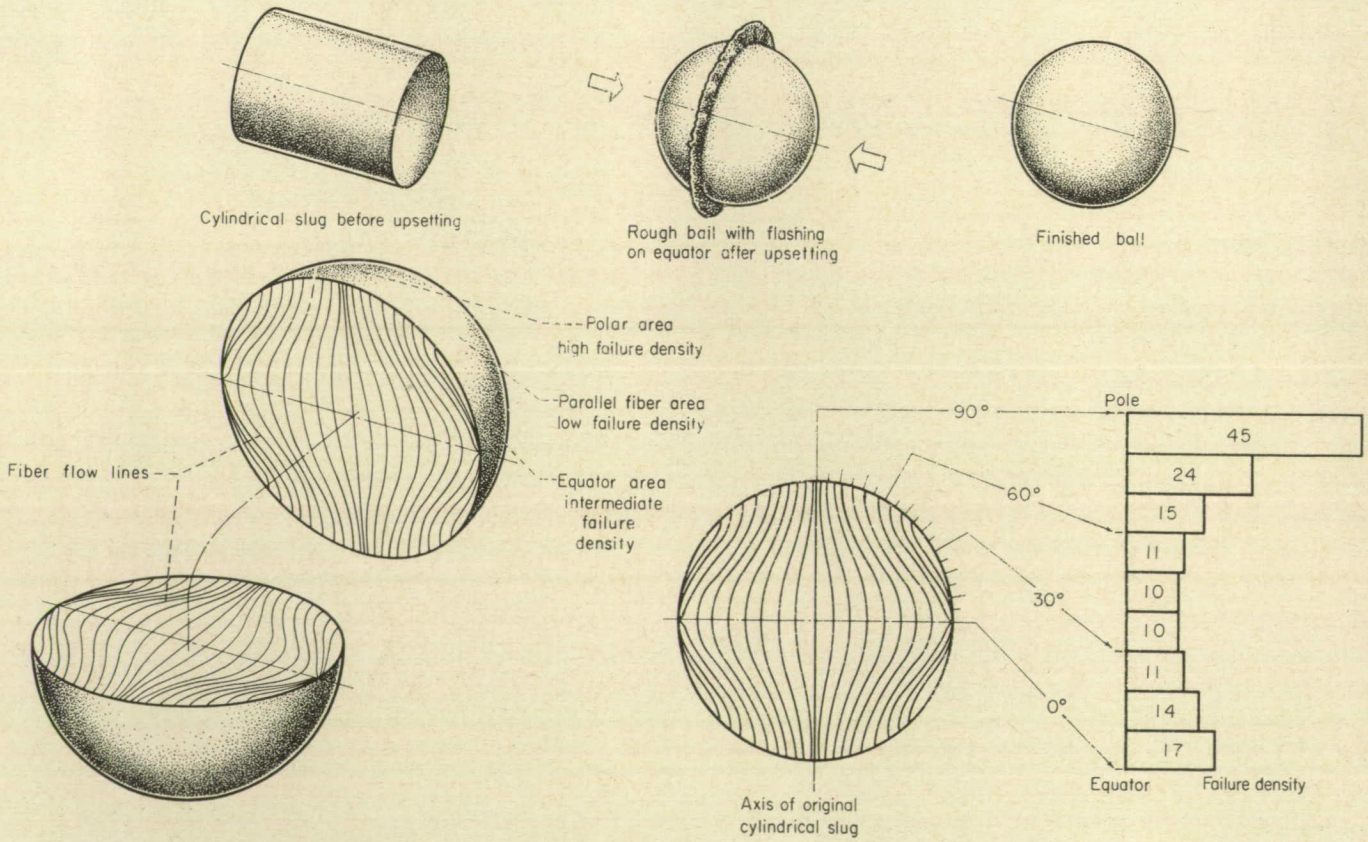

Figure 6.—**Susceptibility to fatigue failure in bearing balls as influenced by forging fiber orientation.**

Reactor Facility. Experiments applicable to space-flight systems are being planned and designed for both of these facilities.

Methods have been devised for evaluating weights of shields for aircraft and rocket systems. Studies of various methods of shield design, including the statistical methods, are continuing. Equipment is being fabricated to study the attenuation of gamma photons in various shield materials and also to study the gamma ray streaming through ducts in shields.

The effort on reactor analysis has been devoted to studies of reactors for jet engine propulsion systems and various rocket systems in order to determine effects of core size, composition, reflector thickness and material, moderator material, and fuel-element material on uranium requirements, and flux and power distributions. Analyses and experiments are being conducted to develop methods of predicting nuclear characteristics of reactors of unusual or complex geometry for space-flight systems.

A number of heat-transfer and flow problems associated with nuclear powerplants are being studied. This work is intended to provide pertinent information of a fundamental nature that will be of general usefulness in the development of various types of nuclear propulsion systems.

Sodium hydroxide is in many ways an attractive choice as a high-temperature, heat-transfer fluid. Unfortunately, only a few materials are suitable for containing it in the molten condition at temperatures of 1,500° to 1,700° F. Among these are nickel, copper, silver, gold, and some nickel-base alloys. Even these materials exhibit a form of corrosion termed "thermal-gradient mass transfer." Thermal-gradient mass transfer is the phenomenon by which the container metal is removed (either chemically or physically) from the hotter regions of a system and deposited in colder regions by the heat transfer fluid. With the previously listed metals the deposit is in the form of needlelike crystals, the size of which depend upon the experimental conditions. (Fig. 7.)

In order to find ways of inhibiting this type of corrosion, an investigation was conducted concerning the possible mechanisms. The mechanisms were found to depend on chemical reactions between hot and cold zones and molecular diffusion within each zone.

The diffusion of the molecular species in the melt will allow the process to continue indefinitely. In dynamic tests, the rate of transfer is controlled by the rate of the zone reactions and thus is constant with time. In static tests, the rate of transfer is controlled by the rate of diffusion and increases with time.

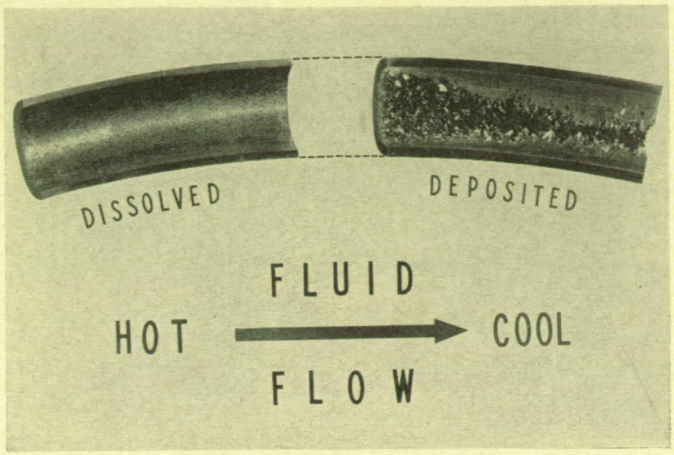

Figure 7.—**Mass transfer of structural materials by a coolant.**

The effects of additives upon the rate of transfer were also explained. Additives which effectively increased the sodium oxide concentration increase the rate of transfer; those which decrease this concentration decrease the rate of transfer. Reducing agents decrease the rate of transfer in static tests and have no effect in dynamic tests. Oxidizing agents have the opposite effect in static tests.

Experiments are being set up on the 60-inch cyclotron to study the heat-transfer characteristics of ionized gases and also to study the range of fission fragments in ionized gases. Such studies are directly applicable to the space nuclear-propulsion systems now being evaluated.

A two-dimensional diffusion theory has been developed for determination of reactivity effects of a fuel-plate-removal experiment. This and other diffusion theory analyses are being checked experimentally by duplicating the essential neutron-diffusion phenomena with a point source of fast neutrons.

Heat-transfer characteristics of liquid metals flowing over a flat plate were analyzed using laminar boundary-layer equations. Numerical solutions of the appropriate differential equations were carried for the situation of uniform wall temperature and uniform wall heat flux.

Laminar free convection from a vertical flat plate with nonuniform surface temperature was analyzed. Analyses of transient forced-convection flow and heat transfer, and of effects of internal heat sources on forced convection in ducts were completed.

AIRCRAFT, MISSILE, AND SPACECRAFT CONSTRUCTION

It is in the field of construction that the designers' ideas are translated into structure or "hardware" which will possess the serviceability and structural integrity necessary to attain the desired vehicle mission.

The operation of hypersonic aircraft and missiles and the venturing into space raise many new problems with regard to structural design, materials, and influences of environment for which solutions are actively being sought. A great deal of attention has been required in the way of defining new problems and developing new facilities.

STRUCTURES

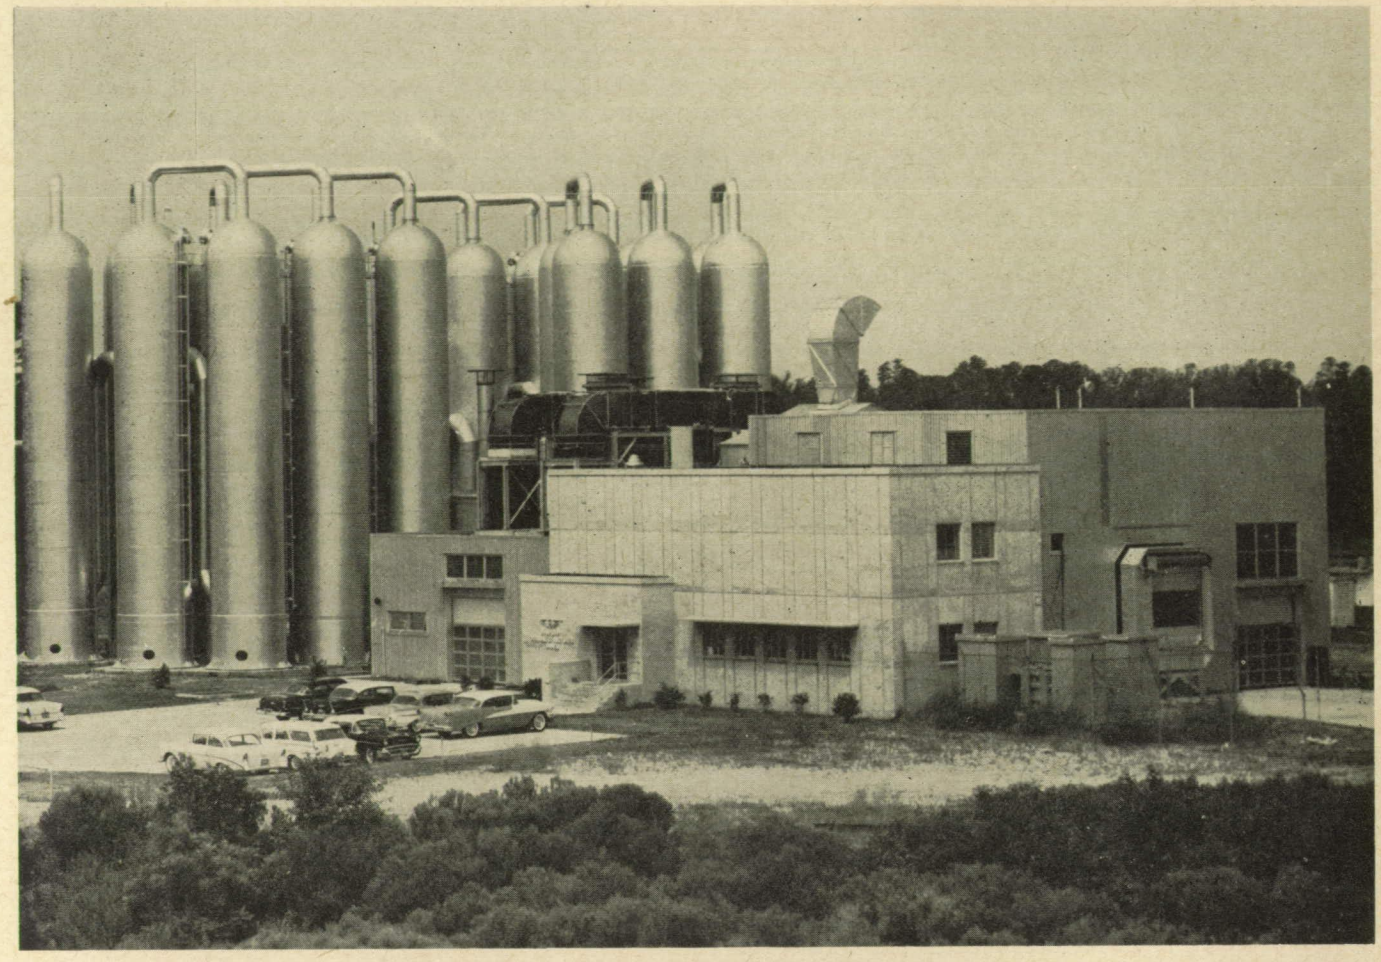
Structures research during the past year has been directed primarily to the problems of aerodynamic heating, with particular attention being focused upon the problems associated with hypersonic gliders and various types of reentry vehicles. Consideration was also given to the structural problems of space vehicles, and some fundamental structural studies were reoriented in this direction.

The types of structural configurations suitable for hypersonic boost-glide aircraft and orbital reentry vehicles were investigated. Comparisons were made of the various structural approaches such as the use of unprotected structures, heat sink structures, insulation, cooling, and ablation. The successful use of unprotected structures is dependent on development and improvement of refractory metals, whereas insulated and cooled structures may be developed using existing materials. Research on insulation and cooling has included experimental and theoretical studies of the effectiveness of gas coolants in the passages of corrugated core sandwiches, investigations of the feasibility of using built-up ceramic coatings as thermal shields, and simple methods of providing coolant as an integral, noncirculating part of sandwich construction. The optimum combination of insulation with various types of structural elements has been studied theoretically, and structural integrity tests have been made on several types of thermal shields and insulating panels.

The thermal stresses induced in structures by transient aerodynamic heating can have adverse effects on their strength and stiffness. Theoretical and experimental studies of these effects have been conducted for various structural configurations. Experimental studies of the effect of thermal stress on the buckling and ultimate strength of ring stiffened cylinders and multiweb beams have continued. Additional data have been obtained on the combination of compressive, shear, and thermal stresses that cause permanent buckling of plates. An analytical determination of the minimum weight of a multiweb beam subjected to combined bending and thermal stress is nearing completion.

A reasonably accurate knowledge of the temperature distribution in a structure is a prerequisite to all elevated-temperature structural analyses. The relative importance of heat transfer by conduction, convection, and radiation in sandwich panels was studied and an approximate procedure for estimating radiation effects was devised.

A program for the development of several basic type insulating structures is currently in progress. The structures as conceived are applicable to hypersonic vehicles and manned satellites, and are capable of extended operation with wall temperatures in the range from 1,500° to 2,500° F. Conventional metals as well as materials such as graphite have been used for the outer walls, and fibrous materials have been employed as insulators. Tests of some specimens have been conducted in radiant heater and hot-jet facilities with promising results.



Creep of structures at high temperatures can lead to large deformations and premature failures. Data have been obtained on the creep behavior of stainless-steel plates at temperatures from 700° to 1,000° F., and on the creep behavior of built-up structures such as box beams and unstiffened cylinders.

If all of the complex interactions between aerodynamic heating and loading are to be studied, it is essential that some structural testing be done in an aerodynamic environment. Work of this type was initiated several years ago, using small facilities and has continued during the past year. A new facility, the 9- by 6-foot Thermal Structures Tunnel, was put into operation during the past year. This facility can produce a Mach 3 airstream with a stagnation pressure of 200 psi and a stagnation temperature of 660° F. This facility affords testing of structures under realistic aerodynamic and thermal conditions.

Accurate methods of deflection analysis are essential to the determination of the response of structures to dynamic loads. Studies of structural dynamics included the vibration characteristics of an integrally stiffened 60° delta wing, secondary effects in the vibration of monocoque beams, and a comparative analysis of the accuracy of several methods for calculating transient

526597—60——5

Preceding Page Blank

The 9- by 6-foot thermal structures tunnel.

response. A blast simulator apparatus is being used to study the failure of multiweb beams subjected to very short time, high-intensity loadings.

The problem of designing a structure of minimum weight and of the desired strength at room and elevated temperatures is basic to all aircraft and missile designs, and requires continued research if the performance goals of future vehicles are to be achieved. Sandwich construction is the most probable configuration for efficient utilization of high density and refractory metals in high-speed vehicles; consequently, research on sandwich construction is continuing and has included analytical studies of the local instability of the elements of truss-core sandwiches, tests of sandwich elements, plates and beams at room temperatures, and crippling tests of shell sandwich construction at temperatures up to 1,200° F. with temperature gradients through the thickness. Investigations of sandwich materials suitable for use in the 2,000° to 2,500° F. range have been initiated.

Cylindrical and conical shell structures find extensive use in long-range missiles and space vehicles, but many configurations are in a range where theory is inadequate and data are scarce. The work in this area has been intensified to determine the cause of the deficiencies of present theoretical methods and to formulate new shell theories. Experimental work is also in progress to determine the strength of longitudinally stiffened curved sheet and of ring-stiffened cylinders.

Fatigue problems continue to be a major factor in the operation of many civilian and military aircraft. Recent investigation of the fatigue of structures has been principally concerned with the fail-safe design approach. Structures designed under this approach can tolerate appreciable damage by fatigue cracks without suffering catastrophic failure. During the past year tests have been continued on panels and box beams to better understand the factors affecting fatigue crack growth and the reduction in static strength resulting from cracks. Tests of full-scale airplane wings have been continued to provide information on their resistance to fatigue.

LOADS

The effort devoted to various phases of loads research continues to change because parameters important to structural design such as airspeed, range, structural flexibility, ratio of payload to total weight, heat transfer into the structure, and control inputs continue to vary over wide limits. Accordingly, increasing em-

phasis is being placed on the theoretical and analytical methods for predicting effects of these variables and on methods for analyzing experimental data so as to permit generalization of results.

Because of the high rate of fuel consumption and the wide range in altitude that is rapidly traversed in some aircraft operations, it is becoming increasingly important to account for fuel consumption, air density, etc., as function of time rather than handling these quantities as constant for short time periods. Studies have shown that it is practicable to extend existing analytical procedures to account for these additional complexities.

The manner in which the newer types of aircraft and spacecraft will be operated is expected to change so radically from present-day operation that philosophies of structural design which are based on past experience in the low-speed range will be outmoded; as a result, various types of craft having differing missions are being studied to determine how present structural load requirements must be modified to place the design of such craft on a more rational basis.

The problems concerned with the effects of flexibility on the loads and structural strains experienced by an airplane in rough air are becoming increasingly important because of the higher flight speeds and the use of thin sweptback wings. A flight investigation of structural response showed large amplifications in the structural strains and wing deformations. The strain amplification factor measured during rough air flights varied from 10 to 20 percent at the wing root to values in excess of 100 percent at the midspan station. The major source of aerodynamic forces that are developed in rough air are due to wing structural deflection and twisting, particularly at frequencies corresponding to the first wing-bending mode.

In order to obtain turbulence data which may be used in synthesizing the gust histories for a wide variety of operations, the airline gust data collection programs have been supplemented with projects aimed at establishing the turbulence characteristics for particular flight conditions. Among these conditions are the very low altitudes (below 1,000 feet), high-speed flight, and the more severe weather disturbances represented by hurricanes or tornadoes. The very low altitude data have been derived primarily from tower measurements, while results for other weather conditions are being obtained from cooperative flight tests with the Air Force, Weather Bureau, and Navy. In addition to determining the intensity of the turbulence for direct application to airplane and missile operations, effort is also being made to establish the significant meteorological parameters associated with the turbulence.

Rocket-propelled, free-flight models are used to obtain data on the effect of high Mach number flight on the airplane response to gusts. Because autopilots and yaw dampers add artificial damping to the airplane motions, the effect of these devices on wing and tail loads in rough air has been investigated experimentally and analytically, and for one airplane showed that increased damping of the lateral mode was effective in reducing the gust loads on the vertical tail by about 50 percent. These and other available gust data and studies have been applied to both airplane and missile operations to developing gust-load design criteria.

For several years landing impact loads have been studied intensively; consequently, methods have been developed for calculating these loads for a given landing gear with a good degree of accuracy if the initial conditions at touchdown are known. Vertical velocity at contact is the most important single parameter connected with impact loads, and an accurate statistical determination of this quantity for routine operations will make it possible to specify more precisely the value of this important design quantity. A method for obtaining statistical data on airplane vertical velocity at ground contact from measurements of center-of-gravity acceleration has been utilized to interpret acceleration peaks from VGH recorders obtained during routine operational landings. Measurements of vertical velocity for over 600 separate landings representing 6 different airlines' operations were also obtained at mile-high Denver and sea-level San Francisco airports. This new information, together with that previously available, provides a statistical sample of sufficient size for reliable analysis.

Other primary problems associated with landing aircraft result from the high speed of landings, characteristics of tires, and the friction coefficient between the tire and runway. Landing requirements for future high-speed aircraft have increased the desirability of using skid-type landing gear; consequently, a model with skid landing gear and nose wheel was investigated on a treadmill-type runway and it was found that changes which reduced the side loads on the wheel or moving the skid aft reduced the tendency toward a divergent notion. A comprehensive summary of research on the elastic and mechanical properties of tires has been prepared. For each tire characteristic semi-empirical equations which account for the major factors pertinent to the characteristic were developed. A significant contribution to the complete understanding of friction coefficient and drag loads for which a landing gear must be designed was obtained from realistic, closely controlled impact tests of a modern heavily loaded aircraft tire conducted on the Landing Loads Track for many conditions, such as vertical velocities up to 9.3 fps, forward speeds up to 110 knots, tire pressure ranging from 35 to 210 psi, wet and dry concrete surface, and wheels partially and completely locked.

The landing-impact phenomena is now well understood, although the complete determination of landing

conditions remains to be made; in fact, may never be completed because of changing designs and operational procedures. Not so well understood, however, is the subject of airplane structural response to taxiing and ground handling. It has been known that taxiing and ground handling over runways and taxiways, which are more or less rough, impose loads which are critical for structural design, notably in the attachment of wing-mounted, large-mass items. As a step toward solving the taxiing and ground-handling problems, a comprehensive collection of airport profiles for the United States, Canada, and European NATO countries has been assembled through a cooperative program initiated by the Advisory Group for Aeronautical Research and Development of the North Atlantic Treaty Organization. High-speed analog or digital computers that permit simulation of all the nonlinear landing-gear and tire characteristics are being used to investigate the response of the landing gear, its associated structure, and supported load to accelerations and motions induced by taxiing over representative runway profiles.

Experimental studies of fundamentals of hydrodynamic impact loads have been completed at the Langley Impact Basin. These studies have considered the relation of airplane design and construction parameters and of airplane operating parameters to impact loads. Among the design and construction parameters studied are hull or hydro-ski configuration, airplane weight, and structural elasticity and mass distribution of the airplane. The operational-parameter studies include landing approach conditions such as trim angle, flight-path angle, velocity and aerodynamic lift, and seaway conditions. The hull and hydro-ski configurations studied were limited to basic shapes which could be incorporated in specific designs.

VIBRATION AND FLUTTER

Flutter

Flutter is a self-induced vibration of an aircraft or missile produced by the interaction of the air forces and structural stiffness and inertia. The flag or leaf fluttering in the breeze, the venetian blind vibrating in an open window, are more common examples of flutter. Flutter of an aircraft differs from these examples in that it is relatively more violent and destructive; consequently, aircraft are designed to be free from flutter, not to withstand it.

A major part of flutter research involves the determination of the speed at which flutter occurs and the mode of vibration of wind-tunnel models. One aspect of this research is the establishment of the effects of various parameters by tests of models which represent a systematic variation of particular parameters. Another aspect is to furnish experimental verification of the accuracy of theoretical prediction methods. A third aspect, and one which has become increasingly important, is the determination of the flutter characteristics of models which simulate dynamically a particular aircraft design. This affords a more accurate answer than a theoretical analysis. This is particularly true for aircraft whose structure and weight distribution are such as to produce complicated vibrational patterns and for the transonic speed range in which separated flow aerodynamics may prevail.

One of the more troublesome types of flutter has been that involving control surfaces. Control-surface flutter, including flutter of all-movable tail surfaces as well as flap-type controls, has been studied. The kernel-function method is being used to predict theoretical flutter boundaries for a series of all-movable horizontal stabilizers and these theoretical results are being compared with the experimental flutter boundaries. The widespread use of hydraulic boost servos to operate controls has introduced another factor which has an important effect on the dynamics of the control system. Experimental wind-tunnel flutter studies have been carried out, using models with miniature hydraulic components which simulate full-scale actuators.

Emphasis is being shifted to aeroelastic problems of very high speed aircraft and missiles. Considerable experimental effort has been directed toward aeroelastic studies of components of the X–15 and other hypersonic configurations. Programs to study fuel sloshing, panel flutter, aeroelastic characteristics of ICBM configurations, structural feedback instabilities, boost-glide aeroelastic characteristics, and other dynamic and static aeroelastic problems induced by hypersonic flight capabilities are receiving a larger proportion of research effort.

It has been established that aerodynamic heating increases the tendency of structures to flutter by reducing the effective stiffness. In a continuing study of this problem, a series of multiweb-wing structural models have been designed for tests in the 9- by 6-foot Thermal Structures Tunnel, where flutter data can be obtained under aerodynamic heating conditions.

Aerodynamic Aspects of Flutter

Improvements in theoretical approaches have been aimed at providing oscillatory aerodynamic forces and moments with greater accuracy. As noted in the 1957 annual report, considerable effort has gone into development of methods of flutter analysis using the kernel-function method to obtain the aerodynamic forces. Considerable success has been encountered in developing procedures for programing the kernel-function method for high-speed computing machines.

As noted previously, flutter of flap-type control surfaces has been an increasingly important problem. Particular emphasis has been placed on the measurement at transonic speeds of aerodynamic control surface de-

rivatives pertinent to flutter. This study has included a variation of control surface contours. Similar measurement of the oscillatory derivations have been made on all movable controls and on T-tail configurations.

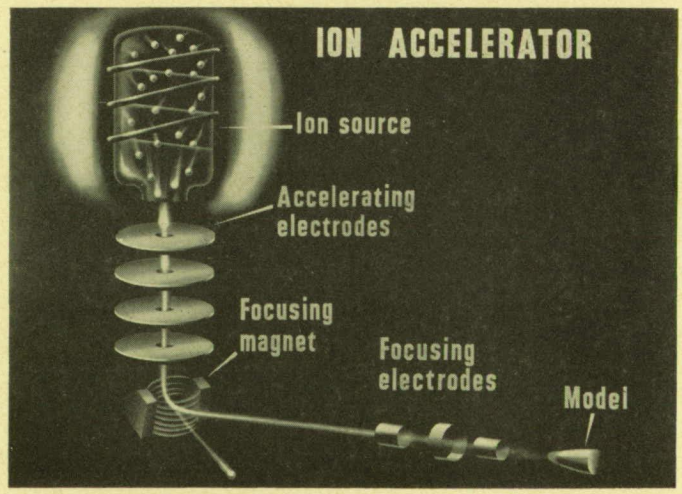
Panel Flutter

Panel flutter is a term used to describe a type of vibration of individual panels on sections of skin that can occur at supersonic speeds. Susceptibility of panels to this type of flutter is greater for thinner skins, larger panels, and for panels having buckles. Thus on hypersonic vehicles or thin-skinned rockets in which buckling of the skin has occurred because of loadings or heating, panel flutter is a serious problem.

Previous theoretical work has produced methods of analyses for flat, rectangular, buckled and unbuckled panels, and for infinitely long, thin cylinders. This work is being extended to include nonlinear flutter analysis of buckled rectangular panels for both large-deflection and small-deflection flutter. Another extension is concerned with the flutter of thin-walled cylinders of finite length.

Panel-flutter tests were conducted in a supersonic jet to determine if heat shields proposed for a hypersonic aircraft would be flutter free. Other experimental programs were initiated to obtain data in the 9- by 6-foot Thermal Structures Tunnel on the flutter of thin-wall cylinders typical of ICBM boosters and of blunt conical shells such as would be used for a manned satellite capsule.

STRUCTURAL MATERIALS



Research on structural materials has continued to be concerned primarily with materials for high-speed aircraft and missiles, although considerable work was also done on problems of fundamental importance to all materials. Consideration was also given to the materials problems created by the environment of space, such as impact on spacecraft of cosmic particles, ranging from ions to micrometeors. It is to be expected that surface pitting by ions striking spacecraft and satellites may constitute operational problems in these environments.

Not enough is known about the properties of our constructional materials at high temperatures to permit the designers to arrive at the most rational and efficient design of high-speed aircraft. The accumulation of data on the mechanical properties of materials at temperatures up to 1,800° F. has continued, and apparatus is being developed to extend the temperature range to 5,000° F. In the past year, tensile and compression creep data were obtained for 2024–T3 and 7075–T6 aluminum alloys, and generalized master curves for predicting rupture, minimum creep rate, and creep strain were derived. Studies of the effects of rapid heating on tensile properties were continued, with special consideration being given to materials of interest for structures of high-speed aircraft. Studies of the dynamic and static modulus of materials have been extended to include the determination of frequency dependence and temperature dependence of the shear and elastic moduli.

As has always been the case in the past, fatigue is still one of the major causes of failure in aircraft. Investigation of fatigue phenomena in materials included: A fundamental study of the role of dislocation and vacancies on fatigue; experimental investigation of effects of cumulative damage, based on gust-frequency spectrum; and the determination of crack propagation rates in sheet material of conventional alloys. The first series of tests to determine the effect of atmospheric corrosion on fatigue of aluminum alloys was completed, and showed that fatigue life of specimens tested out of doors can be lower by a factor of 3, as compared with fatigue life as determined by indoor tests.

Entry into the earth's atmosphere by ballistic missiles or satellites impress conditions of extreme severity. Research work on the most promising method of protecting reentry bodies that will experience the highest heat flux was continued and accelerated. Ablation tests of various promising materials were carried out at heating rates up to 2,000 Btu/ft ^{2}/sec and at stagnation temperatures to 10,000° F. A program for investigating the behavior of other materials for use at lower heating rates was continued, and a large number of conventional metals, as well as refractory metals and ceramics and cermets, were tested in the high-temperature Ceramic Heated Jet. Determination of the emissivity of structural materials, at temperatures up to 2,000° F., was continued, and apparatus is being constructed that will allow emissivity measurements up to 6,000° F.

One of the unknown factors in the operation of space vehicles is the effect of strikes by micrometeoric and larger particles. An investigation is under way of the

Magnets focus beam of ions.

effects of various projectiles striking targets which simulate full-scale structures. Spheres of various materials were fired into targets of various materials at speeds up to 10,000 ft/sec. A theoretical correlation between properties of the projectile and target materials and the results of impact was established.

The apparatus shown is being used to explore the erosion that occurs when ionized particles strike metal surfaces at speeds of 15,000 m.p.h. or faster.

OPERATING PROBLEMS

The daily operations of aircraft and missiles present problems which require solution or alleviation for purposes of safety, efficiency, and economy. Research information is also needed by the designers and manufacturers as well as the operators. For many years, therefore, the NACA has studied various aspects of aircraft operating problems such as atmospheric turbulence, icing, ditching, aircraft and missile noise, crash fire and survival, flight instrumentation, landing and takeoff operations, and aircraft braking.

The NACA has been aided in its research activities in the above areas by the deliberations of the Committee on Operating Problems, the Subcommittee on Meteorological Problems, the Subcommittee on Aircraft Noise, the Subcommittee on Flight Safety, and, until this year, the Subcommittee on Icing Problems. During this year NACA icing research has been limited to writing reports on previous investigations and to supervising the use of NACA icing research facilities by non-NACA personnel who were testing aircraft components under simulated icing conditions.

FLIGHT SAFETY

Flight safety research encompasses many problem areas associated with the operation of aircraft. Hazardous conditions may arise at any time from sources such as the runway, the weather, the engines, the instruments, the controls, and the landing gear. NACA investigations are thus aimed at specific problems to obtain information useful to the manufacturer and the aircraft crew in the industrywide effort to improve safety.

Aircraft Instrumentation

The angle between the relative wind in the plane of symmetry and the longitudinal axis of the airplane is the angle of attack, and its measurement is an important requirement for stall warning, cruise control, and armament considerations. Three types of angle-of-attack sensing devices have been tested in a wind tunnel and in flight to determine calibration and position error data. One result showed that the best sensor location for operation throughout the subsonic, transonic, and supersonic speed ranges is a position ahead of the fuselage nose.

Accurate measurement of airspeed is necessary for safe and efficient flight operations. An investigation has been made to determine the external interference effects of flow through the orifices of an airspeed head such as would occur due to instrument volume at high rates of ascent or descent in flight. The results indicated that the static-pressure error increased almost linearly with increase in mass flow through the orifices.

A study has also been made on the accuracy with which pressure altitude can be measured with current systems. The analysis showed that the accuracy depends on errors in the measuring systems, errors arising from operation of the system, and variation in atmospheric pressure. In another study a survey was made of the errors associated with the measurement of static pressure on aircraft. The errors considered were associated with the static-pressure tube or fuselage vent and the location of the sensor in the flow field of the airplane.

Engine Reliability

Turbojet engines must either be repaired or replaced after specified number of hours of operation. For reasons of safety and economy, it is necessary to know as accurately as possible when engine changes are to be accomplished. An investigation has been made to obtain information on the effect of overtemperature and heat treatment on the life of turbine buckets. Results indicated that overtemperatured buckets did not fracture in abnormally short operating times. Cracking was the principal mode of failure of buckets.

In another study a method was developed to help decide whether jet-engine compressor blades that have been nicked in service are safe from fatigue failure with continued engine operation. These nicks are the result of foreign objects being drawn into the air inlet. A procedure has been worked out for making limit charts that indicate whether a blade showing damage should be accepted or rejected.

Aircraft Ditching

For years the NACA has conducted scale-model ditching investigations of aircraft configurations to furnish designers and operators with information on ditching characteristics and behavior. Models of fighters, bombers, and various types of transports have been tested by utilizing a catapult and water tank system. With the advent of turbojet aircraft, the need for additional ditching data on new configurations has been met by recent tests. In addition, ditching aids such as hydro-skis and hydrofoils attached to the aircraft fuselage bottom have been under study to determine their effectiveness in helping to make a water landing more successful.

In recent studies, an investigation of a 0.043-scale dynamic model of a jet transport was undertaken to study its ditching behavior in rough water. Test results have indicated that hydro-skis or hydrofoils may be made to improve the ditching performance and reduce the damage to the fuselage bottom. Twin hydro-skis with a loading of about 2,500 lbs/square foot resulted in smooth runs with very little damage to the fuselage bottom. Smaller hydro-skis with a loading of 4,400 psf, or twin hydrofoils with a loading of 7,500 psf, or a single hydrofoil with a loading of about 8,300 psf, all resulted in ditching runs which caused moderate damage to the aft fuselage of the model.

In tests with the landing gear extended, the results indicated that the nose gear will fail and that the main gear may or may not fail. When the main gear failed, a deep run resulted causing moderate damage throughout the length of the fuselage bottom. When the main gear did not fail, a dive resulted and the front portion of the fuselage bottom was demolished, causing severe flooding of the entire fuselage.

Flight Operations

Several investigations have been continued in an effort to determine more accurately pilot and aircraft characteristics in different flight areas. Under certain conditions, a pilot's capability to control his airplane may be compromised. The effects of airplane acceleration on the pilot's arm as a result of maneuvers or power changes have been studied with a small side-located controller to allow arm support and hand motions. Several pilots participated in ground tests to obtain measurements of their force capabilities with such a device. (See photo.)

Further tests have been made to determine the suitability of a takeoff indicator to detect abnormal airplane acceleration during takeoff such as occasioned by loss of engine power. The instrument performed satisfactorily in a jet bomber and other tests are being continued in a large, jet-transport-type airplane.

A general flight study of jet transport aircraft has been conducted to obtain operational information in the approach, landing, and cruise regions. Using an airplane similar to the commercial jet transport, preliminary data were obtained on sinking speed prior to touchdown, lift and drag characteristics, high-speed characteristics, lateral control combinations, and yaw damping augmentation.

As a first step in a general investigation of the use in flight of thrust reversers on turbojet-powered airplanes, the effect of a target-type thrust reverser on the aerodynamic characteristics of a full-scale jet airplane has been measured in a wind tunnel. Changes in the aerodynamic characteristics of the airplane, particularly with regard to the pitching moment, were determined for various amounts of thrust reversal.

Pilot's seat with control stick.

In another study, a fully modulating target-type thrust reverser has been installed and tested on a jet-fighter airplane to evaluate the effect of more powerful incremental thrust control devices on the landing-approach characteristics of aircraft. The thrust reverser was also studied to determine its usefulness for inflight deceleration from high speeds and as a braking device to reduce the ground-roll distance in landings.

Runway and Landing-Gear Research

There are several problems associated with airport runways which can lead to hazardous aircraft operating conditions. For example, tire behavior during landing on wet runways has been found to contribute to a number of aircraft accidents. As part of a general program, the NACA has investigated the effects of water depth, tire speed, pressure and tread, braking friction forces, and cornering forces by use of an instrumented tire treadmill. The results indicate that the maximum and the full-skid braking friction coefficients decrease rapidly with increasing velocity until all braking effectiveness is lost and a tire-planing condition is reached.

Runway lights which project above the runway surface are a potential hazard to aircraft operations. Accordingly, an investigation was made to obtain data on

the landing-gear loads developed during landing and taxiing tests over various types of runway lights. The test results indicated that vertical loads on the nose landing gear were larger for landings on the lights than on plain concrete, and that the nose gear loads developed while taxiing over the lights were relatively more severe than those developed on the main gear.

A study was also made of ground-reaction forces measured during landing impacts of a large airplane. Results of the analysis of the data showed the effect of vertical velocity at contact on the vertical force and the variations of coefficients of friction with slip ratio during spinup on wet and dry concrete surfaces.

Crash Survival Research

Several fighter airplanes were crashed under circumstances approximating those observed in the military service; unflared landings at various angles, a ground cartwheel, and a ground loop. The magnitude, duration, and direction of the crash accelerations were measured on the airplane structure and on an anthropomorphic dummy installed in the cockpit. The accelerations measured were compared with existing data on human tolerance to the sudden loads that occur in crashes to see whether the human tolerances had been exceeded.

AERONAUTICAL METEOROLOGY

To achieve the goal of safe and efficient all-weather flight, aircraft and missile designers and operators must take into account the changes in weather conditions and the effects of the meteorological elements on the vehicle. Two of the environmental problems, atmospheric turbulence and icing, have been under study by the NACA for several years, while other factors have only been under investigation from time to time.

Atmospheric Turbulence

Rough air flight of aircraft brings discomfort to passengers and crew, may cause structural damage, may decrease the fatigue life of the airframe, and can present control problems to the pilot. In addition, turbulent air poses problems for missile takeoff and reentry operations. As one approach to the gust-loads problem, the NACA has been active for years in obtaining information on the extent, frequency, and severity of atmospheric turbulence in clouds and free air at altitudes up to 60,000 feet. Data have been obtained by specially instrumented aircraft, parachute assemblies, and rockets over several areas of the world.

The severest turbulence is generally found in the clouds associated with storm areas, but the available gust data are not sufficient for study. Accordingly, a fighter-type airplane has been specially instrumented for probing cumulus-type clouds to obtain gust measurements useful to designers, operators, and meteorologists.

The characteristics of turbulent air below 1,000 feet are not too well known; however, such information is required for landing and takeoff operations as well as low-level military missions. A study of gust data derived primarily from wind-tower measurements indicates that turbulence intensity is affected by windspeed, altitude, temperature lapse rate, and the ground roughness.

At the higher altitudes, investigations of cloud and clear-air turbulence have continued in order to shed more light on these phenomena. The NACA has cooperated with the Navy, Air Force, and Weather Bureau by furnishing VGH (velocity, acceleration, altitude) recorders and by analyzing gust data for several programs. Instrumented aircraft have probed the jetstream and have flown in and near hurricanes to obtain the needed data.

As part of the NACA analytical investigation of the aircraft-gust problem, a method has been developed to calculate the statistical forces and moments exerted on an airplane due to random distributions of gusts. A previous report covered the development of the rolling and yawing moments on a wing in random turbulence. Recent calculations have been made of the complete lateral response of an airplane while flying in continuous isotropic turbulence.

Environmental Data

Besides turbulence, other meteorological elements in and beyond our atmosphere affect the design and operation of aircraft and missiles. From time to time in answer to requests for specific information, the NACA has been able to obtain and analyze data useful to manufacturers, operators, and meteorologists.

Knowledge of atmospheric temperatures is of importance to designers and operators of aircraft and missiles. To provide this information, a study has been made of radiosonde temperature measurements taken over a 5-year period for several locations in the Northern Hemisphere. Probability distributions of temperature up to 100,000 feet have been determined from data provided, sorted, and tabulated by the U.S. Weather Bureau.

In cooperation with the Air Weather Service, an NACA flight program with instrumented U–2 aircraft is continuing to collect data up to 55,000 feet on such variables as water vapor, wind shear, clouds, temperature, the jetstream, clear-air turbulence, ozone, and cosmic rays. Recent data on atmospheric turbulence over the western part of the United States have been published.

526597—60——6

The Icing Cloud

For efficient design of icing protection systems for aircraft and missiles, detailed and statistical knowledge is required of worldwide icing conditions in which these vehicles may operate. The NACA has sought to obtain information on the extent, frequency, and severity of icing conditions by installation of suitable instruments in research, commercial, and military aircraft. Currently, icing-rate meters are on loan to several aircraft companies and Government organizations.

The icing problem for high-altitude, intercepter aircraft has been evaluated and the results published. At two Air Defense Command airbases, fighter-interceptors equipped with NACA icing-rate meters collected data during climb and descent operations, and information was obtained on the frequency and severity of icing clouds over the north-central and northwestern United States.

AIRCRAFT ICING

Because of the state of the art, active NACA icing research on aircraft and engine components has been diminishing since 1956 and was terminated in the fiscal year 1957. NACA icing research activities conducted during the fiscal year 1958 have been concerned primarily with completing the analyses and publication of the results of icing programs conducted over the preceding 24 months.

The Lewis Flight Propulsion Laboratory icing tunnel, because of its unique features, is continually made available to the aircraft industry and Government organizations under a plan whereby industry representatives conduct icing tests on their specific models with guidance by NACA personnel. The raw data obtained from such development studies are available upon request to interested personnel. Analysis and reporting of the data are being made by each company or organization. Thus, NACA reports on these projects are usually not prepared for formal publication.

Water-Droplet Impingement and Icing Protection

In order to design efficient icing protection systems for an aircraft engine component or airframe surface, detailed information is required as to the area and weight of ice accumulation under various icing and operating conditions. To determine droplet impingement characteristics, the NACA has tested both models and full-scale components in the Lewis Laboratory icing research tunnel. In addition, analytical studies have been made to obtain similar data.

An experimental investigation has been conducted to measure the amount and areas of cloud-droplet impingement on a ¼-scale model of a fighter airplane engine inlet. Angles of attack from 2° to 8°, droplet diameters from 7 to 23 microns, and ratios of inlet to free-stream velocity from 0.4 to 1.5 were studied. Significant impingement rates and areas were found on the curved outboard wall of the inlet duct and on regions within a few inches of the cowl lips and leading edges of the duct splitter vanes.

Icing tests were conducted in the 6- by 9-foot icing research tunnel to evaluate the effectiveness of ice protection systems for a jet transport. The proposed systems utilized hot gas to anti-ice the leading edge regions of the wing and cyclic-electric deicing for the tail surfaces. The manufacturer's personnel conducted the tests and the raw data are available for study.

As part of a general study of icing and icing protection for bodies of revolution, an investigation was conducted to determine the impingement characteristics, heat transfer, and icing-protection requirements for simple bodies of revolution. The bodies investigated included spheres, elliptical forebodies, and a conical forebody of 30° included angle. The investigation covered a wide range of conditions both in clear air and in icing, and included studies at angles of attack both with and without rotation.

The rate and the area of cloud-droplet impingement has been obtained for the above types of bodies. Results are presented in the form of dimensionless parameters, which enable the icing characteristics of bodies of revolution to be determined over a wide range of flight and atmospheric conditions.

Data on the heat transfer in clear air from the elliptical body of fineness ratio 3.0 and the conical forebody have also been obtained. Information required in the use of conventional wet-air analysis for the design of anti-icing systems for bodies of revolution was determined from these data.

Penalties Due to Icing

Aerodynamic effects caused by ice formations on an unheated NACA 65A004 airfoil were determined over a wide range of icing conditions and the results published. The drag changes due to these ice formations were correlated with the various icing conditions, as well as with the physical dimensions of the ice accumulated and with the measured droplet-impingement rates. The correlation resulted in an empirical equation that may be used to predict changes in drag coefficients for this airfoil based on meteorological, impingement, and flight conditions. The correlation was also extended to include aerodynamic data for four other airfoils.

Noise Research

The noise produced by current jet engines is of sufficient intensity to cause damage to nearby personnel and aircraft structures and serious discomfort or an-

noyance to personnel over a considerable distance from the engine. Noise annoyance alone is a major problem in the introduction of jet transports and may be an important factor influencing the operation of such transports.

The NACA has been conducting at its Lewis and Langley Research Centers a broad research program to determine the mechanisms by which jet noise is produced and to find means for reducing jet noise. Conclusive evidence from this research program shows that the major source of noise from a turbojet or rocket engine is the exhaust and that the noise from this source dominates all other noise during full power operations. The jet exhaust noise is caused by the intense turbulence produced by the mixing of the high speed exhaust stream with the surrounding air as well as by oscillating shock waves within the jet exhaust and interaction of these shock waves and turbulence. The major NACA research effort has been directed toward reduction of noise created by turbulence since this is the dominant factor in the production of noise during take-off and climb of jet aircraft which are the operating conditions producing the noise nuisance in communities near airports. Reducing the velocity of the jet exhaust will reduce the noise; however, this imposes a penalty on the efficiency of the engine. Since most of the jet noise is produced within ten nozzle diameters downstream of a conventional circular nozzle, it has been determined that less noise would be produced if the jet exhaust stream could be slowed down as rapidly as possible after leaving the nozzle; that is in less distance than the ten diameters. This has been accomplished by the development of special jet exit nozzles which rapidly mix low energy surrounding air into the jet exhaust stream and thereby decrease the overall jet velocity and noise. Scores of nozzle configurations have been investigated to determine the basic design parameters required to produce the best nozzles for given conditions. The corrugated multiple-tube and shrouded nozzles now being produced for jet transports are examples of nozzles developed from this program. Some nozzles are designed to produce significant reductions in overall noise output, others are designed to alter the mixing process in such a way as to change the amount of noise in certain frequencies, and still others are designed to reduce the width of the pattern of noise distribution beneath an aircraft so as to minimize the number of people annoyed by take-offs. More research is underway to increase the noise suppression effectiveness of these nozzles.

Although suppressors do reduce the noise level, they also add weight to the aircraft, slightly decrease engine performance, and increase the drag of the airplane. The amount of noise suppression desired must be balanced against the economic and performance penalties imposed by the use of these suppressors. As a result of extensive NACA wind tunnel tests of suppressor configurations, the aerodynamic performance of suppressors has been evaluated to help assess a reasonable balance. Much additional work is required before a satisfactory solution can be attained.

With the advent of supersonic aircraft a new problem has entered into flight operations—the sonic boom. This boom is the shock wave produced by an object traveling through the air at supersonic speeds and is similar to the bow wave from a boat. This boom or wave can easily be of sufficient intensity to crack plaster and break windows in buildings beneath the path of the supersonic aircraft. The NACA has investigated the parameters which affect the strength of this wave when it hits the ground and has found that primary factors are the altitude of the aircraft, the climatic conditions, and the size of the aircraft. The speed of the aircraft is not important after the aircraft is well into the supersonic regime. Data are being obtained which will allow the estimation of the strength of sonic booms for various flight conditions, and more work is being done to establish flight procedures to minimize the boom intensity. Some research has been accomplished on aircraft design concepts for the future which may reduce the magnitude of the boom problem, and more work is underway along such lines.

The effects of sonic boom from one aircraft on other nearby aircraft also have been investigated, and it appears that if the aircraft are not flying at the same speed so that one aircraft remains in the shock wave from the other aircraft, or if the aircraft are separated by distances of approximately 500 feet or more, the sonic boom problem appears to be of negligible importance to aircraft in flight.

RESEARCH PUBLICATIONS

REPORTS

1296. A Theoretical Study of the Aerodynamics of Slender Cruciform-Wing Arrangements and Their Wakes. By John R. Spreiter and Alvin H. Sacks.

1297. Nonlifting Wing-Body Combinations with Certain Geometric Restraints Having Minimum Wave Drag at Low Supersonic Speeds. By Harvard Lomax.

1298. An Analysis of the Effects of Aeroelasticity on Static Longitudinal Stability and Control of a Swept-Wing Airplane. By Richard B. Skoog.

1299. Correlation, Evaluation, and Extension of Linearized Theories for Tire Motion and Wheel Shimmy. By Robert F. Smiley.

1300. Basic Considerations in the Combustion of Hydrocarbon Fuels With Air. By Propulsion Chemistry Division, Lewis Flight Propulsion Laboratory.

1301. Linearized Lifting-Surface and Lifting-Line Evaluations of Sidewash Behind Rolling Triangular Wings at Supersonic Speeds. By Percy J. Bobbitt.

1302. On Panel Flutter and Divergence of Infinitely Long Unstiffened and Ring-Stiffened Thin-Walled Circular Cylinders. By Robert W. Leonard and John M. Hedgepeth.

1303. Wind-Tunnel Investigation of a Number of Total-Pressure Tubes at High Angles of Attack—Subsonic, Transonic, and Supersonic Speeds. By William Gracey.

1304. Flight Investigation of the Effectiveness of an Automatic Aileron Trim Control Device for Personal Airplanes. By William H. Phillips, Helmut A. Kuehnel, and James B. Whitten.

1305. Measurement of Aerodynamic Forces for Various Mean Angles of Attack on an Airfoil Oscillating in Pitch and on Two Finite-Span Wings Oscillating in Bending With Emphasis on Damping in the Stall. By A. Gerald Rainey.

1306. Bodies of Revolution Having Minimum Drag at High Supersonic Airspeeds. By A. J. Eggers, Jr., Meyer M. Resnikoff, and David H. Dennis.

1307. Lift and Center of Pressure of Wing-Body-Tail Combinations at Subsonic, Transonic, and Supersonic Speeds. By William C. Pitts, Jack N. Nielsen, and George E. Kaattari.

1308. Investigation of the Compressive Strength and Creep Lifetime of 2024–T3 Aluminum-Alloy Plates at Elevated Temperatures. By Eldon E. Mathauser and William D. Deveikis.

1309. Aerodynamic Characteristics at High Speeds of Related Full-Scale Propellers Having Different Blade-Section Cambers. By Julian D. Maynard and Leland B. Salters, Jr.

1310. An Investigation of Four Wings of Square Plan Form at a Mach Number of 6.9 in the Langley 11-Inch Hypersonic Tunnel. By Charles M. McLellan, Mitchel H. Bertram, and John A. Moore.

1311. Determination of Vortex Paths by Series Expansion Technique With Application to Cruciform Wings. By Alberta Y. Alksne.

1312. Some Effects of Bluntness on Boundary-Layer Transition and Heat Transfer at Supersonic Speeds. By W. E. Moeckel.

1313. Exploratory Investigation of Boundary-Layer Transition on a Hollow Cylinder at a Mach Number of 6.9. By Mitchel H. Bertram.

1314. Summary of Scale-Model Thrust-Reverser Investigation. By John H. Povolny, Fred W. Steffen, and Jack G. McArdle.

1315. On Slender-Body Theory at Transonic Speeds. By Keith C. Harder and E. B. Klunker.

1316. Torsional Stiffness of Thin-Walled Shells Having Reinforcing Cores and Rectangular, Triangular, or Diamond Cross Section. By Harvey G. McComb, Jr.

1317. Cloud-Droplet Ingestion in Engine Inlets With Inlet Velocity Ratios of 1.0 and 0.7. By Rinaldo J. Brun.

1318. Three-Dimensional Transonic Flow Theory Applied to Slender Wings and Bodies. By Max. A. Heaslet and John R. Spreiter.

1319. Induced Velocities Near a Lifting Rotor With Nonuniform Disk Loading. By Harry H. Heyson and S. Katzoff.

1320. An Evaluation of Four Experimental Methods for Measuring Mean Properties of a Supersonic Turbulent Boundary Layer. By George J. Nothwang.

1321. Theoretical Calculation of the Power Spectra of the Rolling and Yawing Moments on a Wing in Random Turbulence. By John M. Eggleston and Franklin W. Diederich.

1322. Method for Calculating the Aerodynamic Loading on an Oscillating Finite Wing in Subsonic and Sonic Flow. By Harry L. Runyan and Donald S. Woolston.

1323. Investigation of the Laminar Aerodynamic Heat-Transfer Characteristics of a Hemisphere-Cylinder in the Langley 11-Inch Hypersonic Tunnel at a Mach Number of 6.8 By Davis H. Crawford and William D. McCauley.

1324. Comparison of Several Methods for Obtaining the Time Response of Linear Systems to Either a Unit Impulse or Arbitrary Input From Frequency-Response Data. By James J. Donegan and Carl R. Huss.

1325. Average Properties of Compressible Laminar Boundary Layer on Flat Plate With Unsteady Flight Velocity. By Franklin K. Moore and Simon Ostrach.

1326. Flight and Analytical Methods for Determining the Coupled Vibration Response of Tandem Helicopters. By John E. Yeates, Jr., George W. Brooks, and John C. Houbolt.

1327. Theoretical and Experimental Investigation of the Subsonic-Flow Fields Beneath Swept and Unswept Wings With Tables of Vortex-Induced Velocities. By William J. Alford, Jr.

1328. A Second-Order Shock-Expansion Method Applicable to Bodies of Revolution Near Zero Lift. By Clarence A. Syvertson and David H. Dennis.

1329. Far Noise Field of Air Jets and Jet Engines. By Edmund E. Callaghan and Willard D. Coles.

1330. Experimental and Predicted Longitudinal and Lateral-Directional Response Characteristics of a Large Flexible 35° Swept-Wing Airplane at an Altitude of 35,000 Feet. By Henry A. Cole, Jr., Stuart C. Brown, and Euclid C. Holleman.

1331. Influence of Alloying Upon Grain-Boundary Creep. By F. N. Rhines, W. E. Bond, and M. A. Kissel.

Preceding Page Blank

1332. Seat Design for Crash Worthiness. By I. Irving Pinkel and Edmund G. Rosenberg.
1333. Attenuation in a Shock Tube Due to Unsteady-Boundary-Layer Action. By Harold Mirels.
1334. Relation of Turbojet and Ramjet Combustion Efficiency to Second-Order Reaction Kinetics and Fundamental Flame Speed. By J. Howard Childs, Thaine W. Reynolds, and Charles C. Graves.
1335. Minimum Wave Drag for Arbitrary Arrangements of Wings and Bodies. By Robert T. Jones.
1336. An Investigation of Single- and Dual-Rotation Propellers at Positive and Negative Thrust, and in Combination With an NACA 1-Series D-Type Cowling at Mach Numbers up to 0.84. By Robert M. Reynolds, Robert I. Sammonds, and John H. Walker.
1337. Determination of Longitudinal Stability and Control Characteristics From Free-Flight Model Tests With Results at Transonic Speeds for Three Airplane Configurations. By Clarence L. Gillis and Jesse L. Mitchell.
1338. Near Noise Field of a Jet-Engine Exhaust. By Walton L. Howes, Edmund E. Callaghan, Willard D. Coles, and Harold R. Mull.
1339. A Summary and Analysis of the Low-Speed Longitudinal Characteristics of Swept Wings at High Reynolds Number. By G. Chester Furlong and James G. McHugh.
1340. Investigation of Downwash, Sidewash, and Mach Number Distribution Behind a Rectangular Wing at a Mach Number of 2.41. By David Adamson and William B. Boatright.
1341. Influence of Hot-Working Conditions on High-Temperature Properties of a Heat-Resistant Alloy. By John F. Ewing and J. W. Freeman.

TECHNICAL NOTES [1]

3289. The Minimization of Wave Drag for Wings and Bodies With Given Base Area or Volume. By Max A. Heaslet.
3290. On the Minimization of Airplane Responses to Random Gusts. By Murray Tobak.
3585. Determination of Surge and Stall Limits of an Axial-Flow Turbojet Engine for Control Applications. By Ross D. Schmidt, George Vasu, and Edward W. McGraw.
3781. Handbook of Structural Stability. Part I—Buckling of Flat Plates. By George Gerard and Herbert Becker.
3782. Handbook of Structural Stability. Part II—Buckling of Composite Elements. By Herbert Becker.
3783. Handbook of Structural Stability. Part III—Buckling of Curved Plates and Shells. By George Gerard and Herbert Becker.
3784. Handbook of Structural Stability. Part IV—Failure of Plates and Composite Elements. By George Gerard.
3785. Handbook of Structural Stability. Part V—Compressive Strength of Flat Stiffened Panels. By George Gerard.
3786. Handbook of Structural Stability. Part VI—Strength of Stiffened Curved Plates and Shells. By Herbert Becker.
3883. Propellant Vaporization as a Criterion for Rocket-Engine Design; Calculations of a Chamber Length To Vaporize Various Propellants. By Richard J. Priem.
3924. Discharge Coefficients for Combustor-Liner Air-Entry Holes. II—Flush Rectangular Holes, Step Louvers, and Scoops. By Ralph T. Dittrich.
3985. Propellant Vaporization as a Criterion for Rocket Engine Design; Calculations of Chamber Length To Vaporize a single n-Heptane Drop. By Richard J. Priem.
3987. Effect of Environments of Sodium Hydroxide, Air, and Argon on the Stress-Rupture Properties of Nickel at 1,500° F. By Howard T. McHenry and H. B. Probst.
3988. Experimental and Calculated Histories of Vaporizing Fuel Drops. By R. J. Priem, G. L. Borman, M. M. El Wakil, O. A. Uyehara, and P. S. Myers.
3989. Strength and Ductility of Bainitic Steels. By Donald H. Desy, J. O. Brittain, and M. Gensamer.
3990. Effect of Crystal Orientation on Fatigue-Crack Initiation in Polycrystalline Aluminum Alloys. By J. G. Weinberg and J. A. Bennett.
3991. Interface Thermal Conductance of Twenty-Seven Riveted Aircraft Joints. By Martin E. Barzelay and George F. Holloway.
3995. An Investigation of Flow in Circular and Annular 90° Bends With a Transition in Cross Section. By Stafford W. Wilbur.
4005. An Experimental Investigation of the Effect of Various Parameters Including Tip Mach Number on the Flutter of Some Model Helicopter Rotor Blades. By George W. Brooks and John E. Baker.
4007. An Investigation of Discharge and Thrust Characteristics of Flapped Outlets for Stream Mach Numbers From 0.40 to 1.30. By Allen R. Vick.
4013. Low-Speed Experimental Investigation of the Magnus Effect on Various Sections of a Body of Revolution With and Without A Propeller. By M. J. Queijo and Herman S. Fletcher.
4014. Recent Research on the Creep of Airframe Components. By Eldon E. Mathauser, Avraham Berkovits, and Bland A. Stein.
4016. Some Factors Affecting the Variation of Pitching Moment With Sideslip of Aircraft Configurations. By Edward C. Polhamus.
4017. Momentum Transfer for Flow Over a Flat Plate With Blowing. By H. S. Mickley and R. S. Davis.
4018. Influence of Turbulence on Transfer of Heat From Cylinders. By J. Kestin and P. F. Maeder.
4019. Some Observations on Stress-Corrosion Cracking of Single Crystals of AZ61X Magnesium Alloy. By F. Meller and M. Metzger.
4020. Investigation of Minimum Drag and Maximum Lift-Drag Ratios of Several Wing-Body Combinations Including a Cambered Triangular Wing at Low Reynolds Numbers and at Supersonic Speeds. By Clinton E. Brown and L. K. Hargrave.
4026. Effects of Thermal Relaxation and Specific-Heat Changes on Measurements With a Pneumatic-Probe Pyrometer. By P. W. Kuhns.
4027. Application of Obliquely Mounted Strain Gage to Measurement of Residual Stresses in Disks. By M. H. Hirschberg, R. H. Kemp, and S. S. Manson.
4028. Preliminary Investigation of Propane Combustion in a 3-Inch-Diameter Duct at Inlet-Air Temperatures of 1,400° to 1,600° F. By Erwin A. Lezberg.
4029. Turbulence Measurements in Multiple Interfering Air Jets. By James C. Laurence and Jean M. Benninghoff.
4030. Experimental Investigation of Cermet Turbine Blades in an Axial-Flow Turbojet Engine. By William C. Morgan and George C. Deutsch.
4031. Stability Limits and Burning Velocities for Some Laminar and Turbulent Propane and Hydrogen Flames at Reduced Pressure. By Burton Fine.

[1] The missing numbers in the series of Technical Notes were released before or after the period covered by this report.

4032. Reduction of Oxidized Nichrome V Powders and Sintering of Nichrome V Bodies. By Paul Sikora and Philip Clarkin.

4033. Screen-Type Noise Reduction Devices for Ground Running of Turbojet Engines. By Willard D. Coles and Warren J. North.

4034. Effect of Fluid-System Parameters on Starting Flow in a Liquid Rocket. By Richard P. Krebs.

4035. Impingement of Cloud Droplets on 36.5-Percent-Thick Joukowski Airfoil at Zero Angle of Attack and Discussion of Use as Cloud Measuring Instrument in Dye-Tracer Technique. By R. J. Brun and Dorothea E. Vogt.

4036. Creep of Aluminum-Copper Alloys During Age Hardening. By E. E. Underwood, L. L. Marsh, and G. K. Manning.

4037. Stability of Laminar Boundary Layer Near a Stagnation Point Over an Impermeable Wall and a Wall Cooled by Normal Fluid Injection. By Morris Morduchow, Richard G. Grape, and Richard P. Shaw.

4039. Investigation of the Effects of Profile Shape on the Aerodynamic and Structural Characteristics of Thin, Two-Dimensional Airfoils at Supersonic Speeds. By Elliott D. Katzen, Donald M. Kuehn, and William A. Hill, Jr.

4040. Estimation of Incremental Pitching Moments Due to Trailing-Edge Flaps on Swept and Triangular Wings. By Harry A. James and Lynn W. Hunton.

4041. The Subsonic Static Aerodynamic Characteristics of an Airplane Model Having a Triangular Wing of Aspect Ratio 3. I—Effects of Horizontal-Tail Location and Size on the Longitudinal Characteristics. By Bruce E. Tinling and Armando E. Lopez.

4042. The Subsonic Static Aerodynamic Characteristics of an Airplane Model Having a Triangular Wing of Aspect Ratio 3. II—Lateral and Directional Characteristics. By Howard F. Savage and Bruce E. Tinling.

4043. The Subsonic Static Aerodynamic Characteristics of an Airplane Model Having a Triangular Wing of Aspect Ratio 3. III—Effects of Trailing-Edge Flaps. By Bruce E. Tinling and A. V. Karpen.

4044. Ground Effects on the Longitudinal Characteristics of Two Models With Wings Having Low Aspect Ratio and Pointed Tips. By Donald A. Buell and Bruce E. Tinling.

4045. Elliptic Cones Alone and With Wings at Supersonic Speeds. By Leland H. Jorgensen.

4046. A Comparative Analysis of the Performance of Long-Range Hypervelocity Vehicles. By Alfred J. Eggers, Jr., H. Julian Allen, and Stanford E. Neice.

4047. A Study of the Motion and Aerodynamic Heating of Missiles Entering the Earth's Atmosphere at High Supersonic Speeds. By H. Julian Allen and A. J. Eggers, Jr.

4048. Motion of a Ballistic Missile Angularly Misalined With the Flight Path Upon Entering the Atmosphere and Its Effect Upon Aerodynamic Heating, Aerodynamic Loads, and Miss Distance. By H. Julian Allen.

4050. Studies of Structural Failure Due to Acoustic Loading. By Robert W. Hess, Robert W. Fralich, and Harvey H. Hubbard.

4055. Effects of Airplane Flexibility on Wing Bending Strains in Rough Air. By Thomas L. Coleman, Harry Press, and C. C. Shufflebarger.

4058. Calculated Effect of Some Airplane Handling Techniques on the Ground-Run Distance in Landing on Slippery Runways. By John A. Zalovcik.

4059. Noise Survey of a Full-Scale Supersonic Turbine-Driven Propeller Under Static Conditions. By Max C. Kurbjun.

4061. Flight Measurements of Boundary-Layer Temperature Profiles on a Body of Revolution (NACA RM-10) at Mach Numbers From 1.2 to 3.5. By Andrew G. Swanson, James J. Buglia, and Leo T. Chauvin.

4062. Effect of Sweep on Performance of Compressor Blade Sections as Indicated by Swept-Blade Rotor, Unswept-Blade Rotor, and Cascade Tests. By William R. Godwin.

4063. Equations, Tables, and Figures for Use in the Analysis of Helium Flow at Supersonic and Hypersonic Speeds. By James N. Mueller.

4064. Review and Investigation of Unsatisfactory Control Characteristics Involving Instability of Pilot-Airplane Combination and Methods for Predicting These Difficulties From Ground Tests. By William H. Phillips, B. Porter Brown, and James T. Matthews, Jr.

4065. Tensile Properties of Inconel X Sheet Under Rapid-Heating and Constant-Temperature Conditions. By Ivo M. Kurg.

4066. A Method Utilizing Data on the Spiral, Roll-Subsidence, and Dutch Roll Modes for Determining Lateral Stability Derivatives From Flight Measurements. By Bernard B. Klawans and Jack A. White.

4068. Effects of Blade Plan Form on Free-Space Oscillating Pressures Near Propellers at Flight Mach Numbers to 0.72. By Max C. Kurbjun.

4069. Effect of Angle of Attack and Thickness on Aerodynamic Coefficients of a Rigid Wing Oscillating at Very Low Frequencies in Two-Dimensional Supersonic Flow. By Frank S. Malvestuto, Jr., and Julia M. Goodwin.

4070. Flight-Test Investigation on the Langley Control-Line Facility of a Model of a Propeller-Driven Tail-Sitter-Type Vertical-Take-Off Airplane With Delta Wing During Rapid Transitions. By Robert O. Schade.

4071. A Correlation of Results of a Flight Investigation With Results of an Analytical Study of Effects of Wing Flexibility on Wing Strains Due to Gusts. By C. C. Shufflebarger, Chester B. Payne, and George L. Cahen.

4072. Experimental Investigation of Attenuation of Strong Shock Waves in a Shock Tube With Hydrogen and Helium as Driver Gases. By Jim J. Jones.

4073. Tables for the Numerical Determination of the Fourier Transform of a Function of Time and the Inverse Fourier Transform of a Function of Frequency, With Some Applications to Operational Calculus Methods. By Carl R. Huss and James J. Donegan.

4074. Compressive Stress-Strain Properties of 17-7 PH and AM 350 Stainless-Steel Sheet at Elevated Temperatures. By Bland A. Stein.

4075. Tensile Stress-Strain Properties of 17-7 PH and AM 350 Stainless-Steel Sheet at Elevated Temperatures. By Ivo M. Kurg.

4076. Calculated and Measured Stresses in Simple Panels Subject to Intense Random Acoustic Loading Including the Near Noise Field of a Turbojet Engine. By Leslie W. Lassiter and Robert W. Hess.

4077. Static Longitudinal and Lateral Stability Characteristics at Low Speed of 45° Sweptback-Midwing Models Having Wings With an Aspect Ratio of 2, 4, or 6. By David F. Thomas, Jr., and Walter D. Wolhart.

4078. A Discussion of Cone and Flat-Plate Reynolds Numbers for Equal Ratios of the Laminar Shear to the Shear Caused by Small Velocity Fluctuations in a Laminar Boundary Layer. By Neal Tetervin.

4079. Wind-Tunnel Investigation of External-Flow Jet-Augmented Double Slotted Flaps on a Rectangular Wing at an Angle of Attack of 0° to High Momentum Coefficients. By Edwin E. Davenport.

4080. Some Effects of Vanes and of Turbulence in Two-Dimensional Wide-Angle Subsonic Diffusers. By Carl A. Moore, Jr., and Stephen J. Kline.

4081. Effect of Overheating on Creep-Rupture Properties of S–816 Alloy at 1,500° F. By John P. Rowe and J. W. Freeman.

4082. Abnormal Grain Growth in Nickel-Base Heat-Resistant Alloys. By R. F. Decker, A. I. Rush, A. G. Dano, and J. W. Freeman.

4083. Effect of Overheating on Creep-Rupture Properties of HS–31 Alloy at 1,500° F. By John P. Rowe and J. W. Freeman.

4084. Abnormal Grain Growth in M–252 and S–816 Alloys. By R. F. Decker, A. I. Rush, A. G. Dano, and J. W. Freeman.

4085. Method of Split Rigidities and Its Application to Various Buckling Problems. By P. P. Bijlaard.

4086. Discrete Potential Theory for Two-Dimensional Laplace and Poisson Difference Equations. By Charles Saltzer.

4087. Drop-Size Distribution for Crosscurrent Breakup of Liquid Jets in Airstreams. By Robert D. Ingebo and Hampton H. Foster.

4088. Practical Solution of Plastic Deformation Problems in Elastic-Plastic Range. By A. Mendelson and S. S. Manson.

4089. The Mechanism of Thermal-Gradient Mass Transfer in the Sodium Hydroxide-Nickel System. By Charles E. May.

4090. Analysis of Shock Motion in Ducts During Disturbances in Downstream Pressure. By Herbert G. Hurrell.

4091. Experimental Investigation of Transpiration Cooling for a Turbulent Boundary Layer in Subsonic Flow Using Air as a Coolant. By William E. Brunk.

4092. Experimental Droplet Impingement on Four Bodies of Revolution. By James P. Lewis and Robert S. Ruggeri.

4093. Investigation of Heat Transfer From a Stationary and Rotating Conical Forebody. By Robert S. Ruggeri and James P. Lewis.

4094. Effects of Extreme Surface Cooling on Boundary-Layer Transition. By John R. Jack, Richard J. Wisniewski, and N. S. Diaconis.

4095. An Analysis of the Effect of Several Parameters on the Stability of an Air-Lubricated Hydrostatic Thrust Bearing. By William H. Roudebush.

4096. Flow-Turning Losses Associated With Zero-Drag External-Compression Supersonic Inlets. By Rudolph C. Meyer.

4097. Investigation of Some Mechanical Properties of Thermenol Compressor Blades. By Donald F. Johnson.

4098. Propellant Vaporization as a Criterion for Rocket-Engine Design; Calculations Using Various Log-Probability Distributions of Heptane Drops. By Richard J. Priem.

4099. Heat Transfer and Boundary-Layer Transition on Two Blunt Bodies at Mach Number 3.12. By N. S. Diaconis, Richard J. Wisniewski, and John R. Jack.

4100. Vibration Survey of Four Representative Types of Air-Cooled Turbine Blades. By Howard F. Calvert and Gordon T. Smith.

4101. Effect of Lubricant Viscosity on Rolling-Contact Fatigue Life. By Thomas L. Carter.

4102. Velocity and Friction Characteristics of Laminar Viscous Boundary-Layer and Channel Flow Over Surfaces With Ejection or Suction. By E. R. G. Eckert, Patrick L. Donoughe, and Betty Jo Moore.

4103. Impact-Loads Investigation of Chine-Immersed Model Having a Circular-Arc Transverse Shape. By Philip M. Edge, Jr.

4104. The Use of Pure Twist for Drag Reduction on Arrow Wings With Subsonic Leading Edges. By Frederick C. Grant.

4105. A Method of Computing the Transient Temperature of Thick Walls From Arbitrary Variation of Adiabatic-Wall Temperature and Heat-Transfer Coefficient. By P. R. Hill.

4106. Impact-Loads Investigation of a Chine-Immersed Model Having a Longitudinally Curved Bow and a V-Bottom With a Dead-Rise Angle of 30°. By Philip M. Edge, Jr., and John S. Mixon.

4107. Effects of Airplane Flexibility on Wing Strains in Rough Air at 5,000 Feet as Determined by Flight Tests of a Large Swept-Wing Airplane. By Richard H. Rhyne and Harold N. Murrow.

4108. A Thermal System for Continuous Monitoring of Laminar and Turbulent Boundary-Layer Flows During Routine Flight. By Norman R. Richardson and Elmer A. Horton.

4109. Low-Speed Yawed-Rolling Characteristics and Other Elastic Properties of a Pair of 40-Inch-Diameter, 14-Ply-Rating, Type VII Aircraft Tires. By Walter B. Horne and Robert F. Smiley.

4110. Mechanical Properties of Pneumatic Tires With Special Reference to Modern Aircraft Tires. By Robert F. Smiley and Walter B. Horne.

4111. Investigation of the Compressive Strength and Creep of 7075–T6 Aluminum-Alloy Plates at Elevated Temperatures. By William D. Deveikis.

4112. Generalized Master Curves for Creep and Rupture. By George J. Heimerl and Arthur J. McEvily, Jr.

4113. Study of Pressure Distributions on Simple Sharp-Nosed Models at Mach Numbers From 16 to 18 in Helium Flow. By Wayne D. Erickson.

4114. Weight-Strength Studies of Structures Representative of Fuselage Construction. By James P. Peterson.

4115. Theory of Aircraft Structural Models Subject to Aerodynamic Heating and External Loads. By William J. O'Sullivan, Jr.

4116. Wind-Tunnel Investigation at Low Speeds To Determine Flow-Field Characteristics and Ground Influence on a Model With Jet-Augmented Flaps. By Raymond D. Vogler and Thomas R. Turner.

4117. Experimental Investigation of Lift, Drag, and Pitching Moment of Five Annular Airfoils. By Herman S. Fletcher.

4118. Low-Temperature, Vapor-Phase Oxidation of Fuel-Rich Hydrocarbon Mixtures. By William T. House and Milton Orchin.

4119. Wind-Tunnel Investigation of Effects of Ground Proximity and of Split Flaps on the Lateral Stability Derivatives of a 60° Delta-Wing Model Oscillating in Yaw. By Byron M. Jaquet.

4120. Theoretical Calculations of Supersonic Wave Drag at Zero Lift for a Particular Store Arrangement. By Kenneth Margolis, Frank S. Malvestuto, Jr., and Peter J. Maxie, Jr.

4121. Theory and Apparatus for Measurement of Emissivity for Radioactive Cooling of Hypersonic Aircraft With Data for Inconel and Inconel X. By William J. O'Sullivan, Jr., and William R. Wade.

4122. External Interference Effects of Flow Through Static-Pressure Orifices of an NACA Airspeed Head at a Mach Number of 3. By Norman S. Silsby.

4123. Rough-Water Impact-Load Investigation of a Chine-Immersed V-Bottom Model Having a Dead-Rise Angle of 10°. By Melvin F. Markey and Thomas D. Carpini.

4124. Effect of Ground Proximity on the Aerodynamic Characteristics of a Four-Engine Vertical-Take-Off-and-Landing Transport-Airplane Model With Tilting Wing and Propellers. By William A. Newsom, Jr.

4125. Heat Transfer and Recovery Temperatures on a Sphere With Laminar, Transitional, and Turbulent Boundary Layers at Mach Numbers of 2.00 and 4.15. By Ivan E. Beckwith and James J. Gallagher.

4126. Experimental Investigation of the Effects of Some Shroud Design Variables on the Static Thrust Characteristics of a Small-Scale Shrouded Propeller Submerged in a Wing. By Robert T. Taylor.

4127. The Measurement of Pressure Altitude on Aircraft. By William Gracey.

4128. A Thermocouple Subcarrier Oscillator for Telemetering Temperatures From Pilotless Aircraft. By Clifford L. Fricke.

4129. Analysis of Operational Airline Data To Show the Effects of Airborne Weather Radar on the Gust Loads and Operating Practices of Twin-Engine Short-Haul Transport Airplanes. By Martin R. Copp and Walter G. Walker.

4130. NACA 65-Series Compressor Rotor Performance With Varying Annulus-Area Ratio, Solidity, Blade Angle, and Reynolds Number and Comparison With Cascade Results. By Wallace M. Schulze, John R. Erwin, and George C. Ashby, Jr.

4131. Transition-Flight Investigation of a Four-Engine-Transport Vertical-Take-Off Airplane Model Utilizing a Large Flap and Extensible Vanes for Redirecting the Propeller Slipstream. By Louis P. Tosti.

4132. Fatigue Investigation of Full-Scale Transport-Airplane Wings. Variable-Amplitude Tests With a Gust-Loads Spectrum. By Richard E. Whaley.

4133. Boundary-Layer Displacement Effects in Air at Mach Numbers of 6.8 and 9.6. By Mitchel H. Bertram.

4134. Stall Propagation in a Cascade of Airfoils. By Anthony R. Kriebel, Barry S. Seidel, and Richard G. Schwind.

4135. Influence of Solid-Body Rotation on Screen-Produced Turbulence. By Stephen C. Traugott and Hsuan Yeh.

4136. Theoretical Investigation of Subsonic Oscillatory Blade-Row Aerodynamics. By Frank Land and Manfred Friedman.

4137. Fatigue Behavior of Aircraft Structural Beams. By W. S. Hyler, H. G. Popp, D. N. Gideon, S. A. Gordon, and H. J. Grover.

4138. Creep Deformation Patterns of Joints Under Bearing and Tensile Loads. By E. G. Bodine, R. L. Carlson, and G. K. Manning.

4139. Wall Pressure Fluctuations in a Turbulent Boundary Layer. By William W. Willmarth.

4140. Turbulent Shearing Stress in the Boundary Layer of Yawed Flat Plates. By Harry Ashkenas.

4141. The Useful Heat Capacity of Several Materials for Ballistic Nose-Cone Construction. By Jackson R. Stalder.

4142. Effects of Leading-Edge Blunting on the Local Heat Transfer and Pressure Distributions Over Flat Plates in Supersonic Flow. By Marcus O. Creager.

4143. Development of a Piston-Compressor Type Light-Gas Gun for the Launching of Free-Flight Models at High Velocity. By A. C. Charters, B. Pat Denardo, and Vernon J. Rossow.

4144. Effect of Oxygen Recombination on One-Dimensional Flow at High Mach Numbers. By Steve P. Heims.

4145. An Analysis of the Optimization of a Beam Rider Missile System. By Marvin Shinbrot and Grace C. Carpenter.

4146. Contribution of the Wing Panels to the Forces and Moments of Supersonic Wing-Body Combinations at Combined Angles. By J. Richard Spahr.

4147. Measured and Predicted Dynamic Response Characteristics of a Flexible Airplane to Elevator Control Over a Frequency Range Including Three Structural Modes. By Henry A. Cole, Jr., and Euclid C. Holleman.

4148. Theoretical Pressure Distributions for Several Related Nonlifting Airfoils at High Subsonic Speeds. By John R. Spreiter, Alberta Y. Alksne, and B. Jeanne Hyett.

4149. An Analysis of the Turbulent Boundary-Layer Characteristics on a Flat Plate With Distributed Light-Gas Injection. By Morris W. Rubesin and Constantine C. Pappas.

4150. Approximations for the Thermodynamic and Transport Properties of High-Temperature Air. By C. Frederick Hansen.

4151. Correlations Among Ice Measurements, Impingement Rates, Icing Conditions, and Drag Coefficients for Unswept NACA 65A004 Airfoil. By Vernon H. Gray.

4152. Laminar Boundary Layer With Heat Transfer on a Cone at Angle of Attack in a Supersonic Stream. By Eli Reshotko.

4153. Effect of Wall Cooling on Inlet Parameters of a Scoop Operating in a Turbulent Boundary Layer on a Flat or Conical Surface for Mach Numbers 2 to 10. By Andrew Beke.

4154. Approximate Calculation of the Compressible Turbulent Boundary Layer With Heat Transfer and Arbitrary Pressure Gradient. By Eli Reshotko and Maurice Tucker.

4155. Aerodynamic Effects Caused by Icing of an Unswept NACA 65A004 Airfoil. By Vernon H. Gray and Uwe H. von Glahn.

4156. Effect of Initial Mixture-Temperature on Burning Velocity of Hydrogen-Air-Mixtures With Preheating and Simulated Preburning. By Sheldon Heimel.

4157. Corrosion Resistance of Nickel Alloys in Molten Sodium Hydroxide. By H. B. Probst, C. E. May, and Howard T. McHenry.

4158. Accelerations in Transport-Airplane Crashes. By G. Merritt Preston and Gerard J. Pesman.

4159. Experimental Investigation of Turbojet-Engine Multiple-Loop Controls for Non Afterburning and Afterburning Modes of Engine Operation. By Donald B. Kirsch, Leon M. Wenzel, and Clint E. Hart.

4160. Thermal Fatigue of Ductile Materials. I—Effect of Variations in the Temperature Cycle on the Thermal-Fatigue Life of S–816 and Inconel 550. By Francis J. Clauss and James W. Freeman.

4161. Effect of Lubricant Base Stock on Rolling-Contact Fatigue Life. By Thomas L. Carter.

4162. Study of Some Burner Cross-Section Changes That Increase Space-Heating Rates. By Donald R. Boldman and Perry L. Blackshear, Jr.

4163. Effect of Temperature on Rolling-Contact Fatigue Life With Liquid and Dry Powder Lubricants. By Thomas L. Carter.

4164. Two-Dimensional Diffusion Theory Analysis of Reactivity Effects of a Fuel-Plate-Removal Experiment. By Edward R. Gotsky, James P. Cusick, and Donald Bogart.

4165. Thermal Fatigue of Ductile Materials. II—Effect of Cyclic Thermal Stressing on the Stress-Rupture Life and Ductility of S–816 and Inconel 550. By Francis J. Clauss and James W. Freeman.

4166. An Experimental and Theoretical Study of the Effect of Fuel on Pitching-Translation Flutter. By John L. Sewall.

4167. A Rapid Method for Predicting Attached-Shock Shape. By Eugene S. Love and Ronald H. Long.

4168. A Method for Calculation of Hydrodynamic Lift for Submerged and Planing Rectangular Lifting Surfaces. By Kenneth L. Wadlin and Kenneth W. Christopher.

4169. Atmospheric Temperature Observations to 100,000 Feet for Several Climatological Regions of the Northern Hemisphere. By H. B. Tolefson.

4170. A Reexamination of the Use of Simple Concepts for Predicting the Shape and Location of Detached Shock Waves. By Eugene S. Love.

4171. Some Ground Measurements of the Forces Applied by Pilots to a Side-Located Aircraft Controller. By Roy F. Brissenden.

4172. Noise Survey Under Static Conditions of a Turbine-Driven Full-Scale Modified Supersonic Propeller With an Advance Ratio of 3.2. By Max C. Kurbjun.

4173. An Analytical Investigation of the Gust-Alleviating Properties of a Simple Pitch Damper. By Norman L. Crabill.

4174. Wind-Tunnel Investigation of the Static Lateral Stability Characteristics of Wing-Fuselage Combinations at High Subsonic Speeds. Taper-Ratio Series. By James W. Wiggins and Paul G. Fournier.

4175. Investigation of Deflectors as Gust Alleviators on a 0.09-Scale Model of the Bell X–5 Airplane With Various Wing Sweep Angles From 20° to 60° at Mach Numbers From 0.40 to 0.90. By Delwin R. Croom and Jarrett K. Huffman.

4176. Effect of Flow Incidence and Reynolds Number on Low-Speed Aerodynamic Characteristics of Several Noncircular Cylinders With Applications to Directional Stability and Spinning. By Edward C. Polhamus.

4177. Wind-Tunnel Investigation of the Static Longitudinal Stability and Trim Characteristics of a Sweptback-Wing Jet-Transport Model Equipped With an External-Flow Jet-Augmented Flap. By Joseph L. Johnson, Jr.

4178. Low-Speed Cascade Investigation of Compressor Blades Having Loaded Leading Edges. By James C. Emery.

4179. Analytical Investigation of Acceleration Restriction in a Fighter Airplane With an Automatic Control System. By James T. Matthews, Jr.

4180. Investigation of Spoilers at a Mach Number of 1.93 to Determine the Effects of Height and Chordwise Location on the Section Aerodynamic Characteristics of a Two-Dimensional Wing. By James N. Mueller.

4181. Investigation of the Effects of Propeller Diameter on the Ability of a Flapped Wing, With and Without Boundary-Layer Control, To Deflect a Propeller Slipstream Downward for Vertical Take-Off. By Kenneth P. Spreemann.

4182. Physical Characteristics and Test Conditions of an Ethylene-Heated High-Temperature Jet. By Roland D. English, Abraham Spinak, and Eldred H. Helton.

4183. Investigation of Effects of Distributed Surface Roughness on a Turbulent Boundary Layer Over a Body of Revolution at a Mach Number of 2.01. By John R. Sevier, Jr., and K. R. Czarnecki.

4184. Measurement of Static Pressure on Aircraft. By William H. Gracey.

4185. Wind-Tunnel Investigation of Effect of Sweep on Rolling Derivatives at Angles of Attack up to 13° and at High Subsonic Mach Numbers, Including a Semiempirical Method of Estimating the Rolling Derivatives. By James W. Wiggins.

4186. Heat Transfer in Isotropic Turbulence During the Final Period of Decay. By D. W. Dunn and W. H. Reid.

4187. High-Speed Hydrodynamic Characteristics of a Flat Plate and 20° Dead-Rise Surface in Unsymmetrical Planing Conditions. By Daniel Savitsky, R. E. Prowse, and D. H. Lueders.

4188. Charts Relating the Compressive and Shear Buckling Stresses of Longitudinally Supported Plates to the Effective Deflectional Stiffness of the Supports. By Aldie E. Johnson, Jr.

4189. Lift and Moment on Thin Arrowhead Wings With Supersonic Edges Oscillating in Symmetric Flapping and Roll and Application to the Flutter of an All-Movable Control Surface. By H. J. Cunningham.

4190. Experimental Investigation of the Lateral Trim of a Wing-Propeller Combination at Angles of Attack up to 90° With All Propellers Turning in the Same Direction. By William A. Newsom, Jr.

4191. Analysis of Horizontal-Tail Loads in Pitching Maneuvers on a Flexible Swept-Wing Jet Bomber. By William S. Aiken, Jr.

4192. Three-Degree-of-Freedom Evaluation of the Longitudinal Transfer Functions of a Supersonic Canard Missile Configuration Including Changes in Forward Speed. By Ernest C. Seaberg.

4193. Subsonic Flight Investigation of Methods To Improve the Damping of Lateral Oscillations by Means of a Viscous Damper in the Rudder System in Conjunction With Adjusted Hinge-Moment Parameters. By Harold L. Crane, George J. Hurt, Jr., and John M. Elliott.

4194. Comparison of Hydrodynamic-Impact Acceleration and Response for Systems With Single and With Multiple Elastic Modes. By Robert W. Miller.

4195. Shape of Initial Portion of Boundary of Supersonic Axisymmetric Free Jets at Large Jet Pressure Ratios. By Eugene S. Love and Louise P. Lee.

4196. A Method for the Calculation of the Lateral Response of Airplanes to Random Turbulence. By John M. Eggleston and William H. Phillips.

4197. Summary of Flutter Experiences as a Guide to the Preliminary Design of Lifting Surfaces on Missiles. By Dennis J. Martin.

4198. Effects of Airplane Flexibility on Wing Strains in Rough Air at 35,000 Feet as Determined by a Flight Investigation of a Large Swept-Wing Airplane. By Richard H. Rhyne.

4199. A Flight Investigation of the Effects of Varied Lateral Damping on the Effectiveness of a Fighter Airplane as a Gun Platform. By Helmut A. Kuehnel, Arnold R. Beckhardt, and Robert A. Champine.

4200. Effectiveness of Boundary-Layer Control, Obtained by Blowing Over a Plain Rear Flap in Combination With a Forward Slotted Flap, in Deflecting A Slipstream Downward for Vertical Take-Off. By Kenneth P. Spreemann.

4201. Collection of Zero-Lift Drag Data on Bodies of Revolution From Free-Flight Investigations. By William E. Stoney, Jr.

4202. Qualitative Simulator Study of Longitudinal Stick Forces and Displacements Desirable During Tracking. By Stanley Faber.

4203. Flight Investigation of Effects of Atmospheric Turbulence and Moderate Maneuvers on Bending and Torsional Moments Encountered by a Helicopter Rotor Blade. By LeRoy H. Ludi.

4204. Compilation of Information on the Transonic Attachment of Flows at the Leading Edges of Airfoils. By Walter F. Lindsey and Emma Jean Landrum.

4205. Transient Heating Effects on the Bending Strength of Integral Aluminum-Alloy Box Beams. By Richard A. Pride and John B. Hall, Jr.

4206. Measurements of Total Hemispherical Emissivity of Various Oxidized Metals at High Temperature. By William R. Wade.

4207. Effect of a Stringer on the Stress Concentration Due to a Crack in a Thin Sheet. By J. Lyell Sanders, Jr.

4208. Turbulent Boundary Layer on a Yawed Cone in a Supersonic Stream. By Willis H. Braun.

4209. Experimental Thermal Conductivities of the $N_2O_4 \rightleftarrows 2NO_2$ System. By Kenneth P. Coffin and Cleveland O'Neal, Jr.

4210. Stability of Propane-Air Flames in Vortex Flow. By A. E. Potter, Jr., E. L. Wong, and A. L. Berlad.

4211. Friction Studies of Various Materials in Liquid Nitrogen. By D. W. Wisander, W. F. Hady, and R. L. Johnson.

4212. Central Automatic Data Processing System. By the Staff of the Lewis Laboratory.

4213. Recovery Temperatures and Heat Transfer Near Two-Dimensional Roughness Elements at Mach 3.1. By Paul F. Brinich.

4214. Boundary-Layer Transition on an Open-Nose Cone at Mach 3.1. By Paul F. Brinich.

4215. Application of a High-Temperature Static Strain Gage to the Measurement of Thermal Stresses in a Turbine Stator Vane. By R. H. Kemp, C. R. Morse, and M. H. Hirschberg.

4216. Effect of Fiber Orientation in Races and Balls Under Rolling-Contact Fatigue Conditions. By Thomas L. Carter.

4217. Effect of Jet Temperature on Jet-Noise Generation. By Vern G. Rollin.

4218. Analysis of Stresses and Deflections in a Disk Subjected to Gyroscopic Forces. By M. H. Hirschberg and A. Mendelson.

4219. Propellant Vaporization as a Criterion for Rocket Engine Design; Relation Between Percentage of Propellant Vaporized and Engine Performance. By Marcus F. Heidman and Richard J. Priem.

4220. A Flight Evaluation and Analysis of the Effect of Icing Conditions on the ZPG–2 Airship. By William Lewis and Porter J. Perkins, Jr.

4221. Turbulent Flow Through Porous Resistances Slightly Inclined to the Flow Direction. By Albert L. Loeffler, Jr., and Morris Perlmutter.

4222. Drop-Size Distributions for Impinging-Jet Breakup in Airstream Simulating the Velocity Conditions in Rocket Combustors. By Robert D. Ingebo.

4223. Relation of Journal Bearing Performance to Minimum Oil-Film Thickness. By F. W. Ocvirk and G. B. DuBois.

4224. Effect of Overheating on Creep-Rupture Properties of M–252 Alloy. By John P. Rowe and J. W. Freeman.

4225. Internal-Friction Study of Aluminum Alloy Containing 4 Weight Percent Copper. By B. S. Berry and A. S. Nowick.

4226. Analysis of Harmonic Forces Produced at Hub by Imbalance in Helicopter Rotor Blades. By M. Morduchow and A. Muzyka.

4227. Drag Minimization for Wings in Supersonic Flow, With Various Constraints. By Max A. Heaslet and Franklyn B. Fuller.

4228. Effects of Fixing Boundary-Layer Transition for an Unswept-Wing Model and an Evaluation of Porous Tunnel-Wall Interference for Mach Numbers From 0.60 to 1.40. By Louis S. Stivers, Jr., and Garth W. Lippmann.

4229. Stagnation-Point Heat Transfer to Blunt Shapes in Hypersonic Flight, Including Effects of Yaw. By A. J. Eggers, Jr., C. Frederick Hansen, and Bernard E. Cunningham.

4230. Prandtl-Meyer Expansion of Chemically Reacting Gases in Local Chemical and Thermodynamic Equilibrium By Steve P. Heims.

4231. Skin-Friction Measurements in Incompressible Flow. By Donald W. Smith and John H. Walker.

4232. A Method for the Calculation of Wave Drag on Supersonic-Edged Wings and Biplanes. By Harvard Lomax and Loma Sluder.

4233. Experimental Study of the Equivalence of Transonic Flow About Slender Cone-Cylinders of Circular And Elliptic Cross Section. By William A. Page.

4234. Pressure Distributions at Transonic Speeds for Parabolic-Arc Bodies of Revolution Having Fineness Ratios of 10, 12, and 14. By Robert A. Taylor and John B. McDevitt.

4235. Observations of Turbulent-Burst Geometry and Growth in Supersonic Flow. By Carlton S. James.

4236. Effects of Mach Number and Wall-Temperature Ratio on Turbulent Heat Transfer at Mach Numbers From 3 to 5. By Thorval Tendeland.

4237. General Instability of Stiffened Cylinders. By Herbert Becker.

4238. Normal Component of Induced Velocity for Entire Field of a Uniformly Loaded Lifting Rotor With Highly Swept Wake as Determined by Electromagnetic Analog. By Walter Castles, Jr., Howard L. Durham, Jr., and Jirair Kevorkian.

4239. Experimental Investigation of the Drag of Flat Plates and Cylinders in the Slipstream of a Hovering Rotor. By John W. McKee and Rodger L. Naeseth.

4240. Some Measurements of Aerodynamic Forces and Moments at Subsonic Speeds on a Rectangular Wing of Aspect Ratio 2 Oscillating About the Midchord. By Edward Widmayer, Jr., Sherman A. Clevenson, and Sumner A. Leadbetter.

4241. An Approximate Method for Design or Analysis of Two-Dimensional Subsonic-Flow Passages. By E. Floyd Valentine.

4242. General Solutions for Flow Past Slender Cambered Wings With Swept Trailing Edges and Calculation of Additional Loading Due to Control Surfaces. By E. B. Klunker and Keith C. Harder.

4243. An Experimental Study of the Turbulent Boundary Layer on a Shock-Tube Wall. By Paul B. Gooderum.

4244. On Solutions for the Transient Response of Beams. By Robert W. Leonard.

4245. Flutter Analysis of Rectangular Wings of Very Low Aspect Ratio. By Robert W. Fralich and John M. Hedgepeth.

4246. Further Investigation of Fatigue-Crack Propagation in Aluminum-Alloy Box Beams. By Herbert F. Hardrath and Herbert A. Leybold.

4247. Study of Ground-Reaction Forces Measured During Landing Impacts of a Large Airplane. By Albert W. Hall, Richard H. Sawyer, and James M. McKay.

4248. Summary of Experimental Heat-Transfer Measurements in Turbulent Flow for a Mach Number Range From 0.87 to 5.05. By Maurice J. Brevoort and Barbara D. Arabian.

4249. A Theoretical Analysis of the Effect of Engine Angular Momentum on Longitudinal and Directional Stability in Steady Rolling Maneuvers. By Ordway B. Gates, Jr., and C. H. Woodling.

4250. Effect of the Proximity of the Wing First-Bending Frequency and the Short-Period Frequency on the Airplane Dynamic-Response Factor. By Carl R. Huss and James J. Donegan.

4251. An Experimental Investigation of Wake Effects on Hydro-Skis. By Ellis E. McBride and Lloyd J. Fisher.

4252. Experimental Investigation of an Impulse-Type Supersonic Compressor Rotor Having a Turning of 73° at the Mean Radius. By James R. Sterrett.

4253. Design and Tests of a Six-Stage Axial-Flow Compressor Having a Tip Speed of 550 Feet per Second and a Flat Operating Characteristic at Constant Speed. By Willard R. Westphal and John W. Maynard, Jr.

4254. Flight Investigation of Effects of Retreating-Blade Stall on Bending and Torsional Moments Encountered by a Helicopter Rotor Blade. By LeRoy H. Ludi.

4255. Wind-Tunnel Investigation at Low Speeds of Flight Characteristics of a Sweptback-Wing Jet-Transport Airplane Model Equipped With an External-Flow Jet-Augmented Slotted Flap. By Joseph L. Johnson, Jr.

4256. Water-Impact Theory for Aircraft Equipped With Nontrimming Hydro-Skis Mounted on Shock Struts. By Emanuel Schnitzer.

4257. Results of an Experimental Investigation of Small Viscous Dampers. By Milton A. Silveira, Domenic J. Maglieri, and George W. Brooks.

4258. A Numerical Method for Evaluating Wave Drag. By Maurice S. Cahn and Walter B. Olstad.

4259. Temperature-Pressure-Time Relations in a Closed Cryogenic Container. By Sidney C. Huntley.

4260. Ground Reflection of Jet Noise. By Walton L. Howes.

4261. Acoustic, Thrust, and Drag Characteristics of Several Full-Scale Noise Suppressors for Turbojet Engines. By Carl C. Ciepluch, Warren J. North, Willard D. Coles, and Robert J. Antl.

4262. Analysis of Turbulent Flow and Heat Transfer on a Flat Plate at High Mach Numbers With Variable Fluid Properties. By R. G. Deissler and A. L. Loeffler, Jr.

4263. Effect of Prior Air Force Overtemperature Operation on Life of J47 Buckets Evaluated in a Sea-Level Cyclic Engine Test. By Robert A. Signorelli, James R. Johnston, and Floyd B. Garrett.

4264. Internal Characteristics and Performance of Several Jet Deflectors at Primary-Nozzle Pressure Ratios up to 3.0. By Jack G. McArdle.

4265. Composition and Thermodynamic Properties of Air in Chemical Equilibrium. By W. E. Moeckel and Kenneth C. Weston.

4266. Studies of OH, CO, CH, and C_2 Radiation From Laminar and Turbulent Propane-Air and Ethylene-Air Flames. By Thomas P. Clark.

4267. Preliminary Survey of Propulsion Using Chemical Energy Stored in the Upper Atmosphere. By Lionel V. Baldwin and Perry L. Blackshear.

4268. Droplet Impingement and Ingestion by Supersonic Nose Inlet in Subsonic Tunnel Conditions. By Thomas F. Gelder.

4269. Transonic Drag of Several Jet-Noise Suppressors. By Warren J. North.

4270. A Performance Analysis of Methods for Handling Excess Inlet Flow at Supersonic Speeds. By Donald P. Hearth and James F. Connors.

4271. Maximum Theoretical Tangential Velocity Component Possible From Straight-Back Converging and Converging-Diverging Stators at Supercritical Pressure Ratios. By Thomas P. Moffitt.

4272. Use of the Coanda Effect for Obtaining Jet Deflection and Lift With a Single Flat-Plate Deflection Surface. By Uwe H. von Glahn.

4273. On Pairs of Solutions of a Class of Internal Viscous Flow Problems With Body Forces. By Simon Ostrach and Lynn U. Albers.

4274. Measurement of the Effect of an Axial Magnetic Field on the Reynolds Number of Transition in Mercury Flowing Through a Glass Tube. By Michel Bader and William C. A. Carlson.

4275. Dynamic Stability of Vehicles Traversing Ascending or Descending Paths Through the Atmosphere. By Murray Tobak and H. Julian Allen.

4276. An Approximate Analytical Method for Studying Entry Into Planetary Atmospheres. By Dean R. Chapman.

4277. A Body Modification To Reduce Drag Due to Wedge Angle of Wing With Unswept Trailing Edge. By William C. Pitts and Jack N. Nielsen.

4278. Application of Statistical Theory to Beam-Rider Guidance in the Presence of Noise. II—Modified Wiener Filter Theory. By Elwood C. Stewart.

4279. Effects of Fixing Transition on the Transonic Aerodynamic Characteristics of a Wing-Body Configuration at Reynolds Numbers From 2.4 to 12 Million. By Lynn W. Hunton.

4280. Pressure Distributions at Transonic Speeds for Slender Bodies Having Various Axial Locations of Maximum Diameter. By John B. McDevitt and Robert A. Taylor.

4281. Second-Order Slender-Body Theory-Axisymmetric Flow. By Milton D. Van Dyke.

4282. Boundary-Layer Stability Diagrams for Electrically Conducting Fluids in the Presence of a Magnetic Field. By Vernon J. Rossow.

4283. Full-Scale Wind-Tunnel Tests of a 35° Sweptback-Wing Airplane With Blowing From the Shroud Ahead of the Trailing-Edge Flaps. By William H. Tolhurst, Jr.

4284. Cumulative Fatigue Damage at Elevated Temperature. By William K. Rey.

4285. Transgranular and Intergranular Fracture of Ingot Iron During Creep. By L. A. Shepard and W. H. Giedt.

4286. Mechanism of Beneficial Effects of Boron and Zirconium on Creep-Rupture Properties of a Complex Heat-Resistant Alloy. By R. F. Decker and J. W. Freeman.

4287. Relationship of Metal Surfaces to Heat-Aging Properties of Adhesive Bonds. By J. M. Black and R. F. Blomquist.

4288. Turbulence and Temperature Fluctuations Behind a Heated Grid. By R. R. Mills, Jr., A. L. Kistler, V. O'Brien, and S. Corrsin.

4289. Boundary-Induced Downwash Due to Lift in a Two-Dimensional Slotted Wind Tunnel. By S. Katzoff and Raymond L. Barger.

4290. A Fuselage Addition to Increase Drag-Rise Mach Number of Subsonic Airplanes at Lifting Conditions. By Richard T. Whitcomb.

4291. An Evaluation of Effects of Flexibility on Wing Strains in Rough Air for a Large Swept-Wing Airplane by Means of Experimentally Determined Frequency-Response Functions With an Assessment of Random-Process Techniques Employed. By Thomas L. Coleman, Harry Press, and May T. Meadows.

4292. Local Instability of the Elements of a Truss-Core Sandwich Plate. By Melvin S. Anderson.

4293. Special Bodies Added on a Wing To Reduce Shock-Induced Boundary-Layer Separation at High Subsonic Speeds. By Richard T. Whitcomb.

4294. Effects of Nose Shape and Spray Control Strips on Emergence and Planing Spray of Hydro-Ski Models. By John R. McGehee.

4295. Reflection and Transmission of Sound by a Slotted Wall Separating Two Moving Fluid Streams. By Raymond L. Barger.

4296. Compressive Strength and Creep of 17–7 PH Stainless-Steel Plates at Elevated Temperatures. By Bland A. Stein.

4297. Flight Investigation of the Acceptability of a Small Side-Located Controller Used With an Irreversible Hydraulic Control System. By Helmut A. Kuehnel and Robert W. Sommer.

4298. Exploratory Wind-Tunnel Investigation To Determine the Lift Effects of Blowing Over Flaps From Nacelles Mounted Above the Wing. By John M. Riebe and Edwin E. Davenport.

4299. Effects of Fabrication-Type Roughness on Turbulent Skin Friction at Supersonic Speeds. By K. R. Czarnecki, John R. Sevier, Jr., and Melvin M. Carmel.

4300. Heat-Transfer and Pressure Measurements on Flat-Faced Cylinders at a Mach Number of 2. By William E. Stoney, Jr., and J. Thomas Markley.

4301. Effects of Boundary-Layer Displacement and Leading-Edge Bluntness on Pressure Distribution, Skin Friction, and Heat Transfer of Bodies at Hypersonic Speeds. By Mitchel H. Bertram and Arthur Henderson, Jr.

4302. Analytical and Experimental Investigation of Aerodynamic Forces and Moments on Low-Aspect-Ratio Wings Undergoing Flapping Oscillations. By Donald S. Woolston, Sherman A. Clevenson, and Sumner A. Leadbetter.

4303. Measurements and Power Spectra of Runway Roughness at Airports in Countries of the North Atlantic Treaty Organization. By Wilbur E. Thompson.

4304. Matrix Method for Obtaining Spanwise Moments and Deflections of Torsionally Rigid Rotor Blades With Arbitrary Loadings. By Alton P. Mayo.

4305. Wind-Tunnel Investigation of Effects of Spoiler Location, Spoiler Size, and Fuselage Nose Shape on Directional Characteristics of a Model of a Tandem-Rotor Helicopter Fuselage. By James L. Williams.

4306. Temperature and Thermal-Stress Distributions in Some Structural Elements Heated at a Constant Rate. By William A. Brooks, Jr.

4307. Experimental Measurements of the Effects of Airplane Motions on Wing and Tail Angles of Attack of a Swept-Wing Bomber in Rough Air. By Jerome N. Engel.

4308. Transient Temperature Distribution in a Two-Component Semi-Infinite Composite Slab of Arbitrary Materials Subjected to Aerodynamic Heating With a Discontinuous Change in Equilibrium Temperature or Heat-Transfer Coefficient. By Robert L. Trimpi and Robert A. Jones.

4309. Use of Short Flat Vanes for Producing Efficient Wide-Angle Two-Dimensional Subsonic Diffusers. By D. L. Cochran and S. J. Kline.

4310. Measurements of the Motions of a Large Swept-Wing Airplane in Rough Air. By Richard H. Rhyne.

4311. Prandtl Number Effects on Unsteady Forced-Convection Heat Transfer. By E. M. Sparrow and J. L. Gregg.

4312. Internal Characteristics and Performance of an Aerodynamically Controlled, Variable-Discharge Convergent Nozzle. By Jack G. McArdle.

4313. Effect of Favorable Pressure Gradients on Transition for Several Bodies of Revolution at Mach 3.12. By John R. Jack.

4314. Icing Frequencies Experienced During Climb and Descent by Fighter-Interceptor Aircraft. By Porter J. Perkins.

4315. An Estimate of the Fluctuating Surface Pressures Encountered in the Reentry of a Ballistic Missile. By Edmund E. Callaghan.

4316. Friction and Wear With Reactive Gases at Temperatures up to 1200° F. By Gordon P. Allen, Donald H. Buckley, and Robert L. Johnson.

4317. Turbojet Engine Noise Reduction With Mixing Nozzle-Ejector Combinations. By Willard D. Coles, John A. Mihaloew, and Edmund E. Callaghan.

4318. Analytical Relation for Wake Momentum-Thickness and Diffusion Ratio for Low-Speed Compressor Cascade Blades. By Seymour Lieblein.

4319. On Fully Developed Channel Flows: Some Solutions and Limitations, and Effects of Compressibility, Variable Properties, and Body Forces. By Stephen H. Maslen.

4320. Compressible Laminar Flow and Heat Transfer About a Rotating Isothermal Disk. By Simon Ostrach and Philip R. Thornton.

4321. An Analytical Study of Turbulent and Molecular Mixing in Rocket Combustion. By David A. Bittker.

4322. Ordinates and Theoretical Pressure-Distribution Data for NACA 6- and 6A-Series Airfoil Sections With Thicknesses From 2 to 21 and 2 to 15 Percent Chord, Respectively. By Elizabeth W. Patterson and Albert L. Braslow.

4323. Natural Convection Inside a Flat Rotating Container. By Simon Ostrach and Willis H. Braun.

4324. Method for Determining the Need To Rework or Replace Compressor Rotor Blades Damaged by Foreign Objects. By Albert Kaufman.

4325. A Mach 4 Rocket-Powered Supersonic Tunnel Using Ammonia-Oxygen as Working Fluid. By Robert W. Graham, Eleanor Costilow Guentert, and Vearl N. Huff.

4326. Lightning Hazards to Aircraft Fuel Tanks. By J. D. Robb, E. L. Hill, M. M. Newman, and J. R. Stahmann.

4327. Hypersonic Viscous Flow Over Slender Cones. By Lawrence Talbot, Toyoki Koga, and Pauline M. Sherman.

4328. Study of Hydrogen Embrittlement of Iron by Internal-Friction Methods. By R. E. Maringer, E. B. Swetnam, L. L. Marsh, and G. K. Manning.

4329. Influence of Heat Treatment on Microstructure and High-Temperature Properties of a Nickel-Base Precipitation-Hardening Alloy. By R. F. Decker, John P. Rowe, W. C. Bigelow, and J. W. Freeman.

4330. Flow Induced by a Rotor in Power-on Vertical Descent. By Walter Castles, Jr.

4331. An Investigation of the Effects of Atmospheric Corrosion on the Fatigue Life of Aluminum Alloys. By Herbert A. Leybold, Herbert F. Hardrath, and Robert L. Moore.

4332. An Approach to the Problem of Estimating Severe and Repeated Gust Loads for Missile Operations. By Harry Press and Roy Steiner.

4333. Effect of Some External Crosswise Stiffeners on the Heat Transfer and Pressure Distribution on a Flat Plate at Mach Numbers of 0.77, 1.39, and 1.98. By Howard S. Carter.

4334. Lag in Pressure Systems at Extremely Low Pressures. By William T. Davis.

4335. Procedure for Calculating Flutter at High Supersonic Speed Including Camber Deflections, and Comparison With Experimental Results. By Homer G. Morgan, Vera Huckel, and Harry L. Runyan.

4336. Experimental Investigation of Axial and Normal Force Characteristics of Skewed Nozzles. By David J. Carter, Jr., and Allen R. Vick.

4337. An Investigation of Some Phenomena Relating to Aural Detection of Airplanes. By Harvey H. Hubbard and Domenic J. Maglieri.

4338. Graphs of Reduced Variables for Computing Histories of Vaporizing Fuel Drops, and Drop Histories Under Pressure. By G. L. Borman, M. M. El Wakil, O. A. Uyehara, and P. S. Myers.

4339. Hydrodynamic Impact Loads of a —20° Dead-Rise Inverted —V Model and Comparisons With Loads of a Flat-Bottom Model. By Philip M. Edge, Jr.

4340. Wind-Tunnel Investigation of the High-Subsonic Static Longitudinal Stability Characteristics of Several Wing-Body Configurations Designed for High Lift-Drag Ratios at a Mach Number of 1.4. By Paul G. Fournier.

4341. Low-Speed Experimental Determination of the Effects of Leading-Edge Radius and Profile Thickness on Static and Oscillatory Lateral Stability Derivatives for a Delta Wing with 60° of Leading-Edge Sweep. By Herman S. Fletcher.

4342. Flight Measurements of the Vibratory Bending and Torsional Stresses on a Modified Supersonic Propeller for Forward Mach Numbers up to 0.95. By Thomas C. O'Bryan.

4343. A Comparison of Two Methods for Calculating Transient Temperatures for Thick Walls. By James J. Buglia and Helen Brinkworth.

4344. Performance at Low Speeds of Compressor Rotors Having Low-Cambered NACA 65-Series Blades With High Inlet Angles and Low Solidities. By James C. Emery and Paul W. Howard.

4345. Similar Solutions for the Compressible Boundary Layer on a Yawed Cylinder With Transpiration Cooling. By Ivan E. Beckwith.

4346. Approximate Method for Calculating Motions in Angles of Attack and Sideslip Due to Step Pitching- and Yawing-Moment Inputs During Steady Roll. By Martin T. Moul and Teresa R. Brennan.

4347. A Nonlinear Theory for Predicting the Effects of Unsteady Laminar, Turbulent, or Transitional Boundary Layers on the Attenuation of Shock Waves in a Shock Tube With Experimental Comparison. By Robert L. Trimpi and Nathaniel B. Cohen.

4348. Effect of Temperature on Dynamic Modulus of Elasticity of Some Structural Alloys. By Louis F. Vosteen.

4349. Heat Transfer and Thermal Stresses in Sandwich Panels. By Robert T. Swann.

4350. Theoretical Distribution of Laminar-Boundary-Layer Thickness, Boundary-Layer Reynolds Number and Stability Limit, and Roughness Reynolds Number for a Sphere and Disk in Incompressible Flow. By Neal Tetervin.

4351. Summary of Methods of Measuring Angle of Attack on Aircraft. By William Gracey.

4352. Tables and Graphs of Normal-Shock Parameters at Hypersonic Mach Numbers and Selected Altitudes. By Paul W. Huber.

4353. Exploratory Wind-Tunnel Investigation at High Subsonic and Transonic Speeds of Jet Flaps on Unswept Rectangular Wings. By Vernard E. Lockwood and Raymond D. Vogler.

4354. Measurements in a Shock Tube of Heat Transfer Rates at the Stagnation Point of a 1.0-Inch-Diameter Sphere for Real-Gas Temperatures up to 7,900° R. By Alexander P. Sabol.

4355. Low Tip Mach Number Stall Characteristics and High Tip Mach Number Compressibility Effects on a Helicopter Rotor Having an NACA 0009 Tip Airfoil Section. By Robert D. Powell, Jr., and Paul J. Carpenter.

4356. Effects of Compressibility on Rotor Hovering Performance and Synthesized Blade-Section Characteristics Derived From Measured Rotor Performance of Blades Having NACA 0015 Airfoil Tip Sections. By James P. Shivers and Paul J. Carpenter.

4357. Lift and Profile-Drag Characteristics of an NACA 0012 Airfoil Section as Derived From Measured Helicopter-Rotor Hovering Performance. By Paul J. Carpenter.

4358. Supersonic Wave Interference Affecting Stability. By Eugene S. Love.

4359. A Review of the Thermodynamic, Transport, and Chemical Reaction Rate Properties of High-Temperature Air. By C. Frederick Hansen and Steve P. Heims.

4360. Measurements of the Effects of Wall Outflow and Porosity on Wave Attenuation in a Transonic Wind Tunnel With Perforated Walls. By Joseph M. Spiegel, Phillips J. Tunnell, and Warren S. Wilson.

4361. Idealized Wings and Wing-Bodies at a Mach Number of 3. By Elliott D. Katzen.

4362. Force and Pressure Measurements at Transonic Speeds for Several Bodies Having Elliptical Cross Sections. By John B. McDevitt and Robert A. Taylor.

4363. Simplified Method for Determination of Critical Height of Distributed Roughness Particles for Boundary-Layer Transition at Mach Numbers From 0 to 5. By Albert L. Braslow and Eugene C. Knox.

4364. An Investigation of Supersonic Turbulent Boundary Layers on Slender Bodies of Revolution in Free Flight by Use of a Mach-Zehnder Interferometer and Shadowgraphs. By Alvin Seiff and Barbara J. Short.

4365. Large-Scale Wind-Tunnel Tests of an Airplane Model With an Unswept, Aspect-Ratio-10 Wing, Two Propellers, and Area-Suction Flaps. By James A. Weiberg, Roy N. Griffin, Jr., and George L. Florman.

4366. The Effects of an Inverse-Taper Leading-Edge Flap on the Aerodynamic Characteristics in Pitch of a Wing-Body Combination Having an Aspect Ratio of 3 and 45° of Sweepback at Mach Numbers to 0.92. By Fred A. Demele and K. Harmon Powell.

4367. Wind-Tunnel Tests of a Full-Scale Helicopter Rotor With Symmetrical and With Cambered Blade Sections at Advance Ratios From 0.3 to 0.4. By John L. McCloud III and George B. McCullough.

4368. A Study of Several Theoretical Methods for Computing the Zero-Lift Wave Drag of a Family of Open-Nosed Bodies of Revolution in the Mach Number Range of 2.0 to 4.0. By Leroy L. Presley and Emmet A. Mossman.

4369. Slip-Flow Heat Transfer From Cylinders in Subsonic Airstreams. By Lionel V. Baldwin.

4370. Some Numerical Solutions of Similarity Equations for Three-Dimensional Laminar Incompressible Boundary-Layer Flows. By Peggy L. Yohner and Arthur G. Hansen.

4371. Some Observations Relating to Recovery of Internal Friction During Fatigue of Aluminum. By S. R. Valluri.

4372. Effect of Precipitate Particles on Creep of Aluminum-Copper Alloys During Age Hardening. By E. E. Underwood, L. L. Marsh, and G. K. Manning.

4373. Theoretical and Experimental Analysis of the Reduction of Rotor Blade Vibration in Turbomachinery Through the Use of Modified Stator Vane Spacing. By Richard

H. Kemp, Marvin H. Hirschberg, and William C. Morgan.

4374. Rate of Reaction of Gaseous Fluorine With Water Vapor at 35° C. By Vernon A. Slabey and Edward A. Fletcher.

4375. Approximate Solutions of a Class of Similarity Equations for Three-Dimensional, Laminar, Incompressible Boundary-Layer Flows. By Arthur G. Hansen and Howard Z. Herzig.

4376. Analytical and Experimental Investigation of Temperature Recovery Factors for Fully Developed Flow of Air in a Tube. By R. G. Deissler, W. F. Weiland, and W. H. Lowdermilk.

4377. Use of the Coanda Effect for Jet Deflection and Vertical Lift With Multiple-Flat-Plate and Curved-Plate Deflection Surfaces. By Uwe H. von Glahn and Thomas F. Gelder.

4378. Preliminary Heat-Transfer Studies on Two Bodies of Revolution at Angle of Attack at a Mach Number of 3.12. By Norman Sands and John R. Jack.

4379. Torque-Speed Characteristics for High-Specific-Work Turbines. By Warner L. Stewart.

4380. Approximate Method for Calculation of Laminar Boundary Layer With Heat Transfer on a Cone at Large Angle of Attack in Supersonic Flow. By William E. Brunk.

4381. Effect of Pressure and Duct Geometry on Bluff-Body Flame Stabilization. By Andrew E. Potter, Jr., and Edgar L. Wong.

4382. Investigation of Boiling Burnout and Flow Stability for Water Flowing in Tubes. By Warren H. Lowdermilk, Chester D. Lanzo, and Byron L. Siegel.

4383. A Cooled-Gas Pyrometer for Use in High-Temperature Gas Streams. By Lloyd N. Krause, Robert C. Johnson, and George E. Glawe.

4384. Analysis of Turbulent Flow and Heat Transfer in Noncircular Passages. By Robert G. Deissler and Maynard F. Taylor.

4385. Comparison of Shock-Expansion Theory With Experiment for the Lift, Drag, and Pitching-Moment Characteristics of Two Wing-Body Combinations at M=5.0. By Raymond C. Savin.

4386. An Analysis of Ramjet Engines Using Supersonic Combustion. By Richard J. Weber and John S. MacKay.

4387. Experimental Evaluation of Low-Band-Pass Landing-Gear Shock Absorber for Pulse Loadings. By Emanuel Schnitzer.

4388. Effects of Nose Angle and Mach Number on Transition on Cones at Supersonic Speeds. By K. R. Czarnecki and Mary W. Jackson.

4389. Effect of Advance Ratio on Flight Performance of a Modified Supersonic Propeller. By Jerome B. Hammack and Thomas C. O'Bryan.

4390. Effects of Frequency and Amplitude on the Yawing Derivatives of Triangular, Swept, and Unswept Wings and of a Triangular-Wing-Fuselage Combination With and Without a Triangular Tail Performing Sinusoidal Yawing Oscillations. By William Letko and Herman S. Fletcher.

4391. Mass Transfer Cooling Near the Stagnation Point. By Leonard Roberts.

4392. A Theoretical Study of Stagnation-Point Ablation. By Leonard Roberts.

4393. Some Static Longitudinal Stability Characteristics of an Overlapped-Type Tandem-Rotor Helicopter at Low Airspeeds. By Robert J. Tapscott.

4394. The Rate of Fatigue-Crack Propagation in Two Aluminum Alloys. By Arthur J. McEvily, Jr., and Walter Illg.

4395. Use of the Kernel Function in a Three-Dimensional Flutter Analysis With Application to a Flutter-Tested Delta-Wing Model. By Donald S. Woolston and John L. Sewell.

4396. A Phenomenological Theory for the Transient Creep of Metals at Elevated Temperatures. By Elbridge Z. Stowell.

4397. Static Longitudinal and Lateral Stability Characteristics at Low Speed of 60° Sweptback-Midwing Models Having Wings With an Aspect Ratio of 2, 4, or 6. By Walter D. Wolhart and David F. Thomas, Jr.

4398. Analysis of the Creep Behavior of a Square Plate Loaded in Edge Compression. By Harvey G. McComb, Jr.

4399. Relative Motion in the Terminal Phase of Interception of a Satellite or a Ballistic Missile. By Richard A. Hord.

4400. Measurements of Ground-Reaction Forces and Vertical Center-of-Gravity Accelerations of a Bomber Airplane Taxiing Over Obstacles. By James M. McKay, Richard H. Sawyer, and Albert W. Hall.

4401. Hydrodynamic Impact Loads on 30° and 60° V-Step Plan-Form Models With and Without Dead Rise. By Philip M. Edge, Jr., and Jean P. Mason.

4402. Measurements of Aerodynamic Forces and Moments at Subsonic Speeds on a Simplified T-Tail Oscillating in Yaw About the Fin Midchord. By Sherman A. Clevenson and Sumner A. Leadbetter.

4403. Tests of Ring-Stiffened Circular Cylinders Subjected to a Transverse Shear Load. By James P. Peterson and Richard G. Updegraff.

4404. Effects of Propeller Position and Overlap on the Slipstream Deflection Characteristics of a Wing-Propeller Configuration Equipped With a Sliding and Fowler Flap. By William C. Hayes, Jr., Richard E. Kuhn, and Irving R. Sherman.

4405. Free-Flight Investigation To Determine the Drag of Flat- and Vee-Windshield Canopies on a Parabolic Fuselage With and Without Transonic Indentation Between Mach Numbers of 0.75 and 1.35. By Walter L. Kouyoumjian and Sherwood Hoffman.

4406. Low Tire Friction and Cornering Forces on a Wet Surface. By Eziaslav N. Harrin.

4407. Effects of Ground Proximity on the Thrust of a Simple Downward-Directed Jet Beneath a Flat Surface. By Kenneth P. Spreemann and Irving R. Sherman.

4408. The Theory of Diffusion in Strained Systems. By Louis A. Girifalco and Hubert H. Grimes.

4409. Flight Measurements of the Vibration Experienced by a Tandem Helicopter in Transition, Vortex-Ring State, Landing Approach, and Yawed Flight. By John E. Yeates.

4410. Flight Measurements of the Vibratory Stresses on a Propeller Designed for an Advance Ratio of 4.0 and a Mach Number of 0.82. By Thomas C. O'Bryan.

TECHNICAL MEMORANDUMS [1]

1404. Investigation of Aperiodic Time Processes With Autocorrelation and Fourier Analysis. By Marie Luise Exner. From Acustica, v. 4, no. 3, 1954, p. 365–379.

[1] The missing numbers in the series of Technical Memorandums were released before or after the period covered by this report.

1407. Free Convection Under the Conditions of the Internal Problem. By G. A. Ostroumov. From Russian Book, 1952.

1408. The Principles of Turbulent Heat Transfer. By H. Reichardt. Translation from Archiv fur die gesamte Wärmetechnik, no. 6/7, 1951, p. 129–142.

1409. Reflection and Refraction of Acoustic Waves by a Shock Wave. By J. Brillouin. From Acustica, v. 5., no. 3, 1955, p. 149–163.

1410. Theory and Experiments on Supersonic Air-to-Air Ejectors. By J. Fabri and J. Paulon. From Office National d'Etudes et de Recherches Aéronautiques. Note Technique no. 36, 1956.

1411. Study of the Micro-Nonuniformity of the Plastic Deformation of Steel. By B. B. Chechulin. From Fizika Metallov i Metallovedenie, v. 1, no. 2, 1955, p. 251–260.

1412. Aerodynamic Forces on a Vibrating Unstaggered Cascade. By H. Söhngen. From Zeitschrift für angewandte Mathematik und Mechanik, v. 35, no. 3, March 1955, p. 81–88.

1413. Impact on a Compressible Fluid. By I. T. Egorov. From Prikladnaia Matematika i Mekhanika, v. 20, no. 1, 1956, p. 67–72.

1414. Aerodynamic Research on Fuselages With Rectangular Cross Section. By K. Maruhn. From Jahrbuch 1942 der deutschen Luftfahrtforschung, p. 263–279.

1417. On the Spectrum of Natural Oscillations of Two-Dimensional Laminar Flows. By D. Grohne. From Zeitschrift für angewandte Mathematik und Mechanik, v. 34, no. 8–9, Aug.–Sept. 1954, p. 344–357.

1418. The Interaction of a Reflected Shock Wave With the Boundary Layer in a Shock Tube. By Herman Mark.

1431. On the Statistical Theory of Turbulence. By W. Heisenberg. From Zeitschrift für Physik, v. 124, 1948, p. 628–657.

1432. Evaporation, Heat Transfer, and Velocity Distribution in Two-Dimensional and Rotationally Symmetrical Laminar Boundary-Layer Flow. By Nils Frössling. From Lunds Universitets Arsskrift, v. 36, no. 4. Kungl. Fysiografiska Sallskapets Handlingar, v. 51, no. 4, 1940.

1433. Stability of Cylindrical and Conical Shells of Circular Cross Section, With Simultaneous Action of Axial Compression and External Normal Pressure. By Kh. M. Mushtari and A. V. Sachenkov. From Prikladnaia Matematika i Mekhanika, v. 18, no. 6, Nov.–Dec. 1954, p. 667–674.

1434. Extreme Speeds and Thermodynamic States in Supersonic Flight. By Klaus Oswatitsch. From Zeitschrift für Flugwissenschaften, v. 4, no. 3/4, 1956, p. 95–108.

1435. Elliptic Functions and Integrals With Real Modulus in Fluid Mechanics. By Robert Legendre. From Office National d'Etudes et de Recherches Aéronautiques, Publication 71, 1954.

1436. Statistical Study of Turbulence—Spectral Functions and Correlation Coefficients. By Francois N. Frenkiel. From Office National d'Etudes et de Recherches Aéronautiques. Rapport Technique no. 34, 1948.

1437. On Possible Similarity Solutions for Three-Dimensional Incompressible Laminar Boundary-Layer Flows Over Developable Surfaces and With Proportional Mainstream Velocity Components. By Arthur G. Hansen, Case Institute of Technology.

1438. On the Flutter of Cylindrical Shells and Panels Moving in a Flow of Gas. By R. D. Stepanov. From Prikladnaia Matematika i Mekhanika, v. 21, no. 5, 1957, p. 644–657.

1439. Application of the Method of Coordinate Perturbation to Unsteady Duct Flow. By Seymour C. Himmel, Case Institute of Technology.

1440. The Turbulent Boundary Layer on a Rough Curvilinear Surface. By V. F. Droblenkov. From Akademiia Nauk SSSR, Izvestiia, Otdelenie Tekhnicheskikh Nauk, no. 8, 1955, p. 17–21.

1441. The Effect of Free-Stream Turbulence on Heat Transfer From a Flat Plate. By Sugao Sugawara, Takashi Sato, Hiroyasu Komatsu, and Hiroichi Osaka. From Journal of Japan Society of Mechanical Engineering, v. 19, no. 18, 1953, p. 18–25.

Part II—COMMITTEE ORGANIZATION AND MEMBERSHIP

The National Advisory Committee for Aeronautics was established by act of Congress approved March 3, 1915 (U.S. Code, title 50, sec. 151). The organic act as amended provided that the Committee be composed of 17 members appointed by the President, including two representatives each of the Department of the Air Force, the Department of the Navy, and the Civil Aeronautics Authority; one representative each of the Smithsonian Institution, the U.S. Weather Bureau, and the National Bureau of Standards; and "one Department of Defense representative who is acquainted with the needs of aeronautical research and development." The law further provided that the membership include seven members appointed for five-year terms from persons "acquainted with the needs of aeronautical science, either civil or military, or skilled in aeronautical engineering or its allied sciences." The representatives of the Government organizations were appointed without definite terms, and all members served as such without compensation.

In accordance with the regulations of the Committee as approved by the President, the chairman and vice chairman and the chairman and vice chairman of the Executive Committee were elected annually. The officers now serving, reelected at the annual meeting of the Committee October 10, 1957, are: Dr. James H. Doolittle, Chairman of the NACA and Chairman of the Executive Committee; Dr. Leonard Carmichael, Vice Chairman of the NACA; and Dr. Detlev W. Bronk, Vice Chairman of the Executive Committee.

The following changes in membership have taken place during the past year:

On October 22, 1957, President Eisenhower appointed Hon. Paul D. Foote, Assistant Secretary of Defense (Research and Engineering), as the Department of Defense representative on the Committee authorized in the law. He succeeded Hon. Clifford C. Furnas, whose membership on NACA was terminated February 15, 1957, as a result of his resignation as Assistant Secretary of Defense (Research and Development).

The NACA membership of Lt. Gen. Donald L. Putt, who had been serving as Deputy Chief of Staff, Development, of the Air Force, was automatically terminated June 30, 1958, on his retirement from the Air Force. He had been a member of NACA more than nine years, having been appointed March 22, 1949. Because of the legislation then pending in the Congress which would result in the termination of the existence of the NACA, the President did not appoint a successor to General Putt on the Committee. In the interim, Lt. Gen. Roscoe C. Wilson, USAF, General Putt's successor as Deputy Chief of Staff, Development, served as acting member of NACA.

Because of his detachment as Deputy Chief of Naval Operations (Air) and transfer to duty with the Atlantic Fleet, the membership of Vice Adm. William V. Davis, USN, on the NACA was terminated May 22, 1958. As in the case of General Putt, the President did not appoint a successor on the Committee, and in the meantime Vice Adm. Robert B. Pirie, USN, Admiral Davis' successor in his Navy post, served as acting NACA member.

Reference was made in the opening statement of this report to the National Aeronautics and Space Act of 1958 (Public Law 85–568), approved July 29, 1958. In accordance with that act, and by proclamation of the Administrator of the National Aeronautics and Space Administration which he has indicated he will publish in the Federal Register of September 30, 1958, the National Advisory Committee for Aeronautics will cease to exist at the close of business September 30, 1958. At that time all its functions, powers, duties, and obligations, and all real and personal property, personnel (other than members of the Committee), funds, and records will be transferred to the National Aeronautics and Space Administration. All memberships on the NACA will then be terminated.

The members of the National Advisory Committee for Aeronautics at the end of its existence, September 30, 1958, are as follows:

James H. Doolittle, Sc. D., Vice President, Shell Oil Co., Chairman.

Leonard Carmichael, Ph. D., Secretary, Smithsonian Institution, Vice Chairman.

Allen V. Astin, Ph. D., Director, National Bureau of Standards.

Preston R. Bassett, D. Sc.

Detlev W. Bronk, Ph. D., President, Rockefeller Institute for Medical Research.

Frederick C. Crawford, Sc. D., Chairman of the Board, Thompson Products, Inc.

Paul D. Foote, Ph. D., Assistant Secretary of Defense (Research and Engineering).

Wellington T. Hines, Rear Admiral, U.S. Navy, Deputy and Assistant Chief of the Bureau of Aeronautics.

Jerome C. Hunsaker, Sc. D., Massachusetts Institute of Technology.

Charles J. McCarthy, S.B., Chairman of the Board, Chance Vought Aircraft, Inc.

James T. Pyle, A.B., Administrator of Civil Aeronautics.

Francis W. Reichelderfer, Sc. D., Chief, U.S. Weather Bureau.

Edward V. Rickenbacker, Sc. D., Chairman of the Board, Eastern Air Lines, Inc.

Preceding Page Blank

Louis S. Rothschild, Ph. B., Under Secretary of Commerce for Transportation.
Thomas D. White, General, U.S. Air Force, Chief of Staff.

In its coordination of aeronautical research and the formulation of its research programs, the NACA has been assisted for a number of years by four main technical committees. Under each of these committees, subcommittees have been organized varying in number from three to eight, the total number in 1958 being 23. On February 26, 1958, the names of the four main technical committees, as well as those of certain subcommittees, were changed to indicate more definitely their cognizance of problems applicable to missiles and spacecraft as well as aircraft. The four main technical committees now are: Committee on Aircraft, Missile, and Spacecraft Aerodynamics (formerly Committee on Aerodynamics); Committee on Aircraft, Missile, and Spacecraft Propulsion (formerly Committee on Power Plants for Aircraft); Committee on Aircraft, Missile, and Spacecraft Construction (formerly Committee on Aircraft Construction); and Committee on Aircraft Operating Problems (formerly Committee on Operating Problems). Effective January 1, 1958, the Subcommittee on Icing Problems, formerly organized under the Committee on Operating Problems, was discontinued, since it was the opinion of the NACA that the demands for research in this field had decreased to such an extent that the maintenance of a separate subcommittee was not justified, and such research as was needed in this field could be conducted under the cognizance of the Subcommittee on Flight Safety and the Subcommittee on Meteorological Problems.

The NACA at its meeting on November 21, 1957, authorized the establishment of a Special Committee on Space Technology, to be composed of experts especially qualified in the field, to survey the whole problem of space technology from the point of view of needed research and development, and to make recommendations to the NACA. It was pointed out that, while the NACA already had a substantial effort on problems of flight beyond the earth's atmosphere, as exemplified by the X–15 research airplane being constructed by North American Aviation, Inc., as a joint Air Force-Navy-NACA project, and by its research program on ballistic missile problems, there was need for a review of the whole problem of space technology. The Special Committee on Space Technology was organized in January 1958 under the chairmanship of Dr. H. Guyford Stever, Associate Dean of Engineering of the Massachusetts Institute of Technology, and has been engaged in a survey of the entire field, with the aid of seven working groups established for study of the following areas: Space Research Objectives; Vehicular Program; Reentry; Range, Launch, and Tracking Facilities; Instrumentation; Space Surveillance; and Human Factors and Training. The report of the Special Committee on Space Technology will be completed in the near future.

The NACA has also been assisted since 1945 by an Industry Consulting Committee, whose function has been to advise the NACA as to general research policy and programs, especially with regard to the needs of industry.

At the final meeting of the National Advisory Committee for Aeronautics on August 21, 1958, the members of the Committee expressed the firm opinion that the advice and cooperation of NACA committees and subcommittees have been a highly significant factor in the effective discharge of the duties of NACA.

The Administrator of the National Aeronautics and Space Administration, Hon. T. Keith Glennan, has indicated that the proclamation which he will issue for publication in the Federal Register of September 30 will include a provision that the committees and subcommittees of the NACA are being reconstituted advisory committees to the NASA for the purpose of bringing their current work to orderly completion.

The membership of the committees and their subcommittees and working groups is as follows:

COMMITTEE ON AIRCRAFT, MISSILE, AND SPACECRAFT AERODYNAMICS

Mr. Preston R. Bassett, Chairman.
Dr. Theodore P. Wright, Vice President for Research, Cornell University, Vice Chairman.
Maj. Gen. Ralph P. Swofford, Jr., USAF, Assistant Deputy Chief of Staff, Development, U.S. Air Force.
Col. Randall D. Keator, USAF, Chief, Aircraft Laboratory, Wright Air Development Center.
Rear Adm. L. D. Coates, USN, Assistant Chief of the Bureau of Aeronautics for Research and Development, Department of the Navy.
Mr. Abraham Hyatt, Bureau of Aeronautics, Department of the Navy.
Capt. Robert L. Townsend, USN, Assistant Director, Research and Development Division, Bureau of Ordnance, Department of the Navy.
Maj. Gen. H. N. Toftoy, USA, Commanding General, Aberdeen Proving Ground.
Col. George P. Seneff, Jr., USA, Office of the Chief of Research and Development, Department of the Army.
Mr. Harold D. Hoekstra, Civil Aeronautics Administration.
Dr. Hugh L. Dryden (ex officio).
Mr. Floyd L. Thompson, NACA Langley Aeronautical Laboratory.
Mr. Russell G. Robinson, NACA Ames Aeronautical Laboratory.
Dr. Milton U. Clauser, Director, Aeronautical Research Laboratory, The Ramo-Wooldridge Corp.
Capt. W. S. Diehl, USN (Ret.).
Mr. Clarence L. Johnson, Vice President, Research and Development, Lockheed Aircraft Corp.
Dr. A. Kartveli, Vice President, Research and Development, Republic Aviation Corp.
Mr. Schuyler Kleinhans, Assistant Chief Engineer, Santa Monica Division, Douglas Aircraft Co., Inc.
Dr. Clark B. Millikan, Director, Daniel Guggenheim Aeronautical Laboratory, California Institute of Technology.

Mr. Kendall Perkins, Vice President, Engineering, McDonnell Aircraft Corp.
Mr. George S. Schairer, Director of Research, Seattle Division, Boeing Airplane Co.
Prof. William R. Sears, Cornell University.
Mr. R. C. Sebold, Vice President, Engineering, Convair, Division of General Dynamics Corp.
Mr. H. A. Storms, Jr., Chief Engineer, Los Angeles Division, North American Aviation, Inc.
Mr. George S. Trimble Jr., Vice President-Chief Engineer, The Martin Co.

Mr. Milton B. Ames, Jr., Secretary

Subcommittee on Fluid Mechanics

Prof. William R. Sears, Cornell University, Chairman.
Lt. Col. B. W. Marschner, USAF, Air Force Missile Development Center.
Mr. E. Haynes, Air Force Office of Scientific Research.
Dr. Frederick S. Sherman, Office of Naval Research, Department of the Navy.
Mr. John D. Nicolaides, Bureau of Ordnance, Department of the Navy.
Dr. Joseph Sternberg, Ballistic Research Laboratories, Aberdeen Proving Ground.
Dr. G. B. Schubauer, Chief, Fluid Mechanics Section, National Bureau of Standards.
Dr. Adolf Busemann, NACA Langley Aeronautical Laboratory.
Mr. Clinton E. Brown, NACA Langley Aeronautical Laboratory.
Dr. D. R. Chapman, NACA Ames Aeronautical Laboratory.
Mr. Robert T. Jones, NACA Ames Aeronautical Laboratory.
Dr. John C. Evvard, NACA Lewis Flight Propulsion Laboratory.
Dr. J. V. Charyk, Aeronutronic Systems, Inc.
Prof. Wallace D. Hayes, Princeton University.
Prof. Otto Laporte, University of Michigan.
Prof. Lester Lees, California Institute of Technology.
Prof. Hans W. Liepmann, California Institute of Technology.
Prof. C. C. Lin, Massachusetts Institute of Technology.
Prof. E. L. Resler, Jr., Cornell University.

Mr. Ernest O. Pearson, Jr., Secretary

Subcommittee on High-Speed Aerodynamics

Dr. Clark B. Millikan, Director, Daniel Guggenheim Aeronautical Laboratory, California Institute of Technology, Chairman.
Mr. Robert F. Robinson, Air Research and Development Command.
Mr. Oscar Seidman, Bureau of Aeronautics, Department of the Navy.
Dr. H. H. Kurzweg, Associate Technical Director for Aeroballistic Research, Naval Ordnance Laboratory.
Mr. C. L. Poor, Chief, Exterior Ballistics Laboratory, Ballistic Research Laboratories, Aberdeen Proving Ground.
Mr. John Stack, NACA Langley Aeronautical Laboratory.
Mr. H. Julian Allen, NACA Ames Aeronautical Laboratory.
Dr. Abe Silverstein, NACA Lewis Flight Propulsion Laboratory.
Mr. Walter C. Williams, NACA High-Speed Flight Station.
Mr. John R. Clark, Assistant Chief Engineer, Chance Vought Aircraft, Inc.
Mr. Alexander H. Flax, Vice President and Assistant Director, Technical, Cornell Aeronautical Laboratory, Inc.
Mr. L. P. Greene, Chief Aerodynamicist, North American Aviation, Inc.
Mr. R. P. Jackson, General Manager, Tactical Weapon Systems Division, Aeronutronic Systems, Inc.
Mr. C. J. Koch, Chief of Staff, Advanced Design, The Martin Co.
Mr. John G. Lee, Director of Research, United Aircraft Corp.
Dr. Albert E. Lombard, Jr., Director of Research, McDonnell Aircraft Corp.
Mr. Harlowe J. Longfelder, Systems Engineering Director, Boeing Airplane Co.
Prof. John R. Markham, Professor of Aeronautical Engineering, Massachusetts Institute of Technology.
Mr. W. F. Radcliffe, Chief of Aerophysics, Convair, Division of General Dynamics Corp.
Mr. Ronald Smelt, Director, New Design Office, Missile Systems Division, Lockheed Aircraft Corp.

Mr. Albert J. Evans, Secretary

Subcommittee on Aerodynamic Stability and Control

Capt. W. S. Diehl, USN (Ret.), Chairman.
Mr. Melvin Shorr, Wright Air Development Center.
Mr. Jerome Teplitz, Bureau of Aeronautics, Department of the Navy.
Mr. Joseph E. Long, Bureau of Ordnance, Department of the Navy.
Mr. J. G. McHugh, Transportation Research and Engineering Command.
Mr. D. L. Baker, Civil Aeronautics Administration.
Mr. Charles J. Donlan, NACA Langley Aeronautical Laboratory.
Mr. Charles F. Hall, NACA Ames Aeronautical Laboratory.
Mr. Hubert M. Drake, NACA High-Speed Flight Station.
Mr. E. A. Bonney, Applied Physics Laboratory, The Johns Hopkins University.
Mr. W. O. Breuhaus, Cornell Aeronautical Laboratory, Inc.
Mr. Paul C. Emmons, Manager, Development Analysis, Bell Aircraft Corp.
Mr. J. E. Goode, Jr., Convair, Division of General Dynamics Corp., Fort Worth.
Mr. William T. Hamilton, Chief Aerodynamics Engineer, Boeing Airplane Co.
Mr. Maxwell W. Hunter, Chief Missiles Design Engineer, Douglas Aircraft Co., Inc.
Mr. R. B. Katkov, Northrop Aircraft, Inc.
Prof. E. E. Larrabee, Massachusetts Institute of Technology.
Mr. Conrad A. Lau, Chance Vought Aircraft, Inc.

Mr. Jack D. Brewer, Secretary

Subcommittee on Automatic Stabilization and Control

Mr. Warren E. Swanson, North American Aviation, Inc., Chairman.
Mr. George L. Yingling, Wright Air Development Center.
Dr. Gerhard W. Braun, Air Force Missile Development Center.
Mr. William Koven, Bureau of Aeronautics, Department of the Navy.
Mr. J. M. Lee, Bureau of Ordnance, Department of the Navy.
Mr. Karl L. Kocmanek, Signal Corps Engineering Laboratories.
Mr. Charles W. Mathews, NACA Langley Aeronautical Laboratory.
Mr. Harry J. Goett, NACA Ames Aeronautical Laboratory.
Mr. A. S. Boksenbom, NACA Lewis Flight Propulsion Laboratory.
Mr. Joseph Weil, NACA High-Speed Flight Station.
Mr. Frank Andrix, Director of Engineering, Avionics Division, Bell Aircraft Corp.
Mr. Frank A. Gaynor, Aeronautical and Ordnance Systems Division, General Electric Co.
Dr. William J. Jacobi, The Ramo-Wooldridge Corp.

Mr. Floyd E. Nixon, Manager, Systems Analysis Department, The Martin Co.
Mr. Louis A. Payne, Convair, Division of General Dynamics Corp.
Mr. Duncan Pitman, Missiles Division, Douglas Aircraft Co., Inc.
Dr. Allen E. Puckett, Associate Director, Systems Development Laboratories, Hughes Aircraft Co.
Mr. O. H. Schuck, Minneapolis-Honeywell Regulator Co.
Dr. Robert C. Seamans, Jr., RCA Airborne Systems Laboratory.
Mr. Bernard Maggin, Secretary

Subcommittee on Internal Flow

Dr. William J. O'Donnell, Chief, Engineering and Aircraft Missiles Division, Republic Aviation Corp., Chairman.
Mr. Frederick T. Rall, Jr., Wright Air Development Center.
Mr. Robert E. Roy, Wright Air Development Center.
Mr. R. T. Miller, Bureau of Aeronautics, Department of the Navy.
Dr. Thomas W. Williams, Office of Naval Research, Department of the Navy.
Mr. V. S. Kupelian, U.S. Naval Ordnance Experimental Unit.
Mr. John V. Becker, NACA Langley Aeronautical Laboratory.
Mr. Richard Scherrer, NACA Ames Aeronautical Laboratory.
Mr. DeMarquis D. Wyatt, NACA Lewis Flight Propulsion Laboratory.
Mr. Donald R. Bellman, NACA High-Speed Flight Station.
Mr. J. S. Alford, Aircraft Gas Turbine Division, General Electric Co.
Mr. Bernard F. Beckelman, Boeing Airplane Co.
Mr. John A. Drake, Director of Long-Range Planning and Research Programs, Marquardt Aircraft Co.
Mr. Harry Drell, Propulsion Department Manager, Lockheed Aircraft Corp.
Dr. Antonio Ferri, Head, Department of Aeronautical Engineering, Polytechnic Institute of Brooklyn.
Mr. Donald J. Jordan, Pratt & Whitney Aircraft, United Aircraft Corp.
Mr. Darrel B. Parke, McDonnell Aircraft Corp.
Mr. M. A. Sulkin, Chief Thermodynamicist, North American Aviation, Inc.
Mr. Stafford W. Wilbur, Secretary

Subcommittee on Low-Speed Aerodynamics

Mr. R. Richard Heppe, Manager, Advanced Aerodynamics Research, Lockheed Aircraft Corp., Chairman.
Maj. E. B. Owens, USAF, Air Research and Development Command.
Mr. Harvey L. Anderson, Wright Air Development Center.
Mr. Gerald L. Desmond, Bureau of Aeronautics, Department of the Navy.
Maj. Darrell L. Ritter, USMC, Office of Naval Research, Department of the Navy.
Lt. Col. T. E. Haynes, USA, Office of the Chief of Research and Development, Department of the Army.
Mr. John Beebe, Office of the Chief of Transportation, Department of the Army.
Mr. C. W. Von Rosenberg, Chief, Flight Test Branch, Civil Aeronautics Administration.
Mr. Charles H. Zimmerman, NACA Langley Aeronautical Laboratory.
Mr. Charles W. Harper, NACA Ames Aeronautical Laboratory.
Mr. Jack Fischel, NACA High-Speed Flight Station.
Mr. M. M. Blair, North American Aviation, Inc., Columbus, Ohio.
Mr. James B. Edwards, Douglas Aircraft Co., Inc.
Mr. Robert A. Fuhrman, Missile Systems Division, Lockheed Aircraft Corp.
Mr. Robert L. Gustafson, Chief of Aerodynamics, Grumman Aircraft Engineering Corp.
Mr. D. H. Jacobson, Aeroproducts Operations, Allison Division, General Motors Corp.
Mr. Frank W. Kolk, American Airlines, Inc.
Mr. J. M. Mergen, Director of Engineering, Propeller Division, Curtiss-Wright Corp.
Mr. James A. O'Malley, Jr., Chief, Aerodynamic and Propulsion Design Department, Bell Aircraft Corp.
Dean Kenneth Razak, Dean, School of Engineering, University of Wichita.
Mr. W. Z. Stepniewski, Chief, Research and Development, Vertol Aircraft Corp.
Mr. Ralph W. May, Secretary

Subcommittee on Seaplanes

Rear Adm. R. S. Hatcher, USN (Ret.), Aerojet-General Corp., Chairman.
Capt. J. G. Ironmonger, USAF, Air Research and Development Command.
Mr. Eugene H. Handler, Bureau of Aeronautics, Department of the Navy.
Mr. F. W. S. Locke, Jr., Bureau of Aeronautics, Department of the Navy.
Mr. Phillip Eisenberg, Office of Naval Research, Department of the Navy.
Mr. M. St. Denis, David W. Taylor Model Basin.
Comdr. T. E. Maurer, USN, Naval Air Test Center, Patuxent.
Capt. R. R. Johnson, USCG, Western Area, U.S. Coast Guard.
Mr. William J. Husic, Civil Aeronautics Administration.
Mr. John B. Parkinson, NACA Langley Aeronautical Laboratory.
Mr. H. E. Brooke, Chief of Hydrodynamics, Convair, Division of General Dynamics Corp.
Mr. C. L. Fenn, Chief Engineer, Edo Corp.
Mr. Grover Loening.
Mr. J. D. Pierson, The Martin Co.
Mr. Daniel Savitsky, Stevens Institute of Technology.
Mr. Henry B. Suydam, Grumman Aircraft Engineering Corp.
Mr. Ralph W. May, Secretary

Subcommittee on Helicopters

Mr. L. L. Douglas, Vice President, Engineering, Vertol Aircraft Corp., Chairman.
Mr. Bernard Lindenbaum, Wright Air Development Center.
Mr. Paul A. Simmons, Jr., Wright Air Development Center.
Comdr. J. D. Kuser, USN, Bureau of Aeronautics, Department of the Navy.
Mr. T. L. Wilson, Office of Naval Research, Department of the Navy.
Lt. Col. Harry L. Bush, USA, Office of the Chief of Research and Development, Department of the Army.
Mr. L. J. Borges, Office of the Chief of Transportation, Department of the Army.
Capt. W. W. Vennel, USCG, Headquarters, U.S. Coast Guard.
Mr. Herbert M. Toomey, Civil Aeronautics Administration.
Mr. Richard C. Dingeldein, NACA Langley Aeronautical Labortary.
Mr. F. B. Gustafson, NACA Langley Aeronautical Laboratory.
Mr. Donald H. Wood, NACA Ames Aeronautical Laboratory.
Mr. Friedrich L. V. Doblhoff, Chief Engineer, Helicopter Engineering Division, McDonnell Aircraft Corp.

Mr. J. O. Emmerson, Vice President and Chief Engineer, The Kaman Aircraft Corp.
Mr. Jack E. Gallagher, Vice President, Operations, New York Airways, Inc.
Mr. Bartram Kelley, Vice President, Engineering, Bell Helicopter Corp.
Mr. Ralph B. Lightfoot, Chief Engineer, Sikorsky Aircraft, United Aircraft Corp.
Prof. R. H. Miller, Massachusetts Institute of Technology.
Mr. Charles M. Seibel, Chief Engineer, Helicopter Division, Cessna Aircraft Co.
Mr. Robert Wagner, Chief Engineer, Hiller Helicopters.
Mr. P. M. Lovell, Jr., Secretary

COMMITTEE ON AIRCRAFT, MISSILE, AND SPACECRAFT PROPULSION

Dr. Frederick C. Crawford, Chairman of the Board, Thompson Products, Inc., Chairman.
Dean C. R. Soderberg, Dean of Engineering, Massachusetts Institute of Technology, Vice Chairman.
Col. Donald H. Heaton, USAF, Directorate of Research and Development.
Col. John J. B. Calderbank, USAF, Wright Air Development Center.
Capt. Willoughby Mercer, USN, Bureau of Aeronautics, Department of the Navy.
Mr. W. R. Slivka, Aeronautical Turbine Laboratory, Naval Air Turbine Test Station.
Col. Chester W. Clark, USA, Office of the Chief of Ordnance, Department of the Army.
Mr. Donald D. Weidhuner, Office of the Chief of Transportation, Department of the Army.
Mr. Stephen H. Rolle, Chief, Power Plant Branch, Aircraft Engineering Division, Civil Aeronautics Administration.
Dr. Hugh L. Dryden (ex officio).
Dr. Abe Silverstein, NACA Lewis Flight Propulsion Laboratory.
Mr. J. P. Butterfield, Chief Engineer, Missile Operations Division, Chrysler Corp.
Dr. Alfred G. Cattaneo, Shell Development Co.
Mr. Allan Chilton, Director, Weapon Systems Planning Group, Westinghouse Electric Corp.
Mr. D. Cochran, General Manager, Flight Propulsion Laboratory Department, General Electric Co.
Dr. C. Stark Draper, Head, Department of Aeronautical Engineering, Massachusetts Institute of Technology.
Mr. Dimitrius Gerdan, Director of Engineering, Allison Division, General Motors Corp.
Mr. S. K. Hoffman, General Manager, Rocketdyne Division, North American Aviation, Inc.
Mr. Wright A. Parkins, Vice President, Engineering, United Aircraft Corp.
Mr. James A. Reid, Executive Vice President and General Manager, Astrodyne, Inc.
Mr. C. C. Ross, Vice President, Engineering, Aerojet-General Corp.
Mr. Rudolf H. Thielemann, Senior Metallurgist, Stanford Research Institute.
Mr. Don L. Walter, Vice President, Engineering, Marquardt Aircraft Co.
Mr. William H. Woodward, Secretary

Subcommittee on Fuels

Mr. James A. Reid, Executive Vice President and General Manager, Rocketdyne, Inc., Chairman.
Mr. Ben F. Wilkes, Directorate of Research and Development, U.S. Air Force,
Mr. Marc P. Dunnam, Wright Air Development Center.
Comdr. John C. Bangert, USN, Bureau of Aeronautics, Department of the Navy.
Mr. N. L. Klein, Office of the Chief of Ordnance, Department of the Army.
Mr. Ralph S. White, Civil Aeronautics Administration.
Mr. Henry C. Barnett, NACA Lewis Flight Propulsion Laboratory.
Mr. A. J. Blackwood, Esso Research & Engineering Co.
Mr. C. S. Brandt, Convair, Division of General Dynamics Corp.
Mr. J. L. Cooley, Vice President, California Research Corp.
Dr. Allen R. Deschere, Rohm & Haas Co.
Mr. F. G. Dougherty, Allison Division, General Motors Corp.
Mr. E. A. Droegemueller, Pratt & Whitney Aircraft, United Aircraft Corp.
Mr. John B. Duckworth, Research Coordinator, Standard Oil Co. (Indiana).
Mr. D. N. Harris, Shell Oil Co.
Mr. W. M. Holaday, Director of Guided Missiles, Department of Defense.
Dr. Bernard M. Sturgis, Director, Petroleum Laboratory, E. I. du Pont de Nemours & Co.
Dr. R. J. Thompson, Rocketdyne Division, North American Aviation, Inc.
Mr. Harold F. Hipsher, Secretary

Subcommittee on Combustion

Dr. Alfred G. Cattaneo, Shell Development Co., Chairman.
Mr. Howard P. Barfield, Wright Air Development Center.
Mr. Karl Scheller, Wright Air Development Center.
Mr. Nelson F. Rekos, Bureau of Aeronautics, Department of the Navy.
Mr. Alfred G. Lundquist, Office of Naval Research, Department of the Navy.
Dr. Martin Schilling, Redstone Arsenal.
Mr. F. R. Caldwell, National Bureau of Standards.
Dr. Walter T. Olson, NACA Lewis Flight Propulsion Laboratory.
Dr. W. H. Avery, Applied Physics Laboratory, The Johns Hopkins University.
Mr. William J. Bennet, Marquardt Aircraft Co.
Mr. Charles H. King, Jr., United Aircraft Corp.
Mr. Yuan C. Lee, Director of Research, Aerojet-General Corp.
Dr. Robert S. Levine, Rocketdyne Division, North American Aviation, Inc.
Dr. Bernard Lewis, Combustion & Explosives Research, Inc.
Dr. John P. Longwell, Esso Research & Engineering Co.
Dr. S. S. Penner, California Institute of Technology.
Prof. Glenn C. Williams, Massachusetts Institute of Technology.
Mr. L. M. Zubko, General Electric Co.
Mr. Harold F. Hipsher, Secretary

Subcommittee on Lubrication and Wear

Mr. Frank W. Wellons, Assistant Chief Engineer, SKF Industries, Inc., Chairman.
Mr. Bernard Rubin, Wright Air Development Center.
Mr. R. C. Sheard, Wright Air Development Center.
Mr. Sidney M. Collegeman, Bureau of Aeronautics, Department of the Navy.
Mr. R. E. Streets, Office of the Chief of Ordnance, Department of the Army.
Mr. Edmond E. Bisson, NACA Lewis Flight Propulsion Laboratory.

526597—60——7

Mr. G. J. Andreini, Pratt & Whitney Aircraft, United Aircraft Corp.
Dr. Merrell R. Fenske, Director, Petroleum Refining Laboratory, School of Chemistry and Physics, The Pennsylvania State University.
Mr. A. S. Irwin, Director of Research, Marlin-Rockwell Corp.
Dr. E. G. Jackson, Small Aircraft Engine Department, General Electric Co.
Dr. Robert G. Larsen, Research Director, Martinez Refinery, Shell Oil Co.
Dr. M. Eugene Merchant, Cincinnati Milling Machine Co.
Dr. W. H. Millett, Carbide & Carbon Chemicals Co.
Mr. D. H. Moreton, Douglas Aircraft Co.
Mr. Earle A. Ryder.
Mr. J. M. Stokely, California Research Corp.
Mr. George P. Townsend, Jr., Manager of Engineering, Sundstrand Turbo.
Mr. E. J. Zeilberger, Rocketdyne Division, North American Aviation, Inc.
Mr. Harold Hessing, Secretary

Subcommittee on Compressors and Turbines

Dr. George F. Wislicenus, Ordnance Research Laboratory, The Pennsylvania State University, Chairman.
Mr. Ernest C. Simpson, Wright Air Development Center.
Mr. H. D. Rochen, Bureau of Aeronautics, Department of the Navy.
Lt. Comdr. Frank T. Hemler, USN, Office of Naval Research, Department of the Navy.
Mr. Ambrose Ginsburg, NACA Lewis Flight Propulsion Laboratory.
Mr. Gordon Banerian, Manager, Turbo-Machinery Division, Aerojet-General Corp.
Mr. William G. Cornell, General Electric Co.
Prof. Howard W. Emmons, Harvard University.
Mr. John R. Foley, Pratt & Whitney Aircraft, United Aircraft Corp.
Mr. John E. Sanders, Curtiss-Wright Corp.
Dr. Alan H. Stenning, Assistant Professor of Mechanical Engineering, Massachusetts Institute of Technology.
Mr. M. A. Sulkin, Chief Thermodynamicist, North American Aviation, Inc.
Mr. Paul R. Vogt, Assistant Director of Engineering, Rocketdyne Division, North American Aviation, Inc.
Mr. David Novik, Secretary

Subcommittee on Engine Performance and Operation

Mr. Don L. Walter, Vice President, Engineering, Marquardt Aircraft Co., Chairman.
Lt. Col. H. W. Robbins, USAF, Air Research and Development Command.
Mr. Ewell C. Phillips, Wright Air Development Center.
Mr. A. S. Atkinson, Bureau of Aeronautics, Department of the Navy.
Col. William A. Tesch, Division of Reactor Development, Atomic Energy Commission.
Mr. E. J. Briggs, Civil Aeronautics Administration.
Mr. Bruce T. Lundin, NACA Lewis Flight Propulsion Laboratory.
Mr. Rudolph Bodemuller, Bendix Products Division, Bendix Aviation Corp.
Mr. Russell S. Hall, Allison Division, General Motors Corp.
Dr. Krafft A. Ehricke, Convair, Astronautics, Division of General Dynamics Corp.
Mr. R. D. Geckler, Vice President, Solid Rocket Plant, Aerojet-General Corp.
Mr. Elliott V. Mock, Boeing Airplane Co.
Mr. Perry W. Pratt, Vice President and Chief Scientist, United Aircraft Corp.
Mr. John F. Tormey, Director of Development, Astrodyne, Inc.
Mr. George S. Trimble, Jr., Vice President, Engineering, The Martin Co.
Mr. R. H. Widmer, Assistant Chief Engineer, Convair, Division of General Dynamics Corp., Fort Worth.
Mr. E. Woll, Manager, Engineering, Small Aircraft Engine Department, General Electric Co.
Mr. Lee R. Woodworth, Propulsion Research Corp.
Mr. James Lazar, Secretary

Subcommittee on Power Plant Controls

Dr. C. Stark Draper, Head, Department of Aeronautical Engineering, Massachusetts Institute of Technology, Chairman.
Mr. J. G. Barrett, Wright Air Development Center.
Mr. Robert R. Brown, Bureau of Aeronautics, Department of the Navy.
Dr. C. F. Bjork, Redstone Arsenal.
Mr. John C. Sanders, NACA Lewis Flight Propulsion Laboratory.
Dr. John L. Barnes, President, Systems Corp. of America.
Mr. Rudolph Bodemuller, Bendix Products Division, Bendix Aviation Corp.
Mr. R. T. Dungan, Marquardt Aircraft Co.
Mr. Harold E. Francis, Chief Project Engineer, Chandler-Evans Division, Pratt & Whitney Co., Inc.
Dr. Hans R. Friedrich, Convair, Astronautics, Division of General Dynamics Corp.
Dr. E. H. Gamble, General Electric Co.
Mr. William H. Hand, North American Aviation, Inc.
Mr. George F. Kinghorn, Missile Systems Division, Lockheed Aircraft Corp.
Mr. Bruce N. Torell, Pratt & Whitney Aircraft, United Aircraft Corp.
Dr. James W. Wheeler, Director, Instrument Engineering, Sperry Gyroscope Co., Division of Sperry Rand Corp.
Mr. David Novik, Secretary

Subcommittee on Power Plant Materials

Mr. Rudolf H. Thielemann, Senior Metallurgist, Stanford Research Institute, Chairman.
Lt. Col. R. W. Conners, USAF, Air Research and Development Command.
Mr. J. B. Johnson, Wright Air Development Center.
Mr. Nathan E. Promisel, Bureau of Aeronautics, Department of the Navy.
Mr. J. J. Harwood, Office of Naval Research, Department of the Navy.
Mr. Norman L. Reed, Watertown Arsenal.
Mr. S. S. Manson, NACA Lewis Flight Propulsion Laboratory.
Mr. W. L. Badger, Manager, Thomson Laboratory, Small Aircraft Engine Department, General Electric Co.
Mr. Lee S. Busch, Mallory-Sharon Titanium Corp.
Dr. F. N. Darmara, Utica Metals Division, Kelsey-Hayes Co.
Mr. Glenn A. Fritzlen, Technical Director, Development and Technical Services, Haynes Stellite Co.
Mr. L. L. Gilbert, Head, Materials Department, Azusa Operations, Aerojet-General Corp.
Prof. Nicholas J. Grant, Massachusetts Institute of Technology.

Mr. William D. Manly, Associate Director, Metallurgy Division, Oak Ridge National Laboratory, Union Carbide Corp.
Dr. Edward E. Reynolds, Assistant Director of Research, Allegheny Ludlum Steel Corp.
Mr. Francis M. Richmond, Manager of Materials Research, Universal Cyclops Steel Corp.
Mr. W. H. Sharp, Pratt & Whitney Aircraft, United Aircraft Corp.
Dr. E. N. Skinner, International Nickel Co.
Mr. Andrew G. Slachta, Wright Aeronautical Division, Curtiss-Wright Corp.

Mr. Harold Hessing, Secretary

Subcommittee on Rocket Engines

Mr. C. C. Ross, Vice President, Engineering, Aerojet-General Corp., Chairman.
Maj. William J. Henderson, USAF, Air Research and Development Command.
Lt. Col. L. F. Ayres, USAF, Ballistic Missile Division, Air Research and Development Command.
Mr. Oscar Bessio, Bureau of Aeronautics, Department of the Navy.
Mr. Frank I. Tanczos, Bureau of Ordnance, Department of the Navy.
Mr. James R. Patton, Office of Naval Research, Department of the Navy.
Mr. James E. Norman, Redstone Arsenal.
Col. J. L. Armstrong, Division of Reactor Development, Atomic Energy Commission.
Mr. John L. Sloop, NACA Lewis Flight Propulsion Laboratory.
Mr. John D. Alexander, Advanced Projects Engineer Manager, Pilotless Aircraft Division, Boeing Airplane Co.
Mr. Richard B. Canright, Advanced Research Projects Agency, Department of Defense.
Mr. Allen F. Donovan, The Ramo-Wooldridge Corp.
Dr. H. F. Dunholter, Chief Development Engineer, Convair, Astronautics, Division of General Dynamics Corp.
Mr. W. M. Hawkins, Missile Systems Division, Lockheed Aircraft Corp.
Dr. P. L. Nichols, Jr., Jet Propulsion Laboratory, California Institute of Technology.
Dr. H. W. Ritchey, Technical Director, Rocket Divisions, Thiokol Chemical Corp.
Mr. H. L. Thackwell, Jr., Vice President, Grand Central Rocket Co., Inc.
Mr. John F. Tormey, Director of Development, Astrodyne, Inc.
Mr. John R. Youngquist, Denver Division, The Martin Co.
Dr. Maurice J. Zucrow, Professor of Jet Propulsion, School of Mechanical Engineering, Purdue University.

Mr. Benson E. Gammon, Secretary

COMMITTEE ON AIRCRAFT, MISSILE, AND SPACECRAFT CONSTRUCTION

Mr. Charles J. McCarthy, Chairman of the Board, Chance Vought Aircraft, Inc., Chairman.
Mr. George Snyder, Engineering Manager, Pilotless Aircraft Division, Boeing Airplane Co., Vice Chairman.
Mr. Carl E. Reichert, Wright Air Development Center.
Comdr. G. S. Parrett, USN, Bureau of Aeronautics, Department of the Navy.
Mr. D. M. Thompson, Office of the Chief of Transportation, Department of the Army.
Mr. Albert A. Vollmecke, Civil Aeronautics Administration.
Dr. Hugh L. Dryden (ex officio).
Mr. Robert R. Gilruth, NACA Langley Aeronautical Laboratory.
Mr. John F. Parsons, NACA Ames Aeronautical Laboratory.
Prof. Raymond L. Bisplinghoff, Professor of Aeronautical Engineering, Massachusetts Institute of Technology.
Mr. Ralph B. Davidson, Director, Technical Support Division, Radioplane, Division of Northrop Aircraft, Inc.
Mr. Martin Goland, Director, Southwest Research Institute.
Dr. Nicholas J. Hoff, Head, Division of Aeronautical Engineering, Stanford University.
Mr. D. R. Kirk, Convair, Division of General Dynamics Corp., Fort Worth.
Mr. Jerome F. McBrearty, Assistant General Manager, California Division, Lockheed Aircraft Corp.
Dr. J. C. McDonald, Missile Systems Division, Lockheed Aircraft Corp.
Mr. Herman Pusin, Director of Engineering, Engineering Division, The Martin Co.
Mr. George D. Ray, Chief Engineer, Aircraft Division, Bell Aircraft Corp.
Mr. Richard L. Schleicher, Chief Structures Engineer, North American Aviation, Inc.
Mr. C. H. Stevenson, Douglas Aircraft Co., Inc.

Mr. Franklyn W. Phillips, Secretary

Subcommittee on Structures

Mr. C. H. Stevenson, Douglas Aircraft Co., Inc., Chairman.
Capt. W. T. McGinness, USAF, Air Research and Development Command.
Mr. William B. Miller, Wright Air Development Center.
Mr. Ralph L. Creel, Bureau of Aeronautics, Department of the Navy.
Mr. Emil A. H. Hellebrand, Army Ballistic Missile Agency.
Lt. Col. Richard L. Long, USA, Transportation Supply and Maintenance Command.
Mr. James E. Dougherty, Jr., Civil Aeronautics Administration.
Mr. Richard R. Heldenfels, NACA Langley Aeronautical Laboratory.
Mr. Glen Goodwin, NACA Ames Aeronautical Laboratory.
Mr. Lewis H. Abraham, Missiles Division, Douglas Aircraft Co., Inc.
Mr. George N. Mangurian, Chief Analytical Engineer, Northrop Aircraft, Inc.
Mr. William R. Micks, The Rand Corp.
Prof. Paul E. Sandorff, Massachusetts Institute of Technology.
Prof. E. E. Sechler, Professor of Aeronautics, California Institute of Technology.
Mr. Robert S. Shorey, Convair, Astronautics, Division of General Dynamics Corp.
Mr. Arne Sorensen, Boeing Airplane Co.
Mr. E. H. Spaulding, Chief Structures Engineer, Structural Engineering, Lockheed Aircraft Corp.
Mr. John E. Stevens, Chance Vought Aircraft, Inc.

Mr. Melvin G. Rosché, Secretary

Subcommittee on Loads

Mr. Ralph B. Davidson, Director, Technical Support Division, Radioplane, Division of Northrop Aircraft, Inc., Chairman.
Capt. Roy E. Hale, Jr., USAF, Air Research and Development Command.
Mr. Howard E. Kugel, Wright Air Development Center.
Mr. Clinton T. Newby, Bureau of Aeronautics, Department of the Navy.
Mr. John Beebe, Office of the Chief of Transportation, Department of the Army.

Mr. Charles R. Foster, Waterways Experiment Station, Corps of Engineers, U.S. Army.
Mr. Robert Rosenbaum, Civil Aeronautics Administration.
Mr. Philip Donely, NACA Langley Aeronautical Laboratory.
Mr. Manley J. Hood, NACA Ames Aeronautical Laboratory.
Mr. D. E. Beeler, NACA High-Speed Flight Station.
Mr. Albert Epstein, Republic Aviation Corp.
Mr. Robert Goldin, Chief Structural Design Engineer, Bell Aircraft Corp.
Mr. E. Z. Gray, Boeing Airplane Co.
Mr. H. J. Hoge, North American Aviation, Inc.
Mr. H. W. Huntley, Jr., North American Aviation, Inc., Downey.
Mr. Albert J. Kullas, Manager, Flight Vehicle Design Department, The Martin Co.
Mr. W. A. Stauffer, Lockheed Aircraft Corp.
Dr. Leo Stoolman, Head, Aerodynamics Department, Hughes Aircraft Co.
Mr. Yale Weisman, Convair, Division of General Dynamics Corp.

Mr. R. Fabian Goranson, Secretary

Subcommittee on Vibration and Flutter

Mr. Martin Goland, Director, Southwest Research Institute, Chairman.
Mr. Fred L. Daum, Wright Air Development Center.
Mr. W. J. Mykytow, Wright Air Development Center.
Mr. Douglas Michel, Bureau of Aeronautics, Department of the Navy.
Mr. Philipp W. Zettler-Seidel, Army Ballistic Missile Agency.
Maj. Walter B. Schlotterbeck, USA Transportation Research and Engineering Command.
Mr. Robert Rosenbaum, Civil Aeronautics Administration.
Mr. I. E. Garrick, NACA Langley Aeronautical Laboratory.
Mr. Albert Erickson, NACA Ames Aeronautical Laboratory.
Mr. André J. Meyer, Jr., NACA Lewis Flight Propulsion Laboratory.
Mr. Thomas F. Baker, NACA High-Speed Flight Station.
Mr. Walter E. Arnoldi, Hamilton Standard Div., United Aircraft Corp.
Prof. Holt Ashley, Massachusetts Institute of Technology.
Mr. Eugene F. Baird, Chief Flutter and Vibration Engineer, Grumman Aircraft Engineering Corp.
Mr. Michael Dublin, Chief of Dynamics, Convair, Division of General Dynamics Corp.
Mr. Warren T. Hunter, Chief, Automatic Control Section, Missile Engineering, Douglas Aircraft Co., Inc.
Mr. H. Clay Johnson, Jr., Configuration Manager, The Martin Co., Orlando.
Mr. William R. Laidlaw, North American Aviation, Inc., Columbus.
Mr. L. I. Mirowitz, McDonnell Aircraft Corp.
Mr. M. J. Turner, Unit Chief, Structural Dynamics, Seattle Division, Boeing Airplane Co.

Mr. Harvey H. Brown, Secretary

Subcommitee on Structural Materials

Dr. J. C. McDonald, Missile Systems Division, Lockheed Aircraft Corp., Chairman.
Maj. F. C. Krug, USAF, Air Research and Development Command.
Mr. J. B. Johnson, Wright Air Development Center.
Mr. Nathan E. Promisel, Bureau of Aeronautics, Department of the Navy.
Mr. Jerome Persh, Bureau of Ordnance, Department of the Navy.
Dr. W. H. Steurer, Redstone Arsenal.
Mr. George I. Schuck, Transportation Research and Engineering Command.
Dr. Gordon M. Kline, Chief, Organic and Fibrous Materials Division, National Bureau of Standards.
Mr. James E. Dougherty, Jr., Civil Aeronautics Administration.
Mr. Paul Kuhn, NACA Langley Aeronautical Laboratory.
Mr. G. Mervin Ault, NACA Lewis Flight Propulsion Laboratory.
Mr. Robert S. Ames, Goodyear Aircraft Corp.
Mr. Paul W. Boone, The Martin Co.
Mr. Harry A. Campbell, Bell Aircraft Corp.
Mr. Edgar H. Dix, Jr., Assistant Director of Research, Aluminum Co. of America.
Prof. Pol Duwez, California Institute of Technology.
Dr. Walter L. Finlay, Director of Research, Crucible Steel Co. of America.
Mr. L. R. Jackson, Assistant Director, Battelle Memorial Institute.
Mr. Peter Payson, Assistant Director of Research, Crucible Steel Co. of America.
Mr. M. J. Rudick, Chance Vought Aircraft, Inc.
Dr. George V. Smith, Professor of Metallurgical Engineering, Cornell University.
Mr. J. W. Sweet, Boeing Airplane Co.

Mr. R. H. Raring, Secretary

Committee on Aircraft Operating Problems

Capt. E. V. Rickenbacker, Chairman of the Board, Eastern Air Lines, Inc., Chairman.
Hon. James T. Pyle, Administrator of Civil Aeronautics, Vice Chairman.
Col. Joseph Davis, Jr., USAF, Wright Air Development Center.
Capt. J. R. Brown, USN, Bureau of Aeronautics, Department of the Navy.
Col. Hallett D. Edson, USA, Office of the Deputy Chief of Staff for Military Operations, Department of the Army.
Col. J. L. Marinelli, USA, President, U.S. Army Aviation Board.
Mr. William B. Davis, Deputy Administrator, Civil Aeronautics Administration.
Mr. Donald M. Stuart, Director, Technical Development Center, Civil Aeronautics Administration.
Dr. F. W. Reichelderfer (ex officio), Chief, U.S. Weather Bureau.
Dr. Hugh L. Dryden (ex officio).
Mr. Melvin N. Gough, NACA Langley Aeronautical Laboratory.
Mr. Lawrence A. Clousing, NACA Ames Aeronautical Laboratory.
Mr. Eugene J. Manganiello, NACA Lewis Flight Propulsion Laboratory.
Mr. Ralph L. Bayless, Chief Engineer, San Diego Division, Convair, Division of General Dynamics Corp.
Mr. M. G. Beard, Assistant Vice President, Equipment Research, American Airlines, Inc.
Mr. John G. Borger, Pan American World Airways System.
Mr. Warren T. Dickinson, Executive Engineer, Douglas Aircraft Co., Inc.
Mr. Charles Froesch, Vice President, Engineering, Eastern Air Lines, Inc.
Mr. M. Carl Haddon, Director, Marketing, California Division, Lockheed Aircraft Corp.
Mr. Raymond D. Kelly, Superintendent of Technical Development, United Air Lines, Inc.
Mr. Jerome Lederer, Managing Director, Flight Safety Foundation.
Mr. William Littlewood, Vice President, Equipment Research, American Airlines, Inc.

Mr. Maynard L. Pennell, Chief Engineer, Transport Division, Boeing Airplane Co.
Mr. Robert W. Rummel, Vice President, Engineering, Trans World Airlines, Inc.
Mr. Clarence N. Sayen, President, Air Line Pilots Association.
Mr. Arthur E. Smith, Assistant General Manager, Pratt & Whitney Aircraft, United Aircraft Corp.
Dr. T. L. K. Smull, Secretary

Subcommittee on Meteorological Problems

Dr. F. W. Reichelderfer, Chief, U.S. Weather Bureau, Chairman.
Mr. Edmund Bromley, Air Research and Development Command.
Capt. John F. Tatom, USN, Director, Naval Weather Service Division, Office of the Chief of Naval Operations.
Mrs. Frances L. Whedon, Office of the Chief Signal Officer, Department of the Army.
Dr. Harry Wexler, Director of Meteorological Research, U.S. Weather Bureau.
Mr. William R. Krieger, Civil Aeronautics Administration.
Mr. William L. Halnon, Civil Aeronautics Board.
Mr. Harry Press, NACA Langley Aeronautical Laboratory.
Mr. William Lewis, NACA Lewis Flight Propulsion Laboratory.
Dr. Horace R. Byers, Professor of Meteorology, The University of Chicago.
Mr. Carl F. Eck, Air Line Pilots Association.
Mr. Joseph J. George, Eastern Air Lines, Inc.
Dr. Ross Gunn.
Mr. Henry T. Harrison, Jr., Director, Meteorology, United Air Lines, Inc.
Prof. H. G. Houghton, Massachusetts Institute of Technology.
Mr. D. S. Little, Superintendent, Airway Aids and Electronics, American Airlines, Inc.
Mr. H. J. Reid, Manager, Flight Operations, Capital Airlines, Inc.
Dr. George F. Taylor, Missile Systems Division, Lockheed Aircraft Corp.
Mr. Frank C. White, Air Transport Association of America.
Mr. Mason T. Charak, Secretary

Subcommittee on Flight Safety

Mr. Charles Froesch, Vice President, Engineering, Eastern Air Lines, Inc., Chairman.
Dr. Albert W. Hetherington, Jr., Air Research and Development Command.
Col. John P. Stapp, USAF, Chief, Aero Medical Laboratory, Wright Air Development Center.
Mr. Sydney D. Berman, Office of the Inspector General, U.S. Air Force.
Capt. Elwin L. Farrington, USN, Director, Aviation Safety Division, Office of the Chief of Naval Operations.
Col. James F. Wells, USA, Director, U.S. Army Board for Aviation Accident Research.
Mr. W. H. Weeks, Chief, Aircraft Engineering Division, Civil Aeronautics Administration.
Hon. James T. Pyle (ex officio), Administrator of Civil Aeronautics.
Mr. Melvin N. Gough, NACA Langley Aeronautical Laboratory.
Mr. George E. Cooper, NACA Ames Aeronautical Laboratory.
Mr. I. Irving Pinkel, NACA Lewis Flight Propulsion Laboratory.
Mr. Joseph A. Walker, NACA High-Speed Flight Station.
Hon. Joseph P. Adams, Association of Local and Territorial Airlines.
Mr. Robert N. Buck, Trans World Airlines, Inc.
Mr. Carl M. Christenson, United Air Lines, Inc.
Mr. Allen W. Dallas, Director, Engineering Division, Air Transport Association of America.
Dr. Paul M. Fitts, Jr., Department of Psychology, University of Michigan.
Mr. Scott Flower, Pan American World Airways, Inc.
Mr. Dunstan Graham, Lear, Inc.
Mr. A. Howard Hasbrook, Director, Aviation Crash Injury Research of Cornell University.
Mr. Otto E. Kirchner, Sr., Operational Consultant, Transport Division, Boeing Airplane Co.
Mr. Jerome Lederer, Managing Director, Flight Safety Foundation.
Dr. Ross A. McFarland, Harvard School of Public Health.
Mr. William I. Stieglitz, Design Safety Engineer, Republic Aviation Corp.
Mr. R. L. Thoren, Chief Engineer, Flight Test, California Division, Lockheed Aircraft Corp.
Mr. H. H. Young, Flight Safety Engineer, Douglas Aircraft Co., Inc.
Mr. Boyd C. Myers II, Secretary

Subcommittee on Aircraft Noise

Mr. William Littlewood, Vice President, Equipment Research, American Airlines, Inc., Chairman.
Dr. H. O. Parrack, Wright Air Development Center.
Dr. H. E. von Gierke, Wright Air Development Center.
Comdr. B. K. Weaver, USN, Bureau of Aeronautics, Department of the Navy.
Mr. Joseph Matulaitis, Office of the Chief of Transportation, Department of the Army.
Mr. Stephen H. Rolle, Chief, Power Plant Branch, Aircraft Engineering Division, Civil Aeronautics Administration.
Mr. B. S. Spano, Civil Aeronautics Administration.
Mr. Arthur A. Regier, NACA Langley Aeronautical Laboratory.
Mr. Newell D. Sanders, NACA Lewis Flight Propulsion Laboratory.
Dr. Leo L. Beranek, President and Bolt, Beranek & Newman, Inc.
Mr. A. W. Cobb, Aerojet-General Corp.
Mr. Allen W. Dallas, Director, Engineering Division, Air Transport Association of America.
Mr. Harry H. Howell, Transport Division, Boeing Airplane Co.
Mr. E. J. Kirchman, The Martin Co.
Dr. Robert B. Lawhead, Rocketdyne Division, North American Aviation, Inc.
Prof. R. W. Leonard, University of California.
Mr. M. M. Miller, Chief, Acoustics Section, Douglas Aircraft Co., Inc.
Dr. Charles T. Molloy, Lockheed Aircraft Corp.
Mr. John M. Tyler, Pratt & Whitney Aircraft, United Aircraft Corp.
Dr. P. J. Westervelt, Assistant Professor, Department of Physics, Brown University.
Mr. J. F. Woodall, Convair, Division of General Dynamics Corp.
Mr. George P. Bates, Jr., Secretary

INDUSTRY CONSULTING COMMITTEE

Mr. J. L. Atwood, President, North American Aviation, Inc., Chairman.
Mr. M. P. Ferguson, President, Bendix Aviation Corp., Vice Chairman.
Mr. Harvey Gaylord, President, Bell Helicopter Corp.
Mr. William Littlewood, Vice President, Equipment Research, American Airlines, Inc.

Mr. J. S. McDonnell, President, McDonnell Aircraft Corp.
Mr. E. B. Newill, General Manager, Allison Division, General Motors Corp.
Dr. Arthur E. Raymond, Vice President, Engineering, Douglas Aircraft Co., Inc.
Mr. C. J. Reese, President, Continental Motors Corp.
Mr. Juan T. Trippe, President, Pan American World Airways, Inc.

Dr. T. L. K. Smull, Secretary

SPECIAL COMMITTEE ON SPACE TECHNOLOGY

Dr. H. Guyford Stever, Associate Dean of Engineering, Massachusetts Institute of Technology, Chairman.
Col. Norman C. Appold, USAF, Air Research and Development Command.
Mr. Abraham Hyatt, Bureau of Aeronautics, Department of the Navy.
Dr. Wernher von Braun, Army Ballistic Missile Agency.
Dr. Hugh L. Dryden (ex officio).
Mr. Robert R. Gilruth, NACA Langley Aeronautical Laboratory.
Mr. H. Julian Allen, NACA Ames Aeronautical Laboratory.
Dr. Abe Silverstein, NACA Lewis Flight Propulsion Laboratory.
Dr. Hendrik W. Bode, Vice President, Bell Telephone Laboratories, Inc.
Dr. Milton U. Clauser, Director, Aeronautical Research Laboratory, The Ramo-Wooldridge Corp.
Prof. Dale R. Corson, Cornell University.
Mr. J. R. Dempsey, Manager, Convair, Astronautics, Division of General Dynamics Corp.
Mr. S. K. Hoffman, General Manager, Rocketdyne Division, North American Aviation, Inc.
Dr. W. Randolph Lovelace II, Lovelace Foundation for Medical Education and Research.
Dr. W. H. Pickering, Director, Jet Propulsion Laboratory, California Institute of Technology.
Dr. Louis N. Ridenour, Assistant General Manager, Research and Development, Missile Systems Division, Lockheed Aircraft Corp.
Dr. J. A. Van Allen, State University of Iowa.

Mr. Carl B. Palmer, Secretary

Working Group on Space Research Objectives

Dr. J. A. Van Allen, State University of Iowa, Chairman.
Prof. Dale R. Corson, Cornell University, Vice Chairman.
Col. Norman C. Appold, USAF, Air Research and Development Command.
Mr. Robert Cornog, The Ramo-Wooldridge Corp.
Mr. Robert P. Haviland, Systems Planning Engineer, General Electric Co.
Dr. J. R. Pierce, Director of Research, Electrical Communications, Murray Hill Laboratory, Bell Telephone Laboratories, Inc.
Prof. Lyman Spitzer, Jr., Princeton University Observatory.

Mr. E. O. Pearson, Secretary

Working Group on Vehicular Program

Dr. Wernher von Braun, Director, Development Operations Division, Army Ballistic Missile Agency, Chairman.
Mr. S. K. Hoffman, General Manager, Rocketdyne Division, North American Aviation, Inc., Vice Chairman.
Col. Norman C. Appold, USAF, Air Research and Development Command.
Mr. Abraham Hyatt, Bureau of Aeronautics, Department of the Navy.
Dr. Louis N. Ridenour, Assistant General Manager, Research and Development, Missile Systems Division, Lockheed Aircraft Corp.
Dr. Abe Silverstein, NACA Lewis Flight Propulsion Laboratory.
Dr. Krafft A. Ehricke, Convair, Astronautics, Division of General Dynamics Corp.
Mr. M. W. Hunter, Chief Missiles Design Engineer, Douglas Aircraft Co., Inc.
Mr. C. C. Ross, Vice President, Engineering, Aerojet-General Corp.
Dr. Homer J. Stewart, Jet Propulsion Laboratory, California Institute of Technology.
Mr. George S. Trimble, Jr., Vice President, Engineering, The Martin Co.

Mr. William H. Woodward, Secretary

Working Group on Reentry

Dr. Milton U. Clauser, Director, Aeronautical Research Laboratory, The Ramo-Wooldridge Corp., Chairman.
Mr. H. Julian Allen, NACA Ames Aeronautical Laboratory, Vice Chairman.
Dr. Mac C. Adams, Deputy Director, Avco Research Laboratory, Avco Manufacturing Corp.
Dr. Alfred J. Eggers, Jr., NACA Ames Aeronautical Laboratory.
Mr. Maxime A. Faget, NACA Langley Aeronautical Laboratory.
Dr. A. H. Flax, Vice President and Assistant Director, Technical, Cornell Aeronautical Laboratory, Inc.
Prof. Lester Lees, Guggenheim Aeronautical Laboratory, California Institute of Technology.
Mr. Harlowe J. Longfelder, Systems Engineering Director, Boeing Airplane Co.
Dr. J. C. McDonald, Missile Systems Division, Lockheed Aircraft Corp.
Prof. S. A. Schaaf, University of California.
Col. John P. Stapp, USAF, Chief, Aero Medical Laboratory, Wright Air Development Center.

Mr. R. Fabian Goranson, Secretary

Working Group on Range, Launch, and Tracking Facilities

Mr. J. R. Dempsey, Manager, Convair, Astronautics, Division of General Dynamics Corp., Chairman.
Mr. Robert R. Gilruth, NACA Langley Aeronautical Laboratory, Vice Chairman.
Col. Paul T. Cooper, USAF, Deputy Commander, Range, Air Force Missile Test Center.
Mr. L. G. deBey, Chief, Electronic Measurements Branch, Ballistic Research Laboratories, Aberdeen Proving Ground.
Mr. Carl Ernest Duckett, Army Ballistic Missile Agency.
Comdr. Robert F. Freitag, USN, Naval Air Missile Test Center.
Prof. J. Allen Hynek, Astrophysical Observatory, Smithsonian Institution.
Mr. John T. Mengel, Naval Research Laboratory.
Mr. Grayson Merrill, General Manager, Fairchild Guided Missiles Division, Fairchild Engine & Airplane Corp.

Mr. Carl B. Palmer, Secretary

Working Group on Instrumentation

Dr. W. H. Pickering, Director, Jet Propulsion Laboratory, California Institute of Technology, Chairman.
Dr. Louis N. Ridenour, Assistant General Manager, Research and Development, Missile Systems Division, Lockheed Aircraft Corp., Vice Chairman.
Dr. Henrik W. Bode, Vice President, Bell Telephone Laboratories, Inc.

Mr. Robert W. Buchheim, The Rand Corp.
Mr. Harry J. Goett, NACA Ames Aeronautical Laboratory.
Dr. Albert C. Hall, Director of Engineering, Denver Division, The Martin Co.
Mr. Eberhardt Rechtin, Jet Propulsion Laboratory, California Institute of Technology.
Dr. William T. Russell, Space Technology Laboratories, Inc.
Dr. Robert C. Seamans, Jr., RCA Airborne Systems Laboratory.
Mr. Bernard Maggin, Secretary

Working Group on Space Surveillance

Dr. Hendrik W. Bode, Vice President, Bell Telephone Laboratories, Inc., Chairman.
Dr. W. H. Pickering, Director, Jet Propulsion Laboratory, California Institute of Technology, Vice Chairman.
Mr. Wilbur B. Davenport, Jr., Head, Communications and Components Division, Lincoln Laboratory, Massachusetts Institute of Technology.
Mr. W. B. Hebenstreit, Director, Special Programs, Space Technology Laboratories, Inc.
Mr. Richard S. Leghorn, ITEK Corp.
Mr. K. G. Macleish, Assistant Director, Research and Development Department, Apparatus and Optical Division, Eastman Kodak Co.
Dr. William B. McLean, Technical Director, U.S. Naval Ordnance Test Station.
Mr. A. H. Shapley, Boulder Laboratories, National Bureau of Standards.
Dr. Fred L. Whipple, Director, Astrophysical Observatory, Smithsonian Institution.
Mr. Carl B. Palmer, Secretary

Working Group on Human Factors and Training

Dr. W. Randolph Lovelace II, Lovelace Foundation for Medical Education and Research, Chairman.
Mr. A. Scott Crossfield, North American Aviation, Inc.
Mr. Hubert M. Drake, NACA High-Speed Flight Station.
Brig. Gen. Donald D. Flickinger, USAF (MC), Director of Human Factors and Staff Surgeon, Air Research and Development Command.
Col. Edward B. Giller, USAF, Deputy Commander for Special Projects, Air Force Special Weapons Center.
Dr. James D. Hardy, Medical Laboratory, U.S. Naval Air Development Center.
Mr. Wright Haskell Langham, Los Alamos Scientific Laboratory, University of California.
Dr. Ulrich C. Luft, Head, Physiology Department, Lovelace Foundation for Medical Education and Research.
Mr. Boyd C. Myers II, Secretary

Part III—FINANCIAL REPORT

Funds appropriated for the Committee for the fiscal years 1958 and 1959 and obligations against the fiscal year 1958 appropriations are as follows:

	Fiscal year 1958		Fiscal year 1959
	Allotments	Obligations	Allotments
SALARIES AND EXPENSES APPROPRIATION			
NACA Headquarters	$1, 971, 000	$1, 958, 201	$2, 083, 650
Langley Aeronautical Laboratory	28, 947, 150	28, 897, 306	30, 368, 000
Ames Aeronautical Laboratory	15, 194, 498	15, 149, 417	16, 380, 350
Lewis Flight Propulsion Laboratory	25, 221, 525	25, 192, 055	27, 538, 000
High-Speed Flight Station	2, 584, 527	2, 565, 353	2, 833, 100
Pilotless Aircraft Station	1, 750, 310	1, 743, 025	1, 179, 920
Western Coordination Office	40, 797	39, 170	49, 605
Wright-Patterson Liaison Office	19, 000	18, 782	21, 375
Research contracts with educational institutions	410, 000	410, 000	850, 000
Research contracts with Government agencies	90, 000	90, 000	150, 000
Cost of Federal Employees Salary Increase Act of 1958 included above	(1, 508, 807)	(1, 488, 719)	(3, 354, 000)
Unobligated balance	−152, 598	12, 900	
Total	[1] 76, 076, 209	76, 076, 209	[2] 81, 454, 000
CONSTRUCTION AND EQUIPMENT APPROPRIATION			
Langley Aeronautical Laboratory	11, 879, 000	3, 877, 606	11, 350, 000
Ames Aeronautical Laboratory	11, 355, 000	5, 162, 672	3, 720, 000
Lewis Flight Propulsion Laboratory	16, 406, 000	5, 269, 793	7, 800, 000
Pilotless Aircraft Station	1, 560, 000	580, 440	130, 000
Unobligated balance		[4] 26, 309, 489	
Total	[3] 41, 200, 000	41, 200, 000	[5] 23, 000, 000

[1] Appropriated in the Independent Offices Appropriation Act, 1958, approved June 29, 1957; the Second Supplemental Appropriation Act, 1958, approved Mar. 28, 1958; and Public Law 85-472, approved June 30, 1958.

[2] $78,100,000 appropriated in the Independent Offices Appropriation Act, 1959, approved Aug. 28, 1958; includes $3,454,000 to be submitted in a supplemental appropriation request to cover the fiscal year 1959 cost of the Federal Employees Salary Increase Act, 1958.

[3] Appropriated in the Independent Offices Appropriation Act, 1958, approved June 29, 1957; and the Second Supplemental Appropriation Act, 1958, approved Mar. 28, 1958.

[4] This balance remains available until expended.

[5] Appropriated in the Independent Offices Appropriation Act, 1959, approved Aug. 28, 1958.

Funds appropriated in the Supplemental Appropriation Act, 1959, approved August 27, 1958, for the National Aeronautics and Space Administration for the fiscal year 1959 are set forth below. Under authority of the National Aeronautics and Space Act of 1958, approved July 29, 1958, all balances of National Advisory Committee for Aeronautics funds were transferred to National Aeronautics and Space Administration accounts at the close of business September 30, 1958.

	Fiscal year 1959
Salaries and Expenses appropriation	$5, 000, 000
Research and Development appropriation	[1] 167, 000, 000
Construction and Equipment appropriation	25, 000, 000

[1] Includes funds in the amount of $117 million transferred from the Department of Defense.

Part IV—FINAL MEETING OF NACA

The final meeting of the National Advisory Committee for Aeronautics was held at 2 p.m., August 21, 1958, at its headquarters, 1512 H Street NW., Washington, D.C. Present at this meeting were:

James H. Doolittle, Sc. D., Vice President, Shell Oil Co., Chairman.
Leonard Carmichael, Ph. D., Secretary, Smithsonian Institution, Vice Chairman.
Allen V. Astin, Ph. D., Director, National Bureau of Standards.
Preston R. Bassett, Sc. D., retired.
Frederick C. Crawford, Sc. D., Chairman of the Board, Thompson Products Co., Inc.
Paul D. Foote, Ph. D., Assistant Secretary of Defense, Research and Engineering.
Wellington T. Hines, Rear Admiral, USN, Assistant Chief for Procurement, Bureau of Aeronautics, Navy.
Charles J. McCarthy, B.S., Chairman of the Board, Chance Vought Aircraft, Inc.
James T. Pyle, A.B., Administrator of Civil Aeronautics.
Francis W. Reichelderfer, Sc. D., Chief, U.S. Weather Bureau.
Louis S. Rothschild, Ph. B., Undersecretary of Commerce for Transportation.
Thomas D. White, General, U.S. Air Force, Chief of Staff.

And on invitation:

Vice Adm. Robert B. Pirie, USN, acting member.
Maj. Gen. Marvin C. Demler, USAF, representing Lt. Gen. Roscoe C. Wilson, acting member.

And:

Hugh L. Dryden, Director.
John F. Victory, Executive Secretary.
John W. Crowley, Jr., Associate Director for Research.

Also present on invitation of Chairman Doolittle was Dr. T. Keith Glennan, newly appointed Administrator of the National Aeronautics and Space Administration (NASA). The Chairman announced that Dr. Glennan and Dr. Hugh Dryden, Director of NACA, had been confirmed by the Senate and had taken their respective oaths of office as Administrator and Deputy Administrator of NASA at the White House in the presence of President Eisenhower on August 19.

The Chairman welcomed Dr. Glennan and expressed the best wishes of the NACA for complete success in his new duties.

Dr. Glennan said he recognized in some degree the kind of task he was undertaking, and that he thought it quite wonderful to have the NACA staff and organization as a base on which to build. He then exhibited and explained a draft chart of proposed organization based on plans developed by the NACA Headquarters staff, with some modifications. Especially important, he said, would be an Office of Program Planning and Evaluation, reporting to the Administrator and the Deputy Administrator, and cooperating with the National Aeronautics and Space Council in the development of national programs of aeronautical and space activities. Dr. Glennan said he would welcome the advice of members of NACA at any time.

Chairman Doolittle extended to Dr. Glennan the thanks, congratulations, and best wishes of the members of NACA. Dr. Glennan expressed his appreciation of the privilege of appearing before the Committee, and, with the applause of the members, withdrew.

National Aeronautics and Space Act of 1958

The Chairman reported that the National Aeronautics and Space Act of 1958 (Public Law 85–568), approved by the President July 29, 1958, established the National Aeronautics and Space Administration, headed by an Administrator appointed from civilian life by the President by and with the advice and consent of the Senate, with a Deputy Administrator appointed in the same manner.

The functions of the Administration provided by the act are—

1. To plan, direct, and conduct aeronautical and space activities, except activities peculiar to or primarily associated with the development of weapons systems, military operations, or the defense of the United States, which will be the responsibility of the Department of Defense.
2. To arrange for participation by the scientific community in planning scientific measurements and observations to be made through use of aeronautical and space vehicles, and conduct or arrange for the conduct of such measurements and observations.
3. To provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof.

In Section 301 of the act, it is provided:

> The National Advisory Committee for Aeronautics, on the effective date of this section, shall cease to exist. On such date all functions, powers, duties, and obligations, and all real and personal property, personnel (other than members of the Committee), funds, and records of that organization, shall be transferred to the Administration.
>
> This section shall take effect 90 days after the date of the enactment of this act, or on any earlier date on which the Administrator shall determine, and announce by proclamation

Final meeting of National Advisory Committee for Aeronautics, August 21, 1958. Around table clockwise: Hon. James T. Pyle, Administrator of Civil Aeronautics Dr. Hugh L. Dryden, Director, NACA; Mr. Preston R. Bassett; Hon. Louis S. Rothschild, Under Secretary of Commerce for Transportation; Dr. Leonard Carmichael, Secretary, Smithsonian Institution; Dr. James H. Doolittle, Chairman, NACA; Dr. John F. Victory, Executive Secretary, NACA; Dr. Francis W. Reichelderfer, Chief, U.S. Weather Bureau; Dr. Frederick C. Crawford, Chairman of the Board, Thompson Products, Inc.; Maj. Gen. Marvin C. Demler, USAF (attended in place of Lt. Gen. Roscoe C. Wilson, USAF, Deputy Chief of Staff, Development); General Thomas D. White, USAF, Chief of Staff, U.S. Air Force; Hon. Paul D. Foote, Assistant Secretary of Defense (Research and Engineering); Vice Admiral Robert B. Pirie, USN, Deputy Chief of Naval Operations (Air); Rear Admiral Wellington T. Hines, USN, Deputy and Assistant Chief, Bureau of Aeronautics; Mr. Charles J. McCarthy, Chairman of the Board, Chance Vought Aircraft, Inc.; and J. W. Crowley, Associate Director for Research, NACA.

published in the Federal Register, that the Administration has been organized and is prepared to discharge the duties and exercise the powers conferred upon it by this act.

(In accordance with the proclamation issued in accordance with the foregoing authority, the National Aeronautics and Space Administration became the legal successor to the National Advisory Committee for Aeronautics, effective as at the close of business September 30, 1958.)

Further provisions of the act include—

A declaration that it is the policy of the United States that activities in space should be devoted to peaceful purposes for the benefit of all mankind.

The establishment of a nine-member National Aeronautics and Space Council, to include the President, the Secretary of State, the Secretary of Defense, the Administrator of NASA, the Chairman of the Atomic Energy Commission, one additional member to be appointed by the President from Federal Agencies, and three other members to be appointed by the President from among individuals in private life who are eminent in science, engineering, technology, education, administration, or public affairs; the functions of the Council being to advise the President regarding policies, plans, programs, and accomplishments of United States agencies engaged in aeronautical and space activities, and the development of a comprehensive program.

NOTE.—The President on September 4 appointed as members of the Council: James H. Doolittle, Detlev W. Bronk, W. A. M. Burden, and Alan T. Waterman.

Provision for a Civilian-Military Liaison Committee, headed by a chairman to be appointed by the President, and including representatives of the Department of Defense and the Departments of the Army, Navy, and Air Force, and of the NASA.

STATEMENT BY THE PRESIDENT, JULY 29, 1958

I have today signed H.R. 12575, the National Aeronautics and Space Act of 1958.

The enactment of this legislation is a historic step, further equipping the United States for leadership in the space age. I wish to commend the Congress for the promptness with which it has created the organization and provided the authority needed for an effective national effort in the fields of aeronautics and space exploration.

The new act contains one provision that requires comment. Section 205 authorizes cooperation with other nations and groups of nations in work done pursuant to the act and in the peaceful application of the results of such work, pursuant to international agreements entered into by the President with the advice and consent of the Senate. I regard this section merely as recognizing that international treaties may be made in this field, and as not precluding, in appropriate cases, less formal arrangements for cooperation. To construe the section otherwise would raise substantial constitutional questions.

The present National Advisory Committee for Aeronautics (NACA), with its large and competent staff and well-equipped laboratories, will provide the nucleus for the NASA. The NACA has an established record of research performance and of cooperation with the armed services. The combination of space exploration responsibilities with the NACA's traditional aeronautical research functions is a natural evolution.

The enactment of the law establishing the NACA in 1915 proved a decisive step in the advancement of our civil and military aviation. The Aeronautics and Space Act of 1958 should have an even greater impact on our future.

After the Committee disposed of all business before it, including approval of its final statement to the Congress of the United States, submitting its 44th annual report, the following statements were made:

Undersecretary of Commerce Rothschild said that his 4 years of service as a member of the NACA had been a wonderful and illuminating experience and that it had been a great pleasure to serve with men of the caliber of NACA.

Gen. Thomas D. White, Chief of Staff, USAF, said that he would write a letter to the Chairman thanking the NACA for its support, cooperation, and assistance, virtually since the beginning of military aviation.

Vice Adm. Robert B. Pirie, DCNO (Air), expressed the same sentiments regarding the services rendered by the NACA to the Navy throughout the past 43 years.

Dr. Leonard Carmichael, Secretary, Smithsonian Institution, said that he was proud of the fact that the Smithsonian Institution, through its former Secretary, Dr. Charles D. Walcott, had been instrumental in the establishment of NACA and that all Secretaries of the Smithsonian since that time have served as members of NACA.

NOTE.—Dr. Walcott was the father of NACA, the first Chairman of its Executive Committee, 1915–19, and from 1919 until his death in 1927, chairman of the main committee.

Dr. Doolittle said it had been a great pleasure for him to serve with the other members for the past 10 years and thanked them for their cooperation and assistance during his chairmanship.

Dr. Victory said that the nameplate now on the back of each member's chair would be removed, suitably mounted, and transmitted to each member as a souvenir of his service with NACA.

At the conclusion of the brief meeting of the Committee held at the Ames Aeronautical Laboratory, Moffett Field, Calif., in connection with the triennial inspection of that Laboratory, July 14, 1958, the Executive Secretary, Dr. Victory, made a statement on behalf of the NACA staff, expressing appreciation of the leadership

of the members of NACA throughout its history. He was instructed to record that statement. It follows:

This may be the last meeting of the National Advisory Committee for Aeronautics which was established by law in 1915 to supervise and direct the scientific study of the problems of flight with a view to their practical solution. The great record of outstanding contributions to the progress of aeronautics made by the Committee, the members can always remember with pride and satisfaction.

On behalf of the entire staff of the organization, numbering about 7,800, I wish to express to the members of the Committee our profound sense of gratitude for the privilege and the honor that has been ours in working under the inspiring leadership of the members of the Committee and their illustrious chairmen throughout the life of the Committee. From their fine example and patriotic devotion to the cause of American supremacy in the air, from their vision and success in providing novel research facilities and ideal working conditions, we have drawn the inspiration and determination to do our best for the utmost advancement of aeronautical science in America.

We share the pride that is justly yours in the accomplishments of the era that is closing, and whatever the future may hold, it will ever be our high resolve to continue to render to our country loyal and devoted service."

Following are the letters to the Chairman, NACA, which General White, Admiral Pirie, and Secretary Rothschild offered to prepare on behalf of the Air Force, Navy, and Department of Commerce.

DEPARTMENT OF THE AIR FORCE
OFFICE OF THE CHIEF OF STAFF
UNITED STATES AIR FORCE
WASHINGTON, D. C.

26 August 1958

Dr. James H. Doolittle
Chairman
National Advisory Committee
for Aeronautics
1512 H Street, Northwest
Washington 25, D. C.

Dear Dr. Doolittle:

It was with mixed feelings that I attended the last meeting of the National Advisory Committee for Aeronautics on 21 August 1958.

There was regret at the passing of an agency that for 43 years has set the world's standard in aeronautical research. The United States as a nation, and the Air Force in particular, are deeply indebted to the NACA. In war and peace NACA has led the way; and there has always been, for us in the Air Force, the knowledge that NACA was ready to help in any aerodynamic trouble.

I hope that the new National Aeronautics and Space Agency, which will encompass many of the people of the old NACA, will go forward with the same competence and spirit of cooperation to reach new levels of accomplishment in the enlarged field.

Let me, on behalf of the Air Force, express sincerest thanks for all that the NACA has done for us over the years, and ask that you transmit my thanks to all the people of NACA who have served so long and so well.

Sincerely,

THOMAS D. WHITE
Chief of Staff

NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS

September 10, 1958

General Thomas D. White, USAF
Chief of Staff
Department of the Air Force
Washington 25, D. C.

Dear General White:

Your letter of August 26 is deeply appreciated by me personally. I am taking the liberty of bringing it to the attention of the nearly 8,000 employes of the National Advisory Committee for Aeronautics.

The great skill with which these devoted people have performed their researches over the years has been the prime reason for the contributions made by the NACA as a partner, together with the Military Services and the industry, on the air power team.

I know I can assure you, on behalf of these dedicated workers, that they will continue to merit the confidence, and the support, of the American people as they take up new and tremendously important work as the nucleus of the National Aeronautics and Space Administration.

Sincerely,

J. H. Doolittle
Chairman

THE ASSISTANT SECRETARY OF THE NAVY FOR AIR
WASHINGTON

17 SEP 1958

Dear Jimmy:

Upon the occasion of the disestablishment of the National Advisory Committee for Aeronautics, I would like to express the sincere appreciation of the United States Navy for the many achievements made by the NACA in the advancement of American aviation. Through the years, from the birth of the National Advisory Committee for Aeronautics by Congressional Act in 1915, when aircraft speeds of 100 knots were the marvel of the day, research by the NACA has been responsible for world leadership in aviation by the United States. During World War II, when American aviation manufacturing reached fantastic proportions, the superiority of design of American aircraft was in no small measure a compliment to the vision of the laboratories of the NACA in probing the unknown.

The well known fighters of the Navy, the Corsair, the Wildcat, and the Hellcat, which maintained control of the air in the Pacific and did so much to make the eventual naval victories possible, were all products of the application of research done by the NACA. Development in NACA laboratories of high lift devices, low drag wings, high speed propellers, improved engine cooling systems, and improved aircraft structural systems allowed the Navy's carrier task forces to strike the enemy where and when we chose.

Korea found the Navy operating jet aircraft from carriers in combat for the first time, and the distinct success of these operations was in no small measure proof of the validity of basic research conducted by the NACA.

Today, as speeds of manned aircraft near the hypersonic range, and with missile velocities transiting the hypersonic areas, the Free World owes a debt of gratitude to the comprehensive fundamental research in the problems of flight conducted by the NACA. The wealth of knowledge acquired by the NACA in its thirty-three years is a broad foundation upon which the Nation can build as the Jet Age gives way to the Age of Space.

Again, Jimmy, I would like to express the sincere appreciation of the Navy for the outstanding contributions to naval aviation made by the National Advisory Committee for Aeronautics. The National Aeronautics and Space Administration has a rich heritage indeed, and we of the Navy rejoice in the good news of your appointment as a member of the Board.

Sincerely,

GARRISON NORTON

James H. Doolittle, Sc.D.,
Chairman
National Advisory Committee for Aeronautics
1512 H Street NW
Washington 25, D.C.

THE SECRETARY OF COMMERCE
WASHINGTON 25

September 15 1958

Dear General Doolittle:

On behalf of the Department of Commerce and its representatives who serve as members of the National Advisory Committee for Aeronautics, it is a pleasure to express appreciation for the outstanding achievements of the NACA during its 43 years of activity. American leadership in aeronautics is due in no small measure to the research carried forward in NACA laboratories and to developments fostered by the Committee over the years in cooperation with industry and government agencies concerned with aviation. Many studies and discoveries that have led to revolutionary advancements in aeronautics have come directly from the laboratories of the organization. Forthcoming expansion of operations to explore outer space and develop the possibilities of interplanetary vehicles will bring an important transition which the United States will accomplish by building on experience and knowledge to which the NACA has contributed very materially.

From the beginning of the NACA in 1915, the Department of Commerce has always had one or more representatives in the membership of the Committee. The Director of the National Bureau of Standards was ex officio one of the original members. After passage of the Air Commerce Act of 1926 the Assistant Secretary of Commerce for Air also was a member, succeeded later on the Committee by the Administrator of Civil Aeronautics. In 1940 when the Weather Bureau was transferred to the Department of Commerce, the Chief of that Bureau, whose office had been among the original ex officio members, became another from this Department to serve on the Committee. In recent years the Under Secretary of Commerce for Transportation, Mr. Louis S. Rothschild, has made a fourth member from the Department of Commerce.

I express the feelings of these representatives as well as my own when I say that it has been a real privilege to have had an active part in the work of the Committee. It is indeed gratifying to see how successfully this unique group has functioned as an advisory and executive body. Although the organization and its advisory group will change with inauguration of the National

Aeronautics and Space Agency, the interest of the Department of Commerce in future progress in these highly important fields will continue undiminished, and I look forward to continued cooperation and participation by the Department and its representatives in the advancement of aeronautics and space exploration.

Sincerely,

Secretary of Commerce

General James H. Doolittle
Chairman, National Advisory
Committee for Aeronautics
1512 H Street, N.W.
Washington 25, D.C.

APPENDIX

Public Law 85-568
85th Congress, H.R. 12575
July 29, 1958

AN ACT To provide for research into problems of flight within and outside the earth's atmosphere, and for other purposes.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled,

National Aeronautics and Space Act of 1958

TITLE I—SHORT TITLE, DECLARATION OF POLICY AND DEFINITIONS

SHORT TITLE

SEC. 101. This Act may be cited as the "National Aeronautics and Space Act of 1958".

DECLARATION OF POLICY AND PURPOSE

SEC. 102. (a) The Congress hereby declares that it is the policy of the United States that activities in space should be devoted to peaceful purposes for the benefit of all mankind.

(b) The Congress declares that the general welfare and security of the United States require that adequate provision be made for aeronautical and space activities. The Congress further declares that such activities shall be the responsibility of, and shall be directed by, a civilian agency exercising control over aeronautical and space activities sponsored by the United States, except that activities peculiar to or primarily associated with the development of weapons systems, military operations, or the defense of the United States (including the research and development necessary to make effective provision for the defense of the United States) shall be the responsibility of, and shall be directed by, the Department of Defense; and that determination as to which such agency has responsibility for and direction of any such activity shall be made by the President in conformity with section 201(e).

72 Stat. 426.

(c) The aeronautical and space activities of the United States shall be conducted so as to contribute materially to one or more of the following objectives:

72 Stat. 427.

(1) The expansion of human knowledge of phenomena in the atmosphere and space;

(2) The improvement of the usefulness, performance, speed, safety, and efficiency of aeronautical and space vehicles;

(3) The development and operation of vehicles capable of carrying instruments, equipment, supplies, and living organisms through space;

(4) The establishment of long-range studies of the potential benefits to be gained from, the opportunities for, and the problems involved in the utilization of aeronautical and space activities for peaceful and scientific purposes;

(5) The preservation of the role of the United States as a leader in aeronautical and space science and technology and in the application thereof to the conduct of peaceful activities within and outside the atmosphere;

(6) The making available to agencies directly concerned with national defense of discoveries that have military value or significance, and the furnishing by such agencies, to the civilian agency established to direct and control nonmilitary aeronautical and space activities, of information as to discoveries which have value or significance to that agency;

(7) Cooperation by the United States with other nations and groups of nations in work done pursuant to this Act and in the peaceful application of the results thereof; and

(8) The most effective utilization of the scientific and engineering resources of the United States, with close cooperation among all interested agencies of the United States in order to avoid unnecessary duplication of effort, facilities, and equipment.

(d) It is the purpose of this Act to carry out and effectuate the policies declared in subsections (a), (b), and (c).

DEFINITIONS

SEC. 103. As used in this Act—

(1) the term "aeronautical and space activities" means (A) research into, and the solution of, problems of flight within and outside the earth's atmosphere, (B) the development, construction, testing, and operation for research purposes of aeronautical and space vehicles, and (C) such other activities as may be required for the exploration of space; and

(2) the term "aeronautical and space vehicles" means aircraft, missiles, satellites, and other space vehicles, manned and unmanned, together with related equipment, devices, components, and parts.

TITLE II—COORDINATION OF AERONAUTICAL AND SPACE ACTIVITIES

NATIONAL AERONAUTICS AND SPACE COUNCIL

Establishment.

SEC. 201. (a) There is hereby established the National Aeronautics and Space Council (hereinafter called the "Council") which shall be composed of—

(1) the President (who shall preside over the meetings of the Council);

72 Stat. 427.
72 Stat. 428.

(2) the Secretary of State;

(3) the Secretary of Defense;

(4) the Administrator of the National Aeronautics and Space Administration;

(5) the Chairman of the Atomic Energy Commission;

(6) not more than one additional member appointed by the President from the departments and agencies of the Federal Government; and

(7) not more than three other members appointed by the President, solely on the basis of established records of distinguished achievement, from among individuals in private life who are eminent in science, engineering, technology, education, administration, or public affairs.

Alternate.

(b) Each member of the Council from a department or agency of the Federal Government may designate another officer of his department or agency to serve on the Council as his alternate in his unavoidable absence.

(c) Each member of the Council appointed or designated under paragraphs (6) and (7) of subsection (a), and each alternate member designated under subsection (b), shall be appointed or designated to serve as such by and with the advice and consent of the Senate, unless at the time of such appointment or designation he holds an office in the Federal Government to which he was appointed by and with the advice and consent of the Senate.

(d) It shall be the function of the Council to advise the President with respect to the performance of the duties prescribed in subsection (e) of this section.

Duties of President.

(e) In conformity with the provisions of section 102 of this Act, it shall be the duty of the President to—

(1) survey all significant aeronautical and space activities, including the policies, plans, programs, and accomplishments of all agencies of the United States engaged in such activities;

(2) develop a comprehensive program of aeronautical and space activities to be conducted by agencies of the United States;

(3) designate and fix responsibility for the direction of major aeronautical and space activities;

(4) provide for effective cooperation between the National Aeronautics and Space Administration and the Department of Defense in all such activities, and specify which of such activities may be carried on concurrently by both such agencies notwithstanding the assignment of primary responsibility therefor to one or the other of such agencies; and

(5) resolve differences arising among departments and agencies of the United States with respect to aeronautical and space activities under this Act, including differences as to whether a particular project is an aeronautical and space activity.

Employees. Compensation.

(f) The Council may employ a staff to be headed by a civilian executive secretary who shall be appointed by the President by and with the advice and consent of the Senate and shall receive compensation at the rate of

$20,000 a year. The executive secretary, subject to the direction of the Council, is authorized to appoint and fix the compensation of such personnel, including not more than three persons who may be appointed without regard to the civil service laws or the Classification Act of 1949 and compensated at the rate of not more than $19,000 a year, as may be necessary to perform such duties as may be prescribed by the Council in connection with the performance of its functions. Each appointment under this subsection shall be subject to the same security requirements as those established for personnel of the National Aeronautics and Space Administration appointed under section 203(b)(2) of this Act.

63 Stat. 954. 5 USC 1071 note.

Security check.

(g) Members of the Council appointed from private life under subsection (a)(7) may be compensated at a rate not to exceed $100 per diem, and may be paid travel expenses and per diem in lieu of subsistence in accordance with the provisions of section 5 of the Administrative Expenses Act of 1946 (5 U.S.C. 73b–2) relating to persons serving without compensation.

Per diem. 72 Stat. 428. 72 Stat. 429. 69 Stat. 394.

NATIONAL AERONAUTICS AND SPACE ADMINISTRATION

SEC. 202. (a) There is hereby established the National Aeronautics and Space Administration (hereinafter called the "Administration"). The Administration shall be headed by an Administrator, who shall be appointed from civilian life by the President by and with the advice and consent of the Senate, and shall receive compensation at the rate of $22,500 per annum. Under the supervision and direction of the President, the Administrator shall be responsible for the exercise of all powers and the discharge of all duties of the Administration, and shall have authority and control over all personnel and activities thereof.

Administrator.

(b) There shall be in the Administration a Deputy Administrator, who shall be appointed from civilian life by the President by and with the advice and consent of the Senate, shall receive compensation at the rate of $21,500 per annum, and shall perform such duties and exercise such powers as the Administrator may prescribe. The Deputy Administrator shall act for, and exercise the powers of, the Administrator during his absence or disability.

Deputy Administrator.

(c) The Administrator and the Deputy Administrator shall not engage in any other business, vocation, or employment while serving as such.

Restriction.

FUNCTIONS OF THE ADMINISTRATION

SEC. 203. (a) The Administration, in order to carry out the purpose of this Act, shall—

(1) plan, direct, and conduct aeronautical and space activities;

(2) arrange for participation by the scientific community in planning scientific measurements and observations to be made through use of aeronautical and space vehicles, and conduct or arrange for the conduct of such measurements and observations; and

(3) provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof.

(b) In the performance of its functions the Administration is authorized—

(1) to make, promulgate, issue, rescind, and amend rules and regulations governing the manner of its operations and the exercise of the powers vested in it by law;

Rules and regulations.

(2) to appoint and fix the compensation of such officers and employees as may be necessary to carry out such functions. Such officers and employees shall be appointed in accordance with the civil-service laws and their compensation fixed in accordance with the Classification Act of 1949, except that (A) to the extent the Administrator deems such action necessary to the discharge of his responsibilities, he may appoint and fix the compensation (up to a limit of $19,000 a year, or up to a limit of $21,000 a year for a maximum of ten positions) of not more than two hundred and sixty of the scientific, engineering, and administrative personnel of the Administration without regard to such laws, and (B) to the extent the Administrator deems such action necessary to recruit specially qualified scientific and engineering talent, he may establish the entrance grade for scientific and engineering personnel without previous service in the Federal Government at a level up to two grades higher than the grade provided for such personnel under the General Schedule established by the Classification Act of 1949, and fix their compensation accordingly;

Employees. 63 Stat. 954. 5 USC 1071 note. 72 Stat. 429. 72 Stat. 430.

Acquisition of property.

(3) to acquire (by purchase, lease, condemnation, or otherwise), construct, improve, repair, operate, and maintain laboratories, research and testing sites and facilities, aeronautical and space vehicles, quarters and related accommodations for employees and dependents of employees of the Administration, and such other real and personal property (including patents), or any interest therein, as the Administration deems necessary within and outside the continental United States; to lease to others such real and personal property; to sell and otherwise dispose of real and personal property (including patents and rights thereunder) in accordance with the provisions of the Federal Property and Administrative Services Act of 1949, as amended (40 U.S.C. 471 et seq.); and to provide by contract or otherwise for cafeterias and other necessary facilities for the welfare of employees of the Administration at its installations and purchase and maintain equipment therefor;

63 Stat. 377.

Gifts.

(4) to accept unconditional gifts or donations of services, money, or property, real, personal, or mixed, tangible or intangible;

Contracts, etc.
60 Stat. 809.

(5) without regard to section 3648 of the Revised Statutes, as amended (31 U.S.C. 529), to enter into and perform such contracts, leases, cooperative agreements, or other transactions as may be necessary in the conduct of its work and on such terms as it may deem appropriate, with any agency or instrumentality of the United States, or with any State, Territory, or possession, or with any political subdivision thereof, or with any person, firm, association, corporation, or educational institution. To the maximum extent practicable and consistent with the accomplishment of the purpose of this Act, such contracts, leases, agreements, and other transactions shall be allocated by the Administrator in a manner which will enable small-business concerns to participate equitably and proportionately in the conduct of the work of the Administration;

Agency cooperation.

(6) to use, with their consent, the services, equipment, personnel, and facilities of Federal and other agencies with or without reimbursement, and on a similar basis to cooperate with other public and private agencies and instrumentalities in the use of services, equipment, and facilities. Each department and agency of the Federal Government shall cooperate fully with the Administration in making its services, equipment, personnel, and facilities available to the Administration, and any such department or agency is authorized notwithstanding any other provision of law, to transfer to or receive from the Administration, without reimbursement, aeronautical and space vehicles, and supplies and equipment other than administrative supplies or equipment;

Advisory committees.

(7) to appoint such advisory committees as may be appropriate for purposes of consultation and advice to the Administration in the performance of its functions;

Coordination.

(8) to establish within the Administration such offices and procedures as may be appropriate to provide for the greatest possible coordination of its activities under this Act with related scientific and other activities being carried on by other public and private agencies and organizations;

72 Stat. 430.
72 Stat. 431.
60 Stat. 810.

(9) to obtain services as authorized by section 15 of the Act of August 2, 1946 (5 U.S.C. 55a), at rates not to exceed $100 per diem for individuals;

Employment Aliens.

(10) when determined by the Administrator to be necessary, and subject to such security investigations as he may determine to be appropriate, to employ aliens without regard to statutory provisions prohibiting payment of compensation to aliens;

Retired officers.

(11) to employ retired commissioned officers of the armed forces of the United States and compensate them at the rate established for the positions occupied by them within the Administration, subject only to the limitations in pay set forth in section 212 of the Act of June 30, 1932, as amended (5 U.S.C. 59a);

68 Stat. 18.
Agreements.

(12) with the approval of the President, to enter into cooperative agreements under which members of the Army, Navy, Air Force, and Marine Corps may be detailed by the appropriate Secretary for services in the performance of functions under this Act to the same extent as that to which they might be lawfully assigned in the Department of Defense; and

(13) (A) to consider, ascertain, adjust, determine, settle, and pay, on behalf of the United States, in full satisfaction thereof, any claim for $5,000 or less against the United States for bodily injury, death, or damage to or loss of real or personal property resulting from the conduct of the Administration's functions as specified in subsection (a) of this section, where such claim is presented to the Administration in writing within two years after the accident or incident out of which the claim arises; and Claims.

(B) if the Administration considers that a claim in excess of $5,000 is meritorious and would otherwise be covered by this paragraph, to report the facts and circumstances thereof to the Congress for its consideration. Report to Congress.

CIVILIAN-MILITARY LIAISON COMMITTEE

SEC. 204. (a) There shall be a Civilian-Military Liaison Committee consisting of—

(1) a Chairman, who shall be the head thereof and who shall be appointed by the President, shall serve at the pleasure of the President, and shall receive compensation (in the manner provided in subsection (d)) at the rate of $20,000 per annum;

(2) one or more representatives from the Department of Defense, and one or more representatives from each of the Departments of the Army, Navy, and Air Force, to be assigned by the Secretary of Defense to serve on the Committee without additional compensation; and

(3) representatives from the Administration, to be assigned by the Administrator to serve on the Committee without additional compensation, equal in number to the number of representatives assigned to serve on the Committee under paragraph (2).

(b) The Administration and the Department of Defense, through the Liaison Committee, shall advise and consult with each other on all matters within their respective jurisdictions relating to aeronautical and space activities and shall keep each other fully and currently informed with respect to such activities.

(c) If the Secretary of Defense concludes that any request, action, proposed action, or failure to act on the part of the Administrator is adverse to the responsibilities of the Department of Defense, or the Administrator concludes that any request, action, proposed action, or failure to act on the part of the Department of Defense is adverse to the responsibilities of the Administration, and the Administrator and the Secretary of Defense are unable to reach an agreement with respect thereto, either the Administrator or the Secretary of Defense may refer the matter to the President for his decision (which shall be final) as provided in section 201(e). 72 Stat. 431. 72 Stat. 432.

(d) Notwithstanding the provisions of any other law, any active or retired officer of the Army, Navy, or Air Force may serve as Chairman of the Liaison Committee without prejudice to his active or retired status as such officer. The compensation received by any such officer for his service as Chairman of the Liaison Committee shall be equal to the amount (if any) by which the compensation fixed by subsection (a)(1) for such Chairman exceeds his pay and allowances (including special and incentive pays) as an active officer, or his retired pay. Chairman.

INTERNATIONAL COOPERATION

SEC. 205. The Administration, under the foreign policy guidance of the President, may engage in a program of international cooperation in work done pursuant to this Act, and in the peaceful application of the results thereof, pursuant to agreements made by the President with the advice and consent of the Senate.

REPORTS TO THE CONGRESS

SEC. 206. (a) The Administration shall submit to the President for transmittal to the Congress, semiannually and at such other times as it deems desirable, a report of its activities and accomplishments.

(b) The President shall transmit to the Congress in January of each year a report, which shall include (1) a comprehensive description of the programed activities and the acomplishments of all agencies of the United States in the field of aeronautics and space activities during the preceding calendar year, and (2) an evaluation of such activities and acomplishments

in terms of the attainment of or the failure to attain, the objectives described in section 102(c) of this Act.

(c) Any report made under this section shall contain such recommendations for additional legislation as the Administrator or the President may consider necessary or desirable for the attainment of the objectives described in section 102(c) of this Act.

(d) No information which has been classified for reasons of national security shall be included in any report made under this section, unless such information has been declassified by, or pursuant to authorization given by, the President.

TITLE III—MISCELLANEOUS

NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS

Termination. Transfer of functions.

SEC. 301. (a) The National Advisory Committee for Aeronautics, on the effective date of this section, shall cease to exist. On such date all functions, powers, duties, and obligations, and all real and personal property, personnel (other than members of the Committee), funds, and records of that organization, shall be transferred to the Administration.

Definitions. 70A Stat. 127.

(b) Section 2302 of title 10 of the United States Code is amended by striking out "or the Executive Secretary of the National Advisory Committee for Aeronautics." and inserting in lieu thereof "or the Administrator of the National Aeronautics and Space Administration."; and section 2303 of such title 10 is amended by striking out "The National Advisory Committee for Aeronautics." and inserting in lieu thereof "The National Aeronautics and Space Administration."

64 Stat. 476. 72 Stat. 432. 72 Stat. 433.

(c) The first section of the Act of August 26, 1950 (5 U.S.C. 22–1), is amended by striking out "the Director, National Advisory Committee for Aeronautics" and inserting in lieu thereof "the Administrator of the National Aeronautics and Space Administration", and by striking out "or National Advisory Committee for Aeronautics" and inserting in lieu thereof "or National Aeronautics and Space Administration".

63 Stat. 936.

(d) The Unitary Wind Tunnel Plan Act of 1949 (50 U.S.C. 511–515) is amended (1) by striking out "The National Advisory Committee for Aeronautics (hereinafter referred to as the 'Committee')" and inserting in lieu thereof "The Administrator of the National Aeronautics and Space Administration (hereinafter referred to as the 'Administrator')"; (2) by striking out "Committee" or "Committee's" wherever they appear and inserting in lieu thereof "Administrator" and "Administrator's", respectively; and (3) by striking out "its" wherever it appears and inserting in lieu thereof "his".

Effective date.

(e) This section shall take effect ninety days after the date of the enactment of this Act, or on any earlier date on which the Administrator shall

Publication in F.R.

determine, and announce by proclamation published in the Federal Register, that the Administration has been organized and is prepared to discharge the duties and exercise the powers conferred upon it by this Act.

TRANSFER OF RELATED FUNCTIONS

SEC. 302. (a) Subject to the provisions of this section, the President, for a period of four years after the date of enactment of this Act, may transfer to the Administration any functions (including powers, duties, activities, facilities, and parts of functions) of any other department or agency of the United States, or of any officer or organizational entity thereof, which relate primarily to the functions, powers, and duties of the Administration as prescribed by section 203 of this Act. In connection with any such transfer, the President may, under this section or other applicable authority, provide for appropriate transfers of records, property, civilian personnel, and funds.

Reports to Congress.

(b) Whenever any such transfer is made before January 1, 1959, the President shall transmit to the Speaker of the House of Representatives and the President pro tempore of the Senate a full and complete report concerning the nature and effect of such transfer.

(c) After December 31, 1958, no transfer shall be made under this section until (1) a full and complete report concerning the nature and effect of such proposed transfer has been transmitted by the President to the Congress, and (2) the first period of sixty calendar days of regular session of the Congress following the date of receipt of such report by the Congress

has expired without the adoption by the Congress of a concurrent resolution stating that the Congress does not favor such transfer.

ACCESS TO INFORMATION

SEC. 303. Information obtained or developed by the Administrator in the performance of his functions under this Act shall be made available for public inspection, except (A) information authorized or required by Federal statute to be withheld, and (B) information classified to protect the national security: *Provided*, That nothing in this Act shall authorize the withholding of information by the Administrator from the duly authorized committees of the Congress.

SECURITY

SEC. 304. (a) The Administrator shall establish such security requirements, restrictions, and safeguards as he deems necessary in the interest of the national security. The Administrator may arrange with the Civil Service Commission for the conduct of such security or other personnel investigations of the Administration's officers, employees, and consultants, and its contractors and subcontractors and their officers and employees, actual or prospective, as he deems appropriate; and if any such investigation develops any data reflecting that the individual who is the subject thereof is of questionable loyalty the matter shall be referred to the Federal Bureau of Investigation for the conduct of a full field investigation, the results of which shall be furnished to the Administrator.

Requirements.

72 Stat. 433.
72 Stat. 434.

Referral to F.B.I.

(b) The Atomic Energy Commission may authorize any of its employees, or employees of any contractor, prospective contractor, licensee, or prospective licensee of the Atomic Energy Commission or any other person authorized to have access to Restricted Data by the Atomic Energy Commission under subsection 145 b. of the Atomic Energy Act of 1954 (42 U.S.C. 2165(b)), to permit any member, officer, or employee of the Council, or the Administrator, or any officer, employee, member of an advisory committee, contractor, subcontractor, or officer or employee of a contractor or subcontractor of the Administration, to have access to Restricted Data relating to aeronautical and space activities which is required in the performance of his duties and so certified by the Council or the Administrator, as the case may be, but only if (1) the Council or Administrator or designee thereof has determined, in accordance with the established personnel security procedures and standards of the Council or Administration, that permitting such individual to have access to such Restricted Data will not endanger the common defense and security, and (2) the Council or Administrator or designee thereof finds that the established personnel and other security procedures and standards of the Council or Administration are adequate and in reasonable conformity to the standards established by the Atomic Energy Commission under section 145 of the Atomic Energy Act of 1954 (42 U.S.C. 2165). Any individual granted access to such Restricted Data pursuant to this subsection may exchange such Data with any individual who (A) is an officer or employee of the Department of Defense, or any department or agency thereof, or a member of the armed forces, or a contractor or subcontractor of any such department, agency, or armed force, or an officer or employee of any such contractor or subcontractor, and (B) has been authorized to have access to Restricted Data under the provisions of section 143 of the Atomic Energy Act of 1954 (42 U.S.C. 2163).

Access to AEC restricted data.

68 Stat. 942.

68 Stat. 942.

(c) Chapter 37 of title 18 of the United States Code (entitled Espionage and Censorship) is amended by—

(1) adding at the end thereof the following new section:

Espionage and Censorship.
62 Stat. 736–738:
65 Stat. 719.
18 USC 791–798.

"§ 799. Violation of regulations of National Aeronautics and Space Administration

Violation.

"Whoever willfully shall violate, attempt to violate, or conspire to violate any regulation or order promulgated by the Administrator of the National Aeronautics and Space Administration for the protection or security of any laboratory, station, base or other facility, or part thereof, or any aircraft, missile, spacecraft, or similar vehicle, or part thereof, or other property or equipment in the custody of the Administration, or any real or personal property or equipment in the custody of any contractor under any contract with the Administration or any subcontractor of any such contractor, shall be fined not more than $5,000, or imprisoned not more than one year, or both."

Penalty.

(2) adding at the end of the sectional analysis thereof the following new item:

72 Stat. 434.
72 Stat. 435.

"799. Violation of regulations of National Aeronautics and Space Administration."

(d) Section 1114 of title 18 of the United States Code is amended by inserting immediately before "while engaged in the performance of his official duties" the following: "or any officer or employee of the National Aeronautics and Space Administration directed to guard and protect property of the United States under the administration and control of the National Aeronautics and Space Administration,".

Protection of U.S. officers and employees.
62 Stat. 756.

Permission to use firearms.

(e) The Administrator may direct such of the officers and employees of the Administration as he deems necessary in the public interest to carry firearms while in the conduct of their official duties. The Administrator may also authorize such of those employees of the contractors and subcontractors of the Administration engaged in the protection of property owned by the United States and located at facilities owned by or contracted to the United States as he deems necessary in the public interest, to carry firearms while in the conduct of their official duties.

PROPERTY RIGHTS IN INVENTIONS

SEC. 305. (a) Whenever any invention is made in the performance of any work under any contract of the Administration, and the Administrator determines that—

(1) the person who made the invention was employed or assigned to perform research, development, or exploration work and the invention is related to the work he was employed or assigned to perform, or that it was within the scope of his employment duties, whether or not it was made during working hours, or with a contribution by the Government of the use of Government facilities, equipment, materials, allocated funds, information proprietary to the Government, or services of Government employees during working hours; or

(2) the person who made the invention was not employed or assigned to perform research, development, or exploration work, but the invention is nevertheless related to the contract, or to the work or duties he was employed or assigned to perform, and was made during working hours, or with a contribution from the Government of the sort referred to in clause (1),

such invention shall be the exclusive property of the United States, and if such invention is patentable a patent therefor shall be issued to the United States upon application made by the Administrator, unless the Administrator waives all or any part of the rights of the United States to such invention in conformity with the provisions of subsection (f) of this section.

Contract provision.

(b) Each contract entered into by the Administrator with any party for the performance of any work shall contain effective provisions under which such party shall furnish promptly to the Administrator a written report containing full and complete technical information concerning any invention, discovery, improvement, or innovation which may be made in the performance of any such work.

Patent application.

(c) No patent may be issued to any applicant other than the Administrator for any invention which appears to the Commissioner of Patents to have significant utility in the conduct of aeronautical and space activities unless the applicant files with the Commissioner, with the application or within thirty days after request therefor by the Commissioner, a written statement executed under oath setting forth the full facts concerning the circumstances under which such invention was made and stating the relationship (if any) of such invention to the performance of any work under any contract of the Administration. Copies of each such statement and the application to which it relates shall be transmitted forthwith by the Commissioner to the Administrator.

(d) Upon any application as to which any such statement has been transmitted to the Administrator, the Commissioner may, if the invention is patentable, issue a patent to the applicant unless the Administrator, within ninety days after receipt of such application and statement, requests that such patent be issued to him on behalf of the United States. If, within such time, the Administrator files such a request with the Commissioner, the Commissioner shall transmit notice thereof to the applicant, and shall issue

72 Stat. 435.
72 Stat. 436.

Board of Patent Interferences.

such patent to the Administrator unless the applicant within thirty days after receipt of such notice requests a hearing before a Board of Patent Interferences on the question whether the Administrator is entitled under this section to receive such patent. The Board may hear and determine, in accordance with rules and procedures established for interference cases, the question so presented, and its determination shall be subject to appeal by the applicant or by the Administrator to the Court of Customs and Patent Appeals in accordance with procedures governing appeals from decisions of the Board of Patent Interferences in other proceedings.

(e) Whenever any patent has been issued to any applicant in conformity with subsection (d), and the Administrator thereafter has reason to believe that the statement filed by the applicant in connection therewith contained any false representation of any material fact, the Administrator within five years after the date or issuance of such patent may file with the Commissioner a request for the transfer to the Administrator of title to such patent on the records of the Commission. Notice of any such request shall be transmitted by the Commissioner to the owner of record of such patent, and title to such patent shall be so transferred to the Administrator unless within thirty days after receipt of such notice such owner of record requests a hearing before a Board of Patent Interferences on the question whether any such false representation was contained in such statement. Such question shall be heard and determined, and determination thereof shall be subject to review, in the manner prescribed by subsection (d) for questions arising thereunder. No request made by the Administrator under this subsection for the transfer of title to any patent, and no prosecution for the violation of any criminal statute, shall be barred by any failure of the Administrator to make a request under subsection (d) for the issuance of such patent to him, or by any notice previously given by the Administrator stating that he had no objection to the issuance of such patent to the applicant therefor.

Waiver.

(f) Under such regulations in conformity with this subsection as the Administrator shall prescribe, he may waive all or any part of the rights of the United States under this section with respect to any invention or class of inventions made or which may be made by any person or class of persons in the performance of any work required by any contract of the Administration if the Administrator determines that the interests of the United States will be served thereby. Any such waiver may be made upon such terms and under such conditions as the Administrator shall determine to be required for the protection of the interests of the United States. Each such waiver made with respect to any invention shall be subject to the reservation by the Administrator of an irrevocable, nonexclusive, nontransferrable, royalty-free license for the practice of such invention throughout the world by or on behalf of the United States or any foreign government pursuant to any treaty or agreement with the United States. Each proposal for any waiver under this subsection shall be referred to an Inventions and Contributions Board which shall be established by the Administrator within the Administration. Such Board shall accord to each interested party an opportunity for hearing, and shall transmit to the Administrator its findings of fact with respect to such proposal and its recommendations for action to be taken with respect thereto.

Inventions and Contributions Board.

License regulations.

(g) The Administrator shall determine, and promulgate regulations specifying, the terms and conditions upon which licenses will be granted by the Administration for the practice by any person (other than an agency of the United States) of any invention for which the Administrator holds a patent on behalf of the United States.

72 Stat. 436.
72 Stat. 437.

Protection of title.

(h) The Administrator is authorized to take all suitable and necessary steps to protect any invention or discovery to which he has title, and to require that contractors or persons who retain title to inventions or discoveries under this section protect the inventions or discoveries to which the Administration has or may acquire a license of use.

Defense agency.
66 Stat. 805–808.

(i) The Administration shall be considered a defense agency of the United States for the purpose of chapter 17 of title 35 of the United States Code.

Definitions.

(j) As used in this section—

(1) the term "person" means any individual, partnership, corporation, association, institution, or other entity;

(2) the term "contract" means any actual or proposed contract, agreement, understanding, or other arrangement, and includes any assignment, substitution of parties, or subcontract executed or entered into thereunder; and

(3) the term "made", when used in relation to any invention, means the conception or first actual reduction to practice of such invention.

CONTRIBUTIONS AWARDS

SEC. 306. (a) Subject to the provisions of this section, the Administrator is authorized, upon his own initiative or upon application of any person, to make a monetary award, in such amount and upon such terms as he shall determine to be warranted, to any person (as defined by section 305) for any scientific or technical contribution to the Administration which is determined by the Administrator to have significant value in the conduct of aeronautical and space activities. Each application made for any such award shall be referred to the Inventions and Contributions Board established under section 305 of this Act. Such Board shall accord to each such applicant an opportunity for hearing upon such application, and shall transmit to the Administrator its recommendation as to the terms of the award, if any, to be made to such applicant for such contribution. In determining the terms and conditions of any award the Administrator shall take into account—

(1) the value of the contribution to the United States;

(2) the aggregate amount of any sums which have been expended by the applicant for the development of such contribution;

(3) the amount of any compensation (other than salary received for services rendered as an officer or employee of the Government) previously received by the applicant for or on account of the use of such contribution by the United States; and

(4) such other factors as the Administrator shall determine to be material.

(b) If more than one applicant under subsection (a) claims an interest in the same contribution, the Administrator shall ascertain and determine the respective interests of such applicants, and shall apportion any award to be made with respect to such contribution among such applicants in such proportions as he shall determine to be equitable. No award may be made under subsection (a) with respect to any contribution—

(1) unless the applicant surrenders, by such means as the Administrator shall determine to be effective, all claims which such applicant may have to receive any compensation (other than the award made under this section) for the use of such contribution or any element thereof at any time by or on behalf of the United States, or by or on behalf of any foreign government pursuant to any treaty or agreement with the United States, within the United States or at any other place;

72 Stat. 437.
72 Stat. 438.

(2) in any amount exceeding $100,000, unless the Administrator has transmitted to the appropriate committees of the Congress a full and complete report concerning the amount and terms of, and the basis for, such proposed award, and thirty calendar days of regular session of the Congress have expired after receipt of such report by such committees.

72 Stat. 438.

APPROPRIATIONS

SEC. 307. (a) There are hereby authorized to be appropriated such sums as may be necessary to carry out this Act, except that nothing in this Act shall authorize the appropriation of any amount for (1) the acquisition or condemnation of any real property, or (2) any other item of a capital nature (such as plant or facility acquisition, construction, or expansion) which exceeds $250,000. Sums appropriated pursuant to this subsection for the construction of facilities, or for research and development activities, shall remain available until expended.

(b) Any funds appropriated for the construction of facilities may be used for emergency repairs of existing facilities when such existing facilities are made inoperative by major breakdown, accident, or other circumstances and such repairs are deemed by the Administrator to be of greater urgency than the construction of new facilities.

Approved July 29, 1958.

NATIONAL AERONAUTICS AND SPACE ADMINISTRATION

Washington, D. C.

A PROCLAMATION

1. By virtue of the authority vested in me by the National Aeronautics and Space Act of 1958 (Public Law 85-568, approved July 29, 1958, 72 Stat. 426, 433) I hereby proclaim that as of the close of business September 30, 1958, the National Aeronautics and Space Administration has been organized and is prepared to discharge the duties and exercise the powers conferred upon it by said law

2. In accordance with the provisions of the Act, all functions, powers, duties, and obligations, and all real and personal property, personnel (other than members of the Committee), funds, and records of the National Advisory Committee for Aeronautics are hereby transferred to the National Aeronautics and Space Administration.

3. The existing National Advisory Committee for Aeronautics Committees on Aircraft, Missile and Spacecraft Aerodynamics; Aircraft, Missile and Spacecraft Propulsion; Aircraft, Missile and Spacecraft Construction; Aircraft Operating Problems; the Industry Consulting Committee; and the Special Committee on Space Technology and their subcommittees are hereby reconstituted advisory committees to the Administration through December 31, 1958, for the purpose of bringing their current work to an orderly completion.

4. Existing policies, regulations, authorities, and procedural instructions governing the activities of the National Advisory Committee for Aeronautics, not inconsistent with law, and which are applicable to the activities of the National Aeronautics and Space Administration, shall be continued in effect until superseded or revoked.

5. The Langley Aeronautical Laboratory, the Ames Aeronautical Laboratory, and the Lewis Flight Propulsion Laboratory are hereby renamed the Langley Research Center, the Ames Research Center, and the Lewis Research Center, respectively.

DONE at the City of Washington, District of Columbia this 25th day of September in the year Nineteen Hundred and Fifty-Eight.

T. Keith Glennan
Administrator

REPORT 1342

A VARIATIONAL THEOREM FOR CREEP WITH APPLICATIONS TO PLATES AND COLUMNS [1]

By J. Lyell Sanders, Jr., Harvey G. McComb, Jr., and Floyd R. Schlechte

SUMMARY

A variational theorem is presented for a body undergoing creep. Solutions to problems of the creep behavior of plates, columns, beams, and shells can be obtained by means of the direct methods of the calculus of variations in conjunction with the stated theorem. The application of the theorem is illustrated for plates and columns by the solution of two sample problems.

INTRODUCTION

Interest in the various effects of creep in metals has intensified in recent years in the aeronautical field because of actual or envisaged operation of aircraft in an elevated-temperature environment. Much experimental work has been done to determine the creep stress-strain relations of various metals at elevated temperatures, and much data have been accumulated on the creep collapse of columns and plates. Analytically, creep problems for beams, columns, and plates are more difficult than the corresponding elastic problems, because the creep stress-strain relations (which generally include the possibility of elastic and plastic strains) are nonlinear. One consequence of this nonlinearity is that the distribution of the stresses through the thickness of the beam, plate, or column is not nearly so simple as in the elastic case. Mathematical analyses of these structural components have often been restricted to simplified models (**H**-section columns, for example) to avoid this difficulty.

No known systematic procedures have been devised for reducing a given creep problem to a set of differential equations, although some efforts have been made to develop variational methods for use in attacking these problems mathematically. Hoff (refs. 1 and 2) has suggested the use of a minimum-complementary-energy principle based on an analog between the creep-strain rates and the elastic strains in a nonlinearly elastic body; however, elastic and plastic strains are neglected and the method does not apply readily to plate and column problems. Wang and Prager (ref. 3) have given two general extremum principles (for a body with elastic, plastic, thermal, and creep strains) analogous to the minimum-complementary-energy and minimum-potential-energy principles in elasticity. In the present report, an analog of Reissner's variational theorem in elasticity (refs. 4 and 5) is formulated (for a body with elastic, plastic, and creep strains), and special forms of it are found to be convenient for handling creep problems of plates, columns, beams, and shells. The use of the variational theorem presented herein is illustrated by applications to two creep problems: creep collapse of columns and plate bending.

SYMBOLS

E	Young's modulus
I	integral to be varied (see eq. (7))
I_1,I_2,I_3	integrals defined by equations (46)
J_2	second invariant of stress-deviator tensor
M_r,M_t	radial and tangential bending moments, respectively, per unit length
$M_{r,0},M_{t,0},M_{t,1}$	radial and tangential bending-moment coefficients defined by equations (44)
P	compressive load
P_c	buckling load for column
S	surface of a body
S_s	part of surface where stresses are prescribed
S_d	part of surface where displacements are prescribed
T_i	surface traction
$\overline{T}_i$	prescribed surface traction on S_s
U	displacement of neutral surface in x-direction
U_0	displacement coefficient in x-direction (see eqs. (28))
V	displacement of neutral surface in y-direction; also used as volume integral
W	deflection of neutral surface in z-direction
W_0,W_1	deflection coefficients (see eqs. (28) or (44))
R	radius of circular plate
b	width of column
h	thickness of column or plate
l	length of column
m	empirical constant in creep law
n_j	unit external normal to surface of undeformed body
p	empirical constant in creep law
q	lateral load intensity on circular plate
r	radial coordinate

[1] Supersedes NACA Technical Note 4003 by J. Lyell Sanders, Jr., Harvey G. McComb, Jr., and Floyd R. Schlechte, 1957.

Preceding Page Blank

s_{ij}	stress-deviator tensor
t	time
u	displacement in x-direction
u_i	displacement vector
$\bar{u}_i$	prescribed displacement vector on S_d
v	displacement in y-direction
w	displacement in z-direction
x,y,z	coordinates
$\gamma_{xz},\gamma_{yz},\gamma_{xy}$	shear strains in xz-, yz-, and xy-directions, respectively
Δ	amplitude of initial bow of column divided by column thickness
δ_{ij}	Kronecker delta
ϵ	strain, positive in tension
ϵ_{ij}	strain tensor
ϵ'_{ij}	noncreep portion of strain tensor
ϵ''_{ij}	creep strain tensor
ϵ_r,ϵ_t	radial and tangential strains, respectively
$\epsilon_x,\epsilon_y,\epsilon_z$	strain in x-, y-, and z-directions, respectively
θ	angular coordinate
λ	empirical constant in creep law
μ	Poisson's ratio
$\rho=r/R$	
σ	stress, positive in tension
σ_{ij}	stress tensor
σ_0^*,σ_1^*	stresses defined in equation (27)
σ_0,σ_1	stress coefficients in equations (28)
σ_r,σ_t	radial and tangential stresses, respectively

Dots over quantities denote differentiation with respect to time, a single prime denotes the elastic-plastic part of the strain, and a double prime denotes the creep part of the strain.

FORMULATION OF GENERAL VARIATIONAL THEOREM

For a body subject to creep, the equilibrium equations and strain-displacement relations are the same as those for an elastic body; the only difference in the mathematical formulation of a creep problem is in the stress-strain relation. In the present development, the nonlinear strain-displacement relations and equilibrium equations are used because of the intended application of the variational theorem to collapse problems of columns and plates. However, the strains are still assumed to be small, and the stress-strain relations are written as for infinitesimal strains. The total strain rate is separated into a creep part and a part which includes elastic and plastic effects. The creep part of the strain rate is allowed to depend on time and on the stress deviator but not on the stress rate or the first invariant of stress. In this report, the temperature of the body is assumed to be uniform and constant in time.

In tensor notation, a simple example of the creep law assumed is

$$\dot{\epsilon}''_{ij}=f(J_2,t)s_{ij} \tag{1}$$

where s_{ij} is the stress deviator and J_2 is the second invariant $\frac{1}{2}s_{ij}s_{ij}$. For purposes of the present report, the only restriction on the stress-strain relation for the elastic-plastic part of the strain is that the following relation hold (see ref. 6):

$$\dot{\sigma}_{ij}d\dot{\epsilon}'_{ij}\equiv\dot{\epsilon}'_{ij}d\dot{\sigma}_{ij} \tag{2}$$

The equation for the components of finite strain is

$$\epsilon_{ij}=\frac{1}{2}(u_{i,j}+u_{j,i}+u_{k,i}u_{k,j}) \tag{3}$$

or, in differentiated form,

$$\dot{\epsilon}_{ij}=\frac{1}{2}(\dot{u}_{i,j}+\dot{u}_{j,i}+\dot{u}_{k,i}u_{k,j}+u_{k,i}\dot{u}_{k,j}) \tag{4}$$

The equilibrium equation is

$$[(\delta_{ik}+u_{i,k})\sigma_{jk}]_{,j}=0 \tag{5}$$

The equation giving the surface traction T_i in terms of stresses and displacements on the boundary is

$$T_i=\sigma_{jk}n_j(\delta_{ik}+u_{i,k}) \tag{6}$$

where n_j is the unit external normal to the surface of the undeformed body.

The components of the tensor ϵ_{ij} are not true strains, and neither are the components of the tensor σ_{ij} true stresses. However, the specific virtual work due to a virtual displacement δu_i is given by

$$\delta W=\sigma_{ij}\delta\epsilon_{ij}$$

Therefore, the tensor σ_{ij} may be considered to be the generalized force conjugate to the generalized displacement ϵ_{ij}. In reference 7, this tensor is called k_{ij} and in reference 8 it is called σ^*_{ij}.

As in many of the variational theorems of the mathematical theory of plasticity (see ref. 6), the variational theorem to be stated here is for stress rates and strain rates; that is, if the states of stress and strain throughout the body are known at a given instant, then application of the variational theorem singles out the stress rates or strain rates that actually occur from those rates of stress or strain considered in the enunciation of the theorem. Thus, the operator δ in the formal process of taking the variations is applied only to time derivatives of quantities and not to the quantities themselves. Because of this, for example, $\delta\dot{\epsilon}''_{ij}=0$ because $\dot{\epsilon}''_{ij}$ depends upon the state of stress but not upon the stress rate. (See eq. (1).)

The quantity to be varied was constructed by an inverse process guided by the form of Reissner's theorem and the first theorem of Wang and Prager. By trial and error, the terms necessary to obtain the desired result were found for the integral to be varied. Let $\dot{T}_i=\dot{\bar{T}}_i$ be prescribed on the part S_s of the bounding surface S of a body and let $\dot{u}_i=\dot{\bar{u}}$ be prescribed on the remaining part S_d of the boundary. The variational theorem to be proved is $\delta I=0$ where

$$I=\int_V\left[\dot{\epsilon}_{ij}\dot{\sigma}_{ij}+\frac{1}{2}\dot{u}_{k,i}\dot{u}_{k,j}\sigma_{ij}-\frac{1}{2}(\dot{\epsilon}'_{ij}+2\dot{\epsilon}''_{ij})\dot{\sigma}_{ij}\right]dV-\int_{S_s}\dot{\bar{T}}_i\dot{u}_i\,dS-\int_{S_d}(\dot{u}_i-\dot{\bar{u}}_i)\dot{T}_i\,dS \tag{7}$$

In the first term of the volume integral, $\dot{\epsilon}_{ij}$ is understood to

be written in terms of displacements and velocities (eq. (4)). In the third term of the volume integral, $\dot{\epsilon}'_{ij}$ is understood to be written in terms of stresses and stress rates, whereas $\dot{\epsilon}''_{ij}$ is written in terms of stresses.

The variation of I is given by

$$\delta I=\int_V\left[\dot{\epsilon}_{ij}\delta\dot{\sigma}_{ij}+\dot{\sigma}_{ij}\delta\dot{\epsilon}_{ij}+\sigma_{ij}\dot{u}_{k,i}\,\delta\dot{u}_{k,j}-\frac{1}{2}\,\dot{\sigma}_{ij}\delta\dot{\epsilon}'_{ij}-\frac{1}{2}\,(\dot{\epsilon}'_{ij}+2\dot{\epsilon}''_{ij})\delta\dot{\sigma}_{ij}\right]dV-\int_{S_\sigma}\dot{\bar{T}}_i\delta\dot{u}_i dS-\int_{S_d}[(\dot{u}_i-\dot{\bar{u}}_i)\delta\dot{T}_i+\dot{T}_i\delta\dot{u}_i]\,dS \quad (8)$$

where $\delta\dot{\epsilon}''_{ij}=0$ as previously noted. The second term in the volume integral may be transformed by an integration by parts. The following formula applies:

$$\int_V\dot{\sigma}_{ij}\delta\dot{\epsilon}_{ij}dV=\int_S\dot{\sigma}_{ij}n_j(\delta_{ik}+u_{k,i})\delta\dot{u}_k dS-\int_V[(\delta_{ik}+u_{k,i})\dot{\sigma}_{ij}]_{,j}\,\delta\dot{u}_k dV \quad (9)$$

The third term may also be integrated by parts; thus,

$$\int_V\sigma_{ij}\dot{u}_{k,i}\,\delta\dot{u}_{k,j}\,dV=\int_S\sigma_{ij}n_j\dot{u}_{k,i}\,\delta\dot{u}_k dS-\int_V(\sigma_{ij}\dot{u}_{k,i})_{,j}\,\delta\dot{u}_k dV \quad (10)$$

By using equations (9), (10), and (2), equation (8) becomes

$$\delta I=\int_V\{\dot{\epsilon}_{ij}\delta\dot{\sigma}_{ij}-[(\delta_{ik}+u_{k,i})\dot{\sigma}_{ij}]_{,j}\,\delta\dot{u}_k-(\sigma_{ij}\dot{u}_{k,i})_{,j}\,\delta\dot{u}_k-(\dot{\epsilon}'_{ij}+\dot{\epsilon}''_{ij})\delta\dot{\sigma}_{ij}\}dV+\int_S[\dot{\sigma}_{ij}n_j(\delta_{ik}+u_{k,i})+\sigma_{ij}n_j\dot{u}_{k,i}]\delta\dot{u}_k dS-\int_{S_\sigma}\dot{\bar{T}}_i\delta\dot{u}_i dS-\int_{S_d}[(\dot{u}_i-\dot{\bar{u}}_i)\delta\dot{T}_i+\dot{T}_i\,\delta\dot{u}_i]dS \quad (11)$$

or

$$\delta I=\int_V\left\{(\dot{\epsilon}_{ij}-\dot{\epsilon}'_{ij}-\dot{\epsilon}''_{ij})\,\delta\dot{\sigma}_{ij}-\delta\dot{u}_k\frac{d}{dt}[(\delta_{ik}+u_{k,i})\sigma_{ij}]_{,j}\right\}dV+\int_{S_\sigma}(\dot{T}_i-\dot{\bar{T}}_i)\delta\dot{u}_i dS-\int_{S_d}(\dot{u}_i-\dot{\bar{u}}_i)\delta\dot{T}_i dS \quad (12)$$

The coefficient of each of the variations vanishes by virtue of the stress-strain relations, equilibrium equations, stress boundary conditions, and displacement boundary conditions, respectively. Thus, it is proved that $\delta I=0$ for the stress rates and strain rates that actually occur.

A term may be added to the volume integral to include the effects of body forces if necessary. In some special cases, the boundary integrals should be modified if boundary conditions other than those on T_i or u_i are imposed.

In the next section, a form for I appropriate for application to thin-plate and column problems is developed.

THEORETICAL APPLICATION OF VARIATIONAL THEOREM TO PLATE AND COLUMN PROBLEMS

The variational theorem proved in the preceding section provides a powerful means for deriving an appropriate two-dimensional theory for thin plates subject to creep (or one-dimensional theory for beams and columns) analogous to the two-dimensional theory for thin elastic plates. If certain simplifying assumptions are made about the dependence of the various displacements and stresses on the z-coordinate (measured normal to the middle surface), the integrations with respect to z in the integral I may then be carried out. The equations resulting from $\delta I=0$ then involve only x, y, and t as independent variables.

In this report, the same simplifying assumptions with regard to displacements are made that were made in the elastic case. In particular, the Bernoulli-Euler hypothesis is retained. This hypothesis can be regarded as a consequence of the equilibrium equations and the strain-displacement equations as applied to a thin plate. The transverse shear stresses vanish on the surface of the plate and are thus expected to be negligible (compared with inplane stresses) throughout the thickness. By any of the common stress-strain relations (elastic, plastic, or creep), it follows that the transverse shear strains are negligible. If w is assumed to be approximately independent of z, then from

$$\gamma_{xz}=\frac{\partial w}{\partial x}+\frac{\partial u}{\partial z}=0 \quad (13)$$

$$\gamma_{yz}=\frac{\partial w}{\partial y}+\frac{\partial v}{\partial z}=0 \quad (14)$$

it follows that

$$u=U-z\,\frac{\partial W}{\partial x} \quad (15)$$

$$v=V-z\,\frac{\partial W}{\partial y} \quad (16)$$

$$w=W \quad (17)$$

where U, V, and W can now be identified as the displacements of the middle surface. Equations (15), (16), and (17) express the Bernoulli-Euler hypothesis.

A more rigorous treatment, in which the dependence of the various quantities on the z-coordinate is deduced by expanding them in powers of a thickness parameter, might be possible. In some derivations of plate equations, U, V, and W are interpreted as weighted averages of u, v, and w. (See refs. 4 and 9, for example.) However, the consequences of assuming equations (15), (16), and (17) to be true are expected to lead to accurate results for thin plates.

Equation (3) for the finite strains in terms of displacements is simplified by dropping all nonlinear terms except those containing powers or products of slopes. This simplification leads to the Von Kármán equations for an elastic plate. The resulting equations for the strains are

$$\epsilon_x=\frac{\partial U}{\partial x}-z\,\frac{\partial^2 W}{\partial x^2}+\frac{1}{2}\left(\frac{\partial W}{\partial x}\right)^2 \quad (18)$$

$$\epsilon_y=\frac{\partial V}{\partial y}-z\,\frac{\partial^2 W}{\partial y^2}+\frac{1}{2}\left(\frac{\partial W}{\partial y}\right)^2 \quad (19)$$

$$2\epsilon_{xy}=\gamma_{xy}=\frac{\partial U}{\partial y}+\frac{\partial V}{\partial x}-2z\,\frac{\partial^2 W}{\partial x\partial y}+\frac{\partial W}{\partial x}\,\frac{\partial W}{\partial y} \quad (20)$$

$$\epsilon_z=\gamma_{xz}=\gamma_{yz}=0 \tag{21}$$

In order to be consistent with these approximations, only terms containing powers or products of rates of slope are retained in the second term of the volume integral in I. (See eq. (7).)

Before the integration with respect to z can be carried out in the expression for I, the dependence of the stresses upon z must be assumed. Unlike the elastic case, the stresses do not vary linearly through the thickness, even though the strains do vary linearly. The particular advantage of the generalized form of Reissner's variational theorem for use in the present problem is that approximations for the stresses and strains can be made independently. Thus, there is no necessity to invert the stress-strain relations in order to determine appropriate approximations for the stresses; in fact, to invert the stress-strain relations would generally be impossible.

Many possibilities exist for assuming the form of the stresses as functions of z, and each possibility leads to a different set of plate equations; thus, no particular system of equations can be set up which can be called the creep equations for a plate, column, or beam. Generally, it is advantageous to assume the form of the stresses and displacements as functions of x and y also, in which case all the integrations in I may be performed. Setting the variation of the resulting expression equal to zero leads to a set of ordinary differential equations in which the independent variable is the time. Further details of the application of the variational theorem to creep-collapse and creep-bending problems of columns and plates can best be communicated by means of examples, two of which are given in the following sections.

EXAMPLE OF APPLICATION OF VARIATIONAL THEOREM TO CREEP COLLAPSE OF COLUMNS

A simplified treatment of the problem of creep collapse of the uniform, pin-ended, rectangular-section column shown in figure 1 is given as the first example. The plastic part of the strain is omitted, and the stress-strain relation is assumed to be

$$\dot{\epsilon}=\frac{\dot{\sigma}}{E}+\lambda p t^{p-1}\sigma^m \tag{22}$$

where the second term on the right includes the effects of primary and secondary creep. The axial displacement u is assumed to be given by

$$u=U-z\frac{\partial W}{\partial x} \tag{23}$$

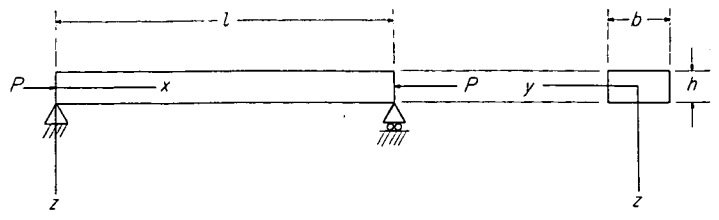

FIGURE 1.—Pin-ended rectangular-section column.

and the axial strain ϵ by

$$\epsilon=\frac{\partial U}{\partial x}-z\frac{\partial^2 W}{\partial x^2}+\frac{1}{2}\left(\frac{\partial W}{\partial x}\right)^2 \tag{24}$$

In the present case, the following terms enter into the expression for I:

$$\left.\begin{aligned}
&\dot{\sigma}_{ij}\dot{\epsilon}_{ij}=\dot{\sigma}\left(\frac{\partial\dot{U}}{\partial x}+\frac{\partial W}{\partial x}\frac{\partial\dot{W}}{\partial x}-z\frac{\partial^2\dot{W}}{\partial x^2}\right)\\
&\frac{1}{2}\sigma_{ij}\dot{u}_{k,i}\dot{u}_{k,j}=\frac{1}{2}\sigma\left(\frac{\partial\dot{W}}{\partial x}\right)^2\\
&\frac{1}{2}(\dot{\epsilon}'_{ij}+2\dot{\epsilon}''_{ij})\dot{\sigma}_{ij}=\frac{\dot{\sigma}^2}{2E}+\lambda p t^{p-1}\dot{\sigma}\sigma^m\\
&\int_{S_\sigma}\dot{\bar{T}}_i\dot{u}_i\,dS=-P\dot{U}(l,t)=0 \qquad (P \text{ is constant})
\end{aligned}\right\} \tag{25}$$

where $U(0, t)=0$. The special form of I for the column is then

$$I=\int_V\left[\dot{\sigma}\left(\frac{\partial\dot{U}}{\partial x}+\frac{\partial W}{\partial x}\frac{\partial\dot{W}}{\partial x}-z\frac{\partial^2\dot{W}}{\partial x^2}\right)+\frac{1}{2}\sigma\left(\frac{\partial\dot{W}}{\partial x}\right)^2-\frac{\dot{\sigma}^2}{2E}-\lambda p t^{p-1}\dot{\sigma}\sigma^m\right]dV \tag{26}$$

For simplicity, the variation of σ in the z-direction is assumed to be linear; thus,

$$\sigma=\sigma_0^*+\frac{z}{h}\sigma_1^* \tag{27}$$

The variation of displacements and stresses in the x-direction is assumed as follows:

$$\left.\begin{aligned}
&W=hW_0\sin\frac{\pi x}{l}\\
&U=U_0 x\\
&\sigma_0^*=\frac{P}{bh}\sigma_0\\
&\sigma_1^*=\frac{P}{bh}\sigma_1\sin\frac{\pi x}{l}
\end{aligned}\right\} \tag{28}$$

where h is the thickness of the column, b is the width, and l is the length. The dimensionless quantities on the right-hand sides of equations (28) are functions of time alone. The integrations in I may be carried out, and the result is (for $m=3$)

$$I=\frac{P^2 l}{bhE}\left[\frac{P_c}{P}\left(6\dot{\sigma}_0W_0\dot{W}_0+\frac{1}{2}\dot{\sigma}_1\dot{W}_0+3\sigma_0\dot{W}_0^2\right)-\frac{1}{2}\left(\dot{\sigma}_0^2+\frac{1}{24}\dot{\sigma}_1^2\right)+\frac{bhE}{P}\dot{\sigma}_0\dot{U}_0-\lambda p t^{p-1}E\left(\frac{P}{bh}\right)^2\left(\sigma_0^3\dot{\sigma}_0+\frac{1}{8}\sigma_0\sigma_1^2\dot{\sigma}_0+\frac{1}{8}\sigma_0^2\sigma_1\dot{\sigma}_1+\frac{3}{640}\sigma_1^3\dot{\sigma}_1\right)\right] \tag{29}$$

where P_c is the buckling load of the column. The system of

differential equations to which the present approximate analysis leads is obtained by equating to zero the partial derivatives of I with respect to each of the dotted quantities; thus, the result is

$$\left.\begin{aligned}
&\dot{\sigma}_0=0\\
&6\dot{\sigma}_0W_0+\frac{1}{2}\dot{\sigma}_1+6\sigma_0\dot{W}_0=0\\
&6\frac{P_c}{P}W_0\dot{W}_0-\dot{\sigma}_0+\frac{bhE}{P}\dot{U}_0-\lambda pt^{p-1}E\left(\frac{P}{bh}\right)^2\left(\sigma_0^3+\frac{1}{8}\sigma_0\sigma_1^2\right)=0\\
&\frac{1}{2}\frac{P_c}{P}\dot{W}_0-\frac{1}{24}\dot{\sigma}_1-\lambda pt^{p-1}E\left(\frac{P}{bh}\right)^2\left(\frac{1}{8}\sigma_0^2\sigma_1+\frac{3}{640}\sigma_1^3\right)=0
\end{aligned}\right\}\quad(30)$$

The solution of this set of equations depends on the initial conditions assigned. Suppose that the column has an initial bow in the form of a half sine wave before the load P is applied. If the load is assumed to be applied rapidly, but not rapidly enough to introduce inertia effects, then the initial conditions for the creep problem are those existing immediately after the load is applied. If the initial bow is given by

$$h\Delta\sin\frac{\pi x}{l}$$

the initial conditions for the dimensionless quantities are

$$\left.\begin{aligned}
W_0(0)&=\frac{\Delta}{1-\frac{P}{P_c}}\\
\sigma_0(0)&=-1\\
\sigma_1(0)&=\frac{12\Delta}{1-\frac{P}{P_c}}
\end{aligned}\right\}\quad(31)$$

The problem can now be reduced to solving the following equation for W_0:

$$\left(\frac{P_c}{P}-1\right)\dot{W}_0-3\lambda pt^{p-1}E\left(\frac{P}{bh}\right)^2\left(W_0+\frac{27}{5}W_0^3\right)=0\quad(32)$$

Except for differences in notation, this equation is similar to one given by Kempner (eq. (27) of ref. 10) for an idealized two-element column problem solved by a collocation method, except that the constant $^{27}/_{5}$ is replaced by $^{3}/_{5}$ and p is replaced by 1. Equation (32) is easily integrated to give

$$t^p=\frac{\frac{P_c}{P}-1}{6\lambda E\left(\frac{P}{bh}\right)^2}\log\left[\frac{W_0^2}{1+\frac{27}{5}W_0^2}\,\frac{1+\frac{27}{5}W_0^2(0)}{W_0^2(0)}\right]\quad(33)$$

The collapse time t_c is found by taking the limit as $W_0\to\infty$; thus,

$$t_c=\left\{\frac{\frac{P_c}{P}-1}{6\lambda E\left(\frac{P}{bh}\right)^2}\log\left[1+\frac{5\left(1-\frac{P}{P_c}\right)^2}{27\Delta^2}\right]\right\}^{1/p}\quad(34)$$

The foregoing analysis is intended merely as an example; more elaborate assumptions as to the stress variation through the thickness and the variation of the several unknowns along the length of the column lead to systems of nonlinear differential equations which may be solved by some numerical method.

EXAMPLE OF APPLICATION OF VARIATIONAL THEOREM TO CREEP BENDING OF PLATES

For a second example, the bending of a simply supported circular plate under a constant uniform load is considered. (See fig. 2.) For simplicity, the analysis is restricted to the time during which the deflections are small so that the linear strain-displacement relations can apply. The general form for I in this case is

$$I=\int_V\left[\dot{\epsilon}_{ij}\dot{\sigma}_{ij}-\frac{1}{2}(\dot{\epsilon}'_{ij}+2\dot{\epsilon}''_{ij})\dot{\sigma}_{ij}\right]dV\quad(35)$$

Here, again, the effects of plasticity are neglected. The creep law is that given by equation (1). The various terms in the integrand must be specialized to apply to the present plate problem. In polar coordinates the shear stress and shear strain are zero from symmetry, and the remaining stresses

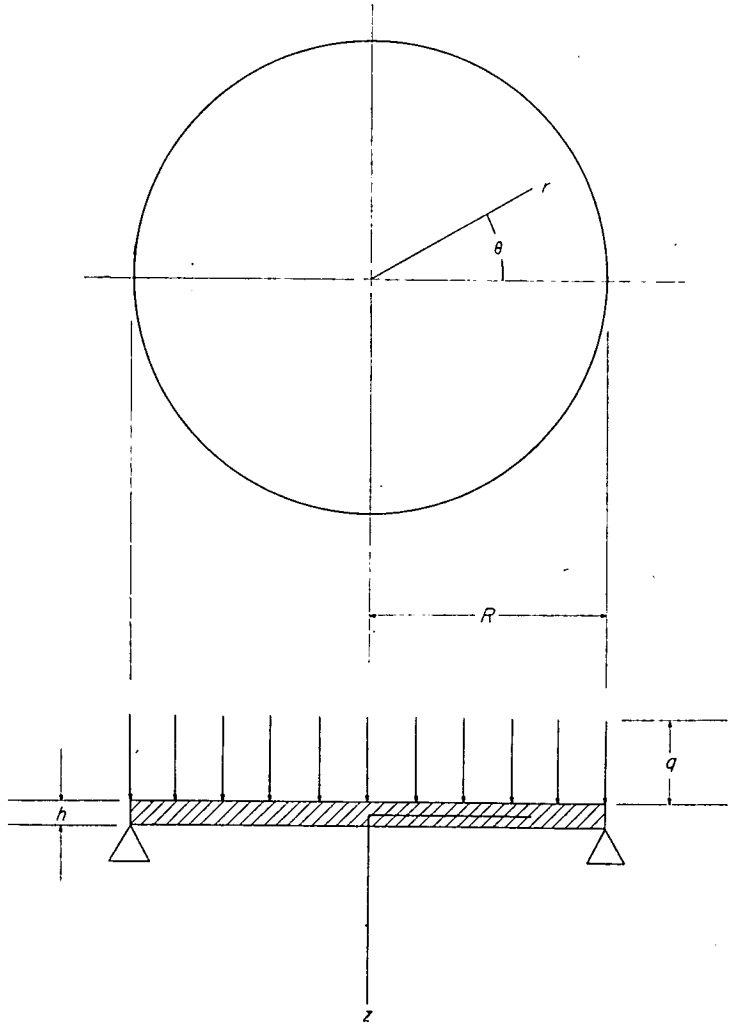

FIGURE 2.—Simply supported circular plate with lateral load.

and strains give

$$\dot{\epsilon}_{ij}\dot{\sigma}_{ij}=\dot{\epsilon}_r\dot{\sigma}_r+\dot{\epsilon}_t\dot{\sigma}_t \tag{36}$$

If a linear strain distribution through the thickness is assumed,

$$\dot{\epsilon}_{ij}\dot{\sigma}_{ij}=-z\frac{\partial^2\dot{W}}{\partial r^2}\dot{\sigma}_r-\frac{z}{r}\frac{\partial\dot{W}}{\partial r}\dot{\sigma}_t \tag{37}$$

For the elastic part of the second term in equation (35)

$$\frac{1}{2}\dot{\epsilon}'_{ij}\dot{\sigma}_{ij}=\frac{1}{2E}(\dot{\sigma}_r^2+\dot{\sigma}_t^2-2\mu\dot{\sigma}_r\dot{\sigma}_t) \tag{38}$$

For the creep part of the second term,

$$\dot{\epsilon}''_{ij}\dot{\sigma}_{ij}=f(J_2)s_{ij}\dot{\sigma}_{ij}=f(J_2)\dot{J}_2 \tag{39}$$

Further, it is assumed that the form of f is such that

$$\dot{\epsilon}''_{ij}\dot{\sigma}_{ij}=\lambda J_2^m\dot{J}_2 \tag{40}$$

In this example, the exponent m is taken to be unity; this assumption corresponds to the cubic law in the uniaxial stress case. Then,

$$\dot{\epsilon}''_{ij}\dot{\sigma}_{ij}=\frac{1}{9}\lambda(\sigma_r^2+\sigma_t^2-\sigma_r\sigma_t)[\dot{\sigma}_r(2\sigma_r-\sigma_t)+\dot{\sigma}_t(2\sigma_t-\sigma_r)] \tag{41}$$

The variation of the stresses through the thickness is assumed to be linear; thus,

$$\left.\begin{aligned}\sigma_r&=\frac{12M_rz}{h^3}\\ \sigma_t&=\frac{12M_tz}{h^3}\end{aligned}\right\} \tag{42}$$

Doubtless, after creep is well established, the stress distribution cannot actually be linear in the thickness direction, but, for purposes of this example, such an approximation is sufficient. When integration in the z-direction is carried out,

$$I=-\int_0^{2\pi}\int_0^1\left\{\rho M_r\dot{W}''+\dot{M}_t\dot{W}'+\frac{6R^2\rho}{Eh^3}(\dot{M}_r^2+\dot{M}_t^2-2\mu\dot{M}_r\dot{M}_t)+\frac{144}{5}\frac{\lambda R^2\rho}{h^7}(M_r^2+M_t^2-M_rM_t)[\dot{M}_r(2M_r-M_t)+\dot{M}_t(2M_t-M_r)]\right\}d\rho\,d\theta \tag{43}$$

where R is the radius of the plate, $\rho=r/R$, and the primes denote differentiation with respect to ρ. The following expressions, based on the elastic solution for this problem, are assumed for the displacements and moments:

$$\left.\begin{aligned}W&=h(1-\rho^2)(W_0+\rho^2W_1)\\ M_r&=Eh^2M_{r,0}(1-\rho^2)\\ M_t&=Eh^2(M_{t,0}+\rho^2M_{t,1})\end{aligned}\right\} \tag{44}$$

Equations (44) are substituted into equation (43) and the integrations carried out. Then, on equating to zero the partial derivatives with respect to the dotted quantities, the following equations are obtained:

$$\left.\begin{aligned}&\dot{M}_{r,0}+2\dot{M}_{t,0}+\dot{M}_{t,1}=0\\ &3\dot{M}_{r,0}+\dot{M}_{t,1}=0\\ &\dot{W}_0+\dot{W}_1-2\left(\frac{R}{h}\right)^2[2\dot{M}_{r,0}-\mu(3\dot{M}_{t,0}+\dot{M}_{t,1})]=2\frac{144\lambda E^3}{5}\left(\frac{R}{h}\right)^2I_1\\ &\dot{W}_0-3\left(\frac{R}{h}\right)^2(2\dot{M}_{t,0}+\dot{M}_{t,1}-\mu\dot{M}_{r,0})=\frac{144\lambda E^3}{5}\left(\frac{R}{h}\right)^2I_2\\ &3\dot{W}_0+\dot{W}_1-6\left(\frac{R}{h}\right)^2(3\dot{M}_{t,0}+2\dot{M}_{t,1}-\mu\dot{M}_{r,0})=6\frac{144\lambda E^3}{5}\left(\frac{R}{h}\right)^2I_3\end{aligned}\right\} \tag{45}$$

where

$$\left.\begin{aligned}(Eh^2)^3I_1&=\int_0^1\rho(1-\rho^2)(2M_r-M_t)(M_r^2-M_rM_t+M_t^2)d\rho\\ (Eh^2)^3I_2&=\int_0^1\rho(2M_t-M_r)(M_r^2-M_rM_t+M_t^2)d\rho\\ (Eh^2)^3I_3&=\int_0^1\rho^3(2M_t-M_r)(M_r^2-M_rM_t+M_t^2)d\rho\end{aligned}\right\} \tag{46}$$

Equations (45) can be solved for the five dotted quantities to give

$$\left.\begin{aligned}\dot{W}_0&=\frac{144\lambda E^3}{5}\left(\frac{R}{h}\right)^2\left[I_2-\frac{3(1+\mu)}{8}(3I_3-I_1-I_2)\right]\\ \dot{W}_1&=\frac{144\lambda E^3}{5}\left(\frac{R}{h}\right)^2\left[\frac{3}{2}(I_1-I_2+I_3)+\frac{3(1+\mu)}{8}(3I_3-I_1-I_2)\right]\\ \dot{M}_{r,0}&=\dot{M}_{t,0}=-\frac{1}{3}\dot{M}_{t,1}=\frac{18\lambda E^3}{5}(3I_3-I_1-I_2)\end{aligned}\right\} \tag{47}$$

where the expressions for I_1, I_2, and I_3 are

$$\left.\begin{aligned}I_1&=\frac{1}{40}(3M_{t,0}^3-3M_{t,0}^2M_{t,1}-3M_{t,0}M_{t,1}^2-M_{t,1}^3)\\ I_2&=\frac{5}{40}(5M_{t,0}^3+9M_{t,0}^2M_{t,1}+7M_{t,0}M_{t,1}^2+2M_{t,1}^3)\\ I_3&=\frac{1}{40}(14M_{t,0}^3+32M_{t,0}^2M_{t,1}+27M_{t,0}M_{t,1}^2+8M_{t,1}^3)\end{aligned}\right\} \tag{48}$$

Equations (47) are a system of first-order nonlinear differential equations with time as the independent variable. The initial conditions required to determine the solution are given by the elastic solution to the loaded plate. (See ref. 11.)

Thus,

$$\left.\begin{aligned} W_0(0)&=\frac{q}{E}\left(\frac{R}{h}\right)^4\frac{3(5+\mu)(1-\mu)}{16}\\ W_1(0)&=-\frac{q}{E}\left(\frac{R}{h}\right)^4\frac{3(1-\mu^2)}{16}\\ M_{r,0}(0)&=M_{t,0}(0)=\frac{q}{E}\left(\frac{R}{h}\right)^2\frac{3+\mu}{16}\\ M_{t,1}(0)&=-\frac{q}{E}\left(\frac{R}{h}\right)^2\frac{1+3\mu}{16} \end{aligned}\right\} \tag{49}$$

Since $\dot{M}_{r,0}=\dot{M}_{t,0}$ and $M_{r,0}(0)=M_{t,0}(0)$, it follows that $M_{r,0}=M_{t,0}$. Equations (47) with initial conditions of equations (49) can be integrated numerically by the modified Euler method (ref. 12). Numerical calculations were made for a plate having a ratio of radius to thickness of 50. The value of E used was 7.4×10^6 psi and the value of λE^3 used was 2.72×10^6 per hour. These values together with the cubic uniaxial creep law correspond approximately to characteristics of 2024–T3 aluminum alloy at a temperature of 600° F. (See ref. 2.) Results showing the time history of the maximum deflection of a circular plate under lateral load are presented in figure 3.

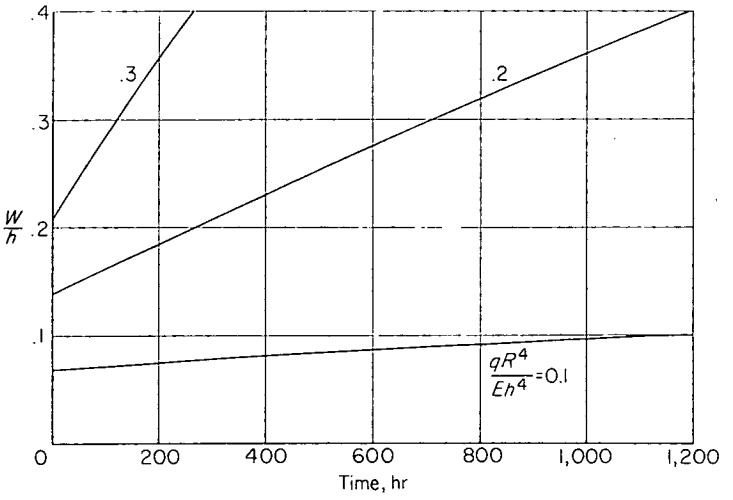

FIGURE 3.—Time history of maximum deflection of simply supported circular plate under lateral load. $\frac{R}{h}=50$; material, 2024–T3 aluminum alloy at 600° F.

CONCLUDING REMARKS

A variational theorem for creep has been formulated which is an extension of a variational theorem developed by Reissner. Various systems of equations leading to approximate solutions to problems of the creep behavior of plates, columns, beams, and shells may be obtained by using direct methods of the calculus of variations in conjunction with the stated theorem. The application of the theorem is illustrated for plates and columns by the solution of two sample problems.

REPORT 1343

A PHENOMENOLOGICAL RELATION BETWEEN STRESS, STRAIN RATE, AND TEMPERATURE FOR METALS AT ELEVATED TEMPERATURES [1]

By Elbridge Z. Stowell

SUMMARY

A phenomenological relation between stress, strain rate, and temperature is suggested to account for the behavior of polycrystalline metals above the equicohesive temperature. The properties of the metal included in the relation are elasticity, linear thermal expansion, and viscosity. The relation may be integrated under various conditions to provide information on creep rates, creep rupture, stress-strain curves, and rapid-heating curves. It is shown that for one material—7075–T6 aluminum-alloy sheet—the information yielded by the relation for these four applications agrees reasonably well with test data.

INTRODUCTION

The behavior of metals at elevated temperatures is constantly becoming a more important problem. Not only must information be at hand concerning creep at these temperatures, but information must also be available concerning when rupture might be expected if the creep were allowed to continue, what the stress-strain curve is likely to be at some particular temperature and strain rate, and how the material will behave when rapidly heated to a high temperature. It would be a useful achievement if some fundamental law characteristic of the material could be found, such that these and other apparently distinct problems could be shown to be simply different aspects of the application of one law.

In studies of the creep of metals, it has become apparent that the creep behavior at elevated temperatures is different from that at low temperatures. For relatively pure metals, the line of demarcation for temperature occurs at about one-half the melting point and may be tentatively identified with the equicohesive temperature. In the high-temperature region, certain laws have been found and explicitly stated (ref. 1). These laws appear to give some promise that the behavior of metals in this region may be predicted for effects other than creep.

Creep is characterized by an initial transient or primary region which is followed by a steady or secondary region in which viscous flow occurs and finally by an accelerating or tertiary region which leads to rupture. A theory based on rate-process considerations is already available and accounts in a qualitative manner for the main effects shown by the steady creep in the high-temperature region (ref. 2). For stable metals, this theory requires a knowledge of only three constants to specify the creep behavior: one constant is roughly predictable from the melting point, and the other two must be determined from tests.

In this report, a phenomenological relation between stress, strain rate, and temperature is suggested for this region, and this relation utilizes the existing rate-process theory for steady creep. The relation is not an equation of state of the type proposed by Hollomon (ref. 3) but is an equation of "rate of change of state." Since different integrals of this relation exist under different conditions, there is no single "equation of state" in this case. These integrals are applied to creep, creep rupture, stress-strain curves, and rapid-heating curves, and comparisons of these numerical results are made with experimental results for 7075–T6 aluminum-alloy sheet.

SYMBOLS

ϵ	strain
t	time, hr
$\dot{\epsilon}$	strain rate, per hr
$\dot{\epsilon}_o$	strain rate used in obtaining stress-strain curves, per hr
σ	stress, ksi
σ_o	constant, ksi
σ_{lim}	limiting stress, ksi
E	Young's modulus, ksi
α	linear expansion coefficient, per °K
T	temperature, °K unless otherwise indicated
$\dot{T}_o$	rate of temperature change, °K per hr unless otherwise indicated
$\Delta T=\dot{T}_o t$	
ΔH	activation energy, cal per mole
R	gas constant, taken as 2 cal per mole per °K
s	constant, per hr per °K
$\beta=\frac{\dot{\epsilon}_o}{2sT}e^{\frac{\Delta H}{RT}}$	
$M=\frac{\sqrt{1+\beta^2}}{2\beta}\frac{E\epsilon}{\sigma_o}$

STATEMENT OF PHENOMENOLOGICAL RELATION

A metal undoubtedly retains a certain elasticity at elevated temperatures, even though the elastic range is reduced from that prevailing at lower temperatures. The elasticity resides in the crystalline grains and is a measure of the resistance of the crystal lattice to distortion by stress. In addition to the elasticity, a polycrystalline metal also possesses a quasi-viscosity in the high-temperature region; in this region the application of a constant stress will result in a constant strain rate. Also, thermal expansion (or contraction) due to temperature change will create an apparent strain which can contribute to the total strain.

The suggested phenomenological relation which includes all these properties and which takes into account possible temperature changes may be stated as follows:

$$\frac{d\epsilon}{dt}=\dot{\epsilon}=\frac{d}{dt}\left(\frac{\sigma}{E}\right)+\alpha\frac{dT}{dt}+2sTe^{-\frac{\Delta H}{RT}}\sinh\frac{\sigma}{\sigma_o} \tag{1}$$

In this relation the first term on the right supplies the contribution to the strain rate due to elasticity; the middle term, the contribution due to possible thermal expansion; and the final term, the contribution due to viscosity. A relation somewhat similar to this but without the middle term has been proposed for plastics. (See ref. 4.)

The form of the viscous term is taken from reference 2 and is now well established. The exponential term describes the principal effect of temperature. The hyperbolic sine term describes the effect of stress. Kauzmann in reference 2 gave this term as $\sinh\left(m\frac{\sigma}{T}\right)$ where m is a constant, but it has been demonstrated repeatedly by tests that the argument of the term is independent of temperature and is of the form $\frac{\sigma}{\sigma_o}$, where σ_o is a constant. The remainder of the expression, which consists of a number of individual constants multiplied by the temperature T as given in reference 2, is replaced here by $2sT$; the factor 2 is retained for convenience.

The quantities E and α are values which are usually known as functions of the temperature. The quantities s, $\Delta H/R$, and σ_o are found from measurements of the steady creep of the metal under constant stress and temperature. A range of temperature in the high-temperature region and also a range of stress are required to establish $\Delta H/R$ and σ_o, respectively.

APPLICATIONS

With different conditions imposed upon the metal, the suggested relation should generate in turn the laws governing such phenomena as steady creep, creep rupture, stress-strain characteristics, and behavior under rapid-heating conditions. These laws are derived from equation (1).

STEADY CREEP

If stress σ and temperature T are constant, equation (1) reduces to

$$\dot{\epsilon}=2sTe^{-\frac{\Delta H}{RT}}\sinh\frac{\sigma}{\sigma_o} \tag{2}$$

or

$$\dot{\epsilon}=sTe^{-\frac{\Delta H}{RT}}e^{\frac{\sigma}{\sigma_o}} \qquad (\sigma\gg\sigma_o) \tag{2a}$$

which indicates steady creep. Equation (2a) may also be written as

$$\frac{\sigma}{\sigma_o}=\frac{\Delta H}{RT}+\log_e\dot{\epsilon}-\log_e sT \tag{3}$$

in which $\log_e sT$ is substantially constant over a limited temperature range. Stress plotted against $\log_e\dot{\epsilon}$ should, therefore, yield straight lines with slope σ_o which are displaced from one another at different temperatures by amounts depending mainly on the value of $\frac{\Delta H}{RT}$. Stress is sometimes plotted against the parameter $\frac{\Delta H}{RT}+\log_e\dot{\epsilon}$ (ref. 5) to demonstrate that data taken at different temperatures will fall on a single curve.

CREEP RUPTURE

At constant stress and temperature, the strain at a time t after the application of stress is

$$\epsilon=\dot{\epsilon}t$$

since the creep is steady under these conditions.

Reference 6 discloses as an experimental fact that if t_r is the time to rupture under conditions of creep, then

$$\dot{\epsilon}t_r\approx\text{Constant}=\epsilon_r$$

Thus,

$$\dot{\epsilon}=\frac{\epsilon_r}{t_r}$$

and equation (3) may be rewritten as

$$\frac{\sigma_r}{\sigma_o}=\frac{\Delta H}{RT}-\log_e t_r+\log_e\frac{\epsilon_r}{sT} \tag{3a}$$

Since the last term is substantially constant, the rupture stress σ_r plotted against the parameter $\frac{\Delta H}{RT}-\log_e t_r$ should yield a single straight line with slope σ_o. Such a parameter has been employed in the correlation of creep-rupture tests (ref. 7).

STRESS-STRAIN CURVES

At constant temperature, equation (1) becomes

$$\dot{\epsilon}=\frac{1}{E}\frac{d\sigma}{dt}+2sTe^{-\frac{\Delta H}{RT}}\sinh\frac{\sigma}{\sigma_o} \tag{4}$$

Obviously, if the stress is applied very rapidly, the effect of the final viscous term may be negligible compared with the term $\frac{1}{E}\frac{d\sigma}{dt}$; thus, the material may appear to be elastic.

If an attempt is made to hold the strain rate constant, as is sometimes done with conventional testing machines, by setting the strain rate equal to the testing rate $\dot{\epsilon}_o$, a differential equation in σ results, and the solution which is a

family of theoretical stress-strain curves is given as follows:

$$\frac{\sigma}{\sigma_o}=\log_e \frac{\sqrt{1+\beta^2}+(1+\beta)\tanh M}{\sqrt{1+\beta^2}+(1-\beta)\tanh M} \tag{5}$$

where

$$\beta=\frac{\dot{\epsilon}_o}{2sT}e^{\frac{\Delta H}{RT}}$$

$$M=\frac{\sqrt{1+\beta^2}}{2\beta}\frac{E\epsilon}{\sigma_o}$$

$$\epsilon=\dot{\epsilon}_o t$$

Replacement of tanh M by exponentials gives

$$\frac{\sigma}{\sigma_o}=\log_e \frac{(\sqrt{1+\beta^2}+1+\beta)e^{2M}+\sqrt{1+\beta^2}-1-\beta}{(\sqrt{1+\beta^2}+1-\beta)e^{2M}+\sqrt{1+\beta^2}-1+\beta}$$

and since ordinarily $\beta \gg 1$, the expression for the stress-strain curves becomes

$$\frac{\sigma}{\sigma_o}=\log_e \frac{(2\beta+1)e^{2M}-1}{e^{2M}+2\beta-1} \tag{6}$$

At the lower end of the curves where the strain is small, M is small, $e^{2M}\approx 1+2M$, and

$$\frac{\sigma}{\sigma_o}=\log_e \frac{2\beta+2M+4M\beta}{2\beta+2M}=\log_e\left(1+\frac{2M\beta}{M+\beta}\right)\approx\frac{2M\beta}{M+\beta}\approx 2M=\frac{E\epsilon}{\sigma_o}$$

which shows that the initial portion of the curves is elastic. At the upper end of the curves where the strains are large, M is large, and from equation (6),

$$\frac{\sigma_{lim}}{\sigma_o}=\log_e(2\beta+1)\approx\log_e 2\beta \tag{7}$$

where σ_{lim} is the limiting stress which can be developed at that temperature and strain rate.

As a corollary, note that the following equation results when the value of 2β is substituted into equation (7):

$$\dot{\epsilon}_o=sTe^{-\frac{\Delta H}{RT}e^{\frac{\sigma_{lim}}{\sigma_o}}}$$

which is of the same form as equation (2a) for steady creep. Thus, the limiting stress σ_{lim} obtainable bears the same relation to the testing rate $\dot{\epsilon}_o$ that any creep stress σ bears to its corresponding creep rate $\dot{\epsilon}$. This correlation has been noted experimentally by Sherby and Dorn in reference 5 where the ultimate strength in tension is used for σ_{lim}.

RAPID-HEATING CURVES

The material composing the skin of a high-speed airplane or missile may be subjected to rapid increases in temperature as a result of aerodynamic heating during flight. It is important to know what to expect from the material under such conditions.

In equation (1), let $\frac{dT}{dt}=\dot{T}_o$ in which $\dot{T}_o$ is a constant. Then, for a constant stress $\sigma \gg \sigma_o$,

$$\epsilon=\int \dot{\epsilon}\,dt=\sigma\int d\left(\frac{1}{E}\right)+\alpha\dot{T}_o t+se^{\frac{\sigma}{\sigma_o}}\int Te^{-\frac{\Delta H}{RT}}dt \tag{8}$$

in which allowance should be made for the variation of E and α with temperature. Equation (8) may be written in terms of finite increments as follows:

$$\epsilon=\frac{\sigma}{E}+\alpha\,\Delta T+se^{\frac{\sigma}{\sigma_o}}\sum Te^{-\frac{\Delta H}{RT}}\Delta t \tag{9}$$

where

$$\Delta T=\dot{T}_o t$$

The initial term $\frac{\sigma}{E}$ gives the contribution to the total strain of the application of stress, the second term gives the contribution due to thermal expansion, and the last term gives the contribution due to viscosity.

COMPARISON OF THEORY AND EXPERIMENT

A comparison of the laws generated by the assumed relation of equation (1) with experiments performed on one material, 7075–T6 aluminum-alloy sheet, is given in this section.

The alloy is in the solution heat treated and aged condition. Further exposure to elevated temperature results in overaging. The material becomes unstable and suffers a marked reduction in strength with time when subsequently heated in the range from 300° to 600° F. In addition, different batches of the material may vary somewhat among themselves in properties. In view of this variability in the material, the constants in the viscous term were adjusted in each case to give a reasonable fit to the data. Table I shows the constants used in the calculations.

The temperature which separates the high and the low regions is about 300° F for this alloy. Tests performed at temperatures below 300° F should not be expected to show any agreement with calculations. In most cases, the results of such tests have been included to show the extent of the disagreement.

TABLE I

VALUES OF THE CONSTANTS USED IN THE APPLICATIONS

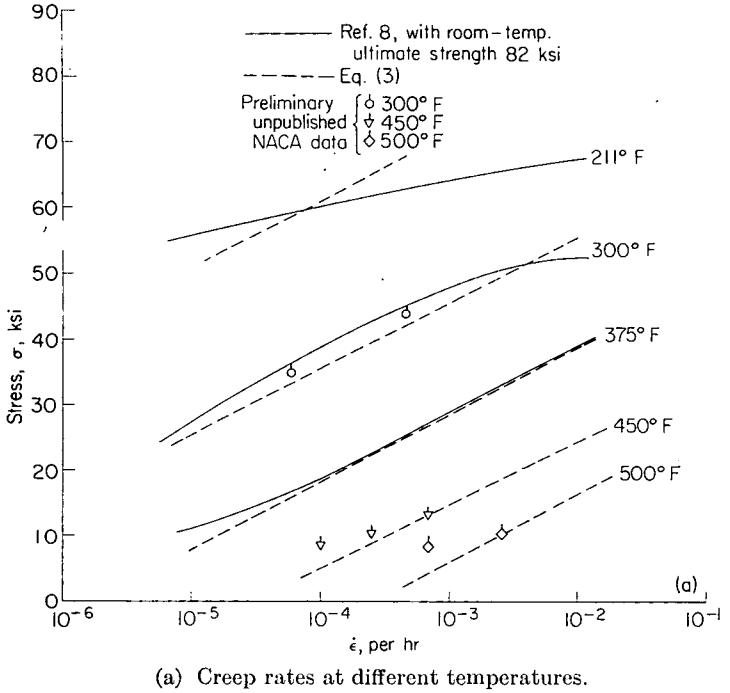

Figure	Application	Reference for experimental data	Equations used in calculations	Constants used in viscous term		
				ΔH, cal per mole	σ_o, ksi	s, per hr per °K
1(a)	Steady creep	8	(3)	35,800	4.3	1.62×10^5

STEADY CREEP

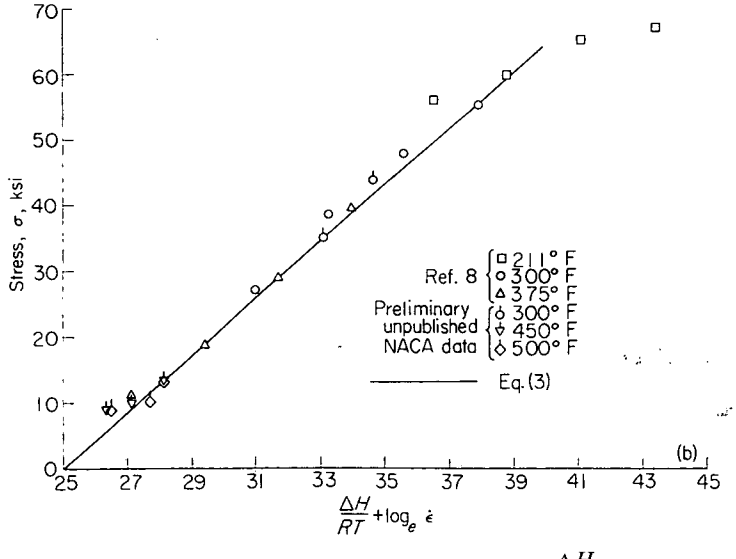

Figure 1 (a) shows steady-creep data for 7075–T6 aluminum-alloy sheet. These data are obtained from reference 8 (solid curves) and from preliminary unpublished NACA data (points). The dashed lines were computed from equation (3) by using the appropriate constants in table I. The dashed lines show a good fit to the data from reference 8 at 300° F and 375° F; the disagreement at 211° F is plainly evident. The dashed lines computed for 450° F and 500° F go through the points obtained at the higher stresses in each case; whereas, the lower stresses give somewhat less creep than would be expected from equation (3). This peculiarity at low stresses has been observed previously by Dorn and Shepard (ref. 1).

Figure 1 (b) shows the same data plotted against the parameter $\frac{\Delta H}{RT}+\log_e \dot{\epsilon}$. All the data fit reasonably well with the calculated curve (eq. (3)) with the exception of the points obtained at 211° F.

(a) Creep rates at different temperatures.

FIGURE 1.—Steady creep rates for 7075–T6 aluminum-alloy sheet.

(b) Correlation of creep rates with parameter $\frac{\Delta H}{RT}+\log_e \dot{\epsilon}$.

FIGURE 1.—Concluded.

CREEP RUPTURE

Figure 2 shows the creep-rupture data, taken from reference 8 and from preliminary unpublished NACA data, plotted against the parameter $\frac{\Delta H}{RT}-\log_e t_r$, where t_r is the rupture time at the stress σ_r and the temperature T. Data show that a reasonable value for the constant ϵ_r is 0.0077; the straight line computed from equation (3a), which uses this value and the values given in table I, goes through the line of points, with the exception as noted before of the very lowest stresses and of the points at 212° F.

STRESS-STRAIN CURVES

Several investigators in the past have pointed out relations between creep and stress-strain data; for example, Hollomon (ref. 3) suggested a graphical procedure for passing from one to the other. In the present report, the passage is accomplished analytically through equation (6).

Figure 3 shows stress-strain curves for the 7075–T6 aluminum-alloy sheet, as given in reference 9, for three temperatures. The strain rate was 0.12 per hr. The theoretical curves obtained by computation from equation (6) (see table I) fit the data well at the higher temperatures but overshoot the 200° F curve by a considerable amount.

RAPID-HEATING CURVES

Figure 4 shows the rapid-heating curves for the 7075–T6 aluminum alloy, taken from reference 9, for three stresses and for widely different temperature rates. The calculated curves represent a severe test of the assumed relation given in equation (1) not only because the cooperation of all four terms is required in equation (9), which is used for computation, but also because the temperatures reached may be considerably higher and the strain rates considerably larger than those encountered in other types of tests. Near the

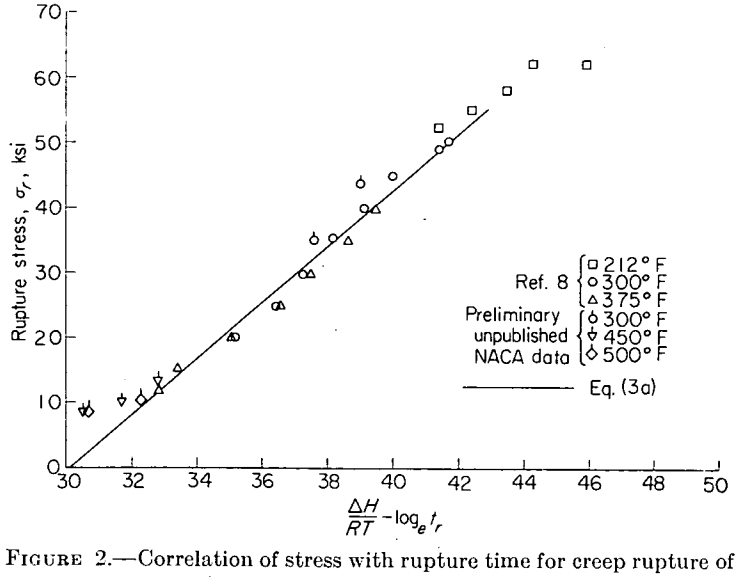

FIGURE 2.—Correlation of stress with rupture time for creep rupture of 7075–T6 aluminum-alloy sheet.

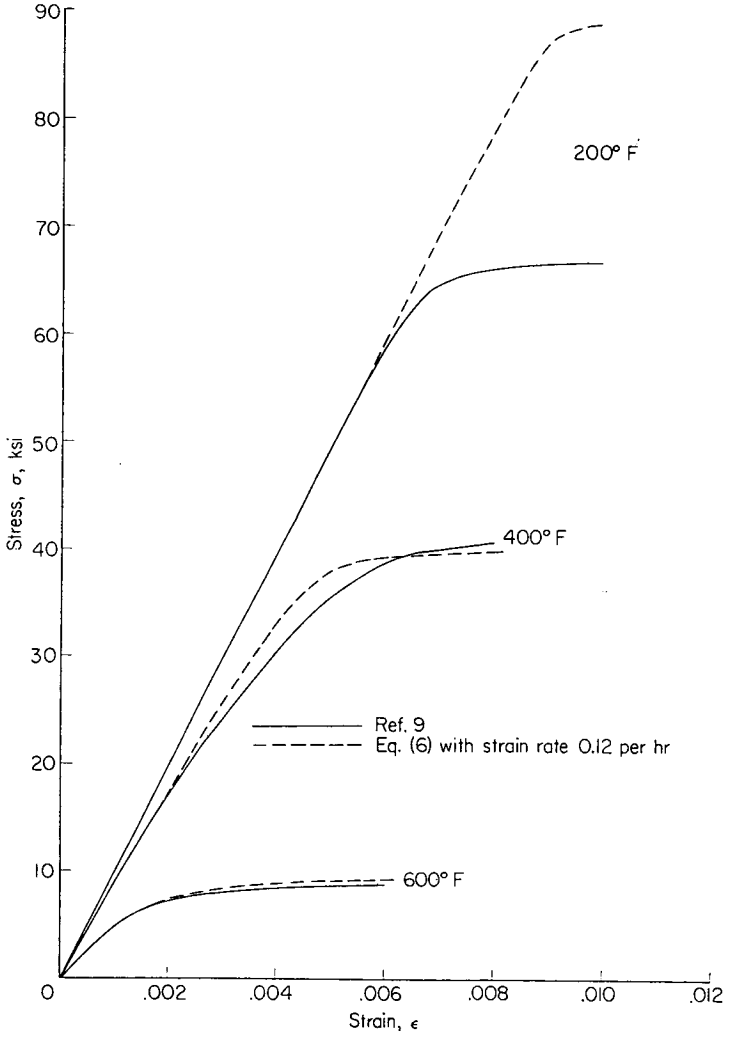

FIGURE 3.—Tensile stress-strain curves for 7075–T6 aluminum-alloy sheet.

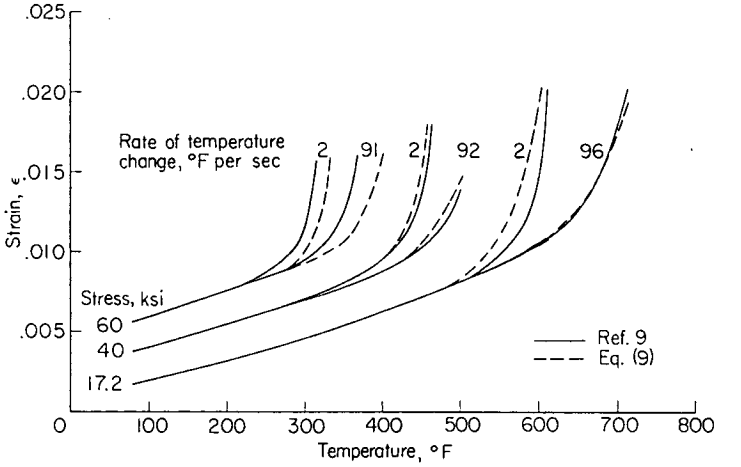

FIGURE 4.—Rapid-heating curves for 7075–T6 aluminum-alloy sheet for three stresses.

upper ends of the curves, calculations were made at sufficiently close intervals of temperature, usually 5° to 10° K, to establish better the points. The shape and the separation of the curves with heating rate are given reasonably well by the theoretical curves except near 300° F, and then the predicted final rapid increases in strain occur at a somewhat higher temperature than that actually observed. The agreement at the lower temperature rate on the curve for 17.2 ksi is not as good as the others.

DISCUSSION

It would appear from the tests reported here that the validity of the relation suggested in equation (1) is borne out for the 7075–T6 aluminum alloy. The relation has shown itself capable of accounting for the steady creep, the creep-rupture data, the stress-strain curves, and the rapid-heating curves for this alloy.

A more satisfactory test of the validity of the relation would be with a more stable material such as pure aluminum. The alloy selected in this report is not such a material but was used because of the existence of the different types of data available. The elevated-temperature phenomena are reasonably well accounted for, however, in spite of this handicap.

The constants in the viscous term vary to different degrees. The activation energy ΔH of the three constants is most nearly constant and is structurally insensitive, being independent of stress, temperature, grain size, and minor alloy additions, and has been tentatively identified with the activation energy for self-diffusion (ref. 1). The magnitude of ΔH is roughly proportional to the melting point of the metal. The quantity σ_o, on the other hand, is structurally sensitive; for pure aluminum, it has a magnitude of about 0.2 ksi, whereas for the 7075–T6 alloy it has a magnitude of 4.3 ksi. For stable materials, it is independent of stress, temperature, and grain size. The quantity s was found to be a constant that is independent of stress and temperature and is subject to the same degree of uncertainty as the strain rate. Repeated steady-creep tests on the same material under identical conditions will yield creep rates within a range of perhaps 2:1. This uncertainty in the creep rate is reflected in a similar uncertainty in the quantity s. It is, therefore, not surprising to find a similar variation in s in the different applications. (See table I.)

For materials which are unstable in the sense that the constants in the viscous term are mainly functions of the temperature, one might expect equation (1) to be still usable if such variations in the constants are allowed for in the computations. If the materials are unstable in the sense that the constants in the viscous term are mainly functions of the time, however, then equation (1) is probably not usable.

Equation (1) is evidently valid for values of stress and temperature which are changing smoothly in one direction, even though these changes may be fairly rapid. For sudden or discontinuous changes in stress or temperature, transients are known to occur which will not be given by equation (1). Some modification of this relation, perhaps by an additional term, will be required to account properly for such transients. Such a modification would have to account for transient creep as well as for other conditions; the nature of the modification is obscure at the present time.

Certain parameters have appeared as a result of this relation and may prove useful in comparing data at different temperatures above the equicohesive temperature. For example, if steady-creep data are available at different stresses and temperatures, stress plotted against the parameter

$\frac{\Delta H}{RT}+\log_e \dot{\epsilon}$ should yield a straight line with slope equal to σ_o. For the stress-strain curves, the parameter which determines the separation of the curves with temperature is $2\beta=\frac{\dot{\epsilon}_o}{sT}e^{\frac{\Delta H}{RT}}$, since the maximum height of the curves is $\sigma_o \log_e 2\beta$. For rupture resulting from creep, rupture stress plotted against $\frac{\Delta H}{RT}-\log_e t_r$ should yield a single straight line with slope equal to σ_o. If the rupture stress were plotted against the parameter $\frac{\Delta H}{RT}+\log_e \frac{\epsilon_r}{sT}-\log_e t_r$, the straight line should pass through the origin.

CONCLUDING REMARKS

The application of the suggested phenomenological rate relation to the determination of steady creep rates, creep-rupture time, stress-strain curves, and rapid-heating curves for 7075–T6 aluminum-alloy sheet has shown that such a relation can be used to cover a wide variety of applications. The possibility of predicting the behavior of materials under widely different load and temperature conditions is indicated for temperatures above the equicohesive temperature for the material. Additional verification of the validity of the relation would be desirable as suitable data over a sufficiently wide range of test conditions become available.

REPORT 1344

A SIMPLIFIED METHOD FOR APPROXIMATING THE TRANSIENT MOTION IN ANGLES OF ATTACK AND SIDESLIP DURING A CONSTANT ROLLING MANEUVER[1]

By Leonard Sternfield

SUMMARY

The transient motion in angles of attack and sideslip during a constant rolling maneuver has been analyzed. Simplified expressions are presented for the determination of the pertinent modes of motion as well as the modal coefficient corresponding to each mode.

Calculations made with and without the derivatives C_{Y_β} (side force due to sideslip) and C_{L_α} (lift-curve slope) indicate that although these derivatives increase the total damping of the system they do not markedly affect the transient motion.

INTRODUCTION

Recent flight tests of airplanes designed with their mass concentrated primarily in the fuselage have indicated that during a rolling maneuver the airplane experiences large uncontrollable motions in angles of attack and sideslip. A fundamental analysis of this pitch-yaw divergence problem, in which the rolling velocity of the airplane is assumed constant, is presented in reference 1. This analysis, concerned primarily with the stability of the system, makes possible the calculation of the divergence boundaries and the prediction of the range of rolling velocities for which the airplane motions will diverge. Analog studies made at the National Advisory Committee for Aeronautics for several research airplanes have indicated that reference 1 is a helpful guide in a roll-coupling investigation, but detailed-motion studies based on five degrees of freedom and with pilot inputs taken into account are essential to the analysis. Also, calculated time histories of the airplane motion indicate that large angles of attack and sideslip which are objectionable to a pilot and which may induce severe loads on the airplane may be encountered for constant rolling velocities outside the critical range.

The purpose of this paper is to extend the analysis of reference 1 by analyzing the transient motion in angles of attack and sideslip. Simplified expressions are presented which permit an accurate and rapid estimate of the maximum angles of attack and sideslip for an airplane rolling at a constant velocity which should apply to the case of an airplane entering a rolling maneuver up to the point of recovery from the maneuver. The airplane is assumed to be initially disturbed by an input in the side-force equation equal to the product of the rolling velocity and trim angle of attack. A comparison is made of the time histories obtained by using the simplified and exact expressions (obtained from the four degrees of freedom assuming constant rolling velocity) for a currently designed swept-wing fighter flying at a Mach number of 0.7 at an altitude of 32,000 feet.

SYMBOLS

b	wing span, ft
$\bar{c}$	wing mean aerodynamic chord, ft
C_L	lift coefficient, $\frac{\text{Lift}}{qS}$
C_l	rolling-moment coefficient, $\frac{\text{Rolling moment}}{qSb}$
C_m	pitching-moment coefficient, $\frac{\text{Pitching moment}}{qS\bar{c}}$
C_n	yawing-moment coefficient, $\frac{\text{Yawing moment}}{qSb}$
C_Y	side-force coefficient, $\frac{\text{Side force}}{qS}$
I_X	moment of inertia of airplane about principal X-axis, slug-ft^2
I_Y	moment of inertia of airplane about principal Y-axis, slug-ft^2
I_Z	moment of inertia of airplane about principal Z-axis, slug-ft^2
M_X	rolling moment, ft-lb
m	airplane mass, slugs
P	period, sec
p	rolling velocity, radians/sec
p_0	steady rolling velocity, radians/sec
q	pitching velocity, radians/sec; dynamic pressure, lb/sq ft
r	yawing velocity, radians/sec
S	wing area, sq ft
t	time, sec
$T_{1/2}$	time to damp to one-half amplitude, sec
T_2	time to double amplitude, sec
V	airplane velocity, ft/sec
α_0	initial angle of attack of airplane principal axis, radians
$\Delta\alpha$	incremental change in angle of attack, radians
$\alpha=\alpha_0+\Delta\alpha$	
β	angle of sideslip, radians
λ	root of characteristic equation
$a\pm i\omega$	complex roots of characteristic equation
λ_1,λ_2	real roots of characteristic equation

$$N_r=\frac{qSb^2}{2V}C_{n_r}$$

$$Y_\beta=qSC_{Y_\beta}$$

EQUATIONS OF MOTION

In this analysis, on the assumption of constant forward velocity and constant rolling velocity, the following linearized equations of motion of an airplane referred to the principal axes were used:

Pitching:

$$\dot{q}-\left(\frac{I_Z-I_X}{I_Y}\right)p_0r=\frac{M_qq}{I_Y}+\frac{M_\alpha}{I_Y}\Delta\alpha \tag{1a}$$

Yawing:

$$\dot{r}-\left(\frac{I_X-I_Y}{I_Z}\right)p_0q=\frac{N_r}{I_Z}r+\frac{N_\beta}{I_Z}\beta \tag{1b}$$

Side force:

$$\dot{\beta}+r-p_0\Delta\alpha=\frac{Y_\beta}{mV}\beta+p_0\alpha_0 \tag{1c}$$

Normal force:

$$\dot{\alpha}-q+p_0\beta=-\frac{L_\alpha}{mV}\Delta\alpha \tag{1d}$$

When the substitutions $q=q_0e^{\lambda t}$, $r=r_0e^{\lambda t}$, $\beta=\beta_0e^{\lambda t}$, and $\Delta\alpha=(\Delta\alpha)_0e^{\lambda t}$ are used in the equations written in determinant form, λ must be a root of the stability equation

$$A\lambda^4+B\lambda^3+C\lambda^2+D\lambda+E=0 \tag{2}$$

where

$$A=1$$

$$B=-\frac{N_r}{I_Z}-\frac{M_q}{I_Y}-\frac{Y_\beta}{mV}+\frac{L_\alpha}{mV}$$

$$C=-\left(\frac{I_X-I_Y}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2-\frac{M_\alpha}{I_Y}+\frac{N_\beta}{I_Z}+\frac{M_q}{I_Y}\frac{N_r}{I_Z}+p_0^2+\frac{Y_\beta}{mV}\frac{N_r}{I_Z}+\frac{Y_\beta}{mV}\frac{M_q}{I_Y}-\frac{L_\alpha}{mV}\frac{N_r}{I_Z}-\frac{L_\alpha}{mV}\frac{M_q}{I_Y}-\frac{L_\alpha}{mV}\frac{Y_\beta}{mV}$$

$$D=-\left(\frac{N_r}{I_Z}+\frac{M_q}{I_Y}\right)p_0^2-\frac{M_q}{I_Y}\frac{N_\beta}{I_Z}+\frac{M_\alpha}{I_Y}\frac{N_r}{I_Z}-\frac{M_q}{I_Y}\frac{N_r}{I_Z}\frac{Y_\beta}{mV}+\frac{M_q}{I_Y}\frac{N_r}{I_Z}\frac{L_\alpha}{mV}+\frac{N_\beta}{I_Z}\frac{L_\alpha}{mV}+\frac{M_\alpha}{I_Y}\frac{Y_\beta}{mV}+\frac{L_\alpha}{mV}\frac{Y_\beta}{mV}\frac{N_r}{I_Z}+\frac{L_\alpha}{mV}\frac{Y_\beta}{mV}\frac{M_q}{I_Y}+\frac{Y_\beta}{mV}\left(\frac{I_X-I_Y}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2-\frac{L_\alpha}{mV}\left(\frac{I_X-I_Y}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2$$

and

$$E=-\left(\frac{I_X-I_Y}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^4-\frac{M_\alpha}{I_Y}\left(\frac{I_X-I_Y}{I_Z}\right)p_0^2-\frac{N_\beta}{I_Z}\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2+\frac{M_q}{I_Y}\frac{N_r}{I_Z}p_0^2-\frac{M_\alpha}{I_Y}\frac{N_\beta}{I_Z}-\frac{M_q}{I_Y}\frac{N_\beta}{I_Z}\frac{L_\alpha}{mV}-\frac{M_\alpha}{I_Y}\frac{N_r}{I_Z}\frac{Y_\beta}{mV}-\frac{M_q}{I_Y}\frac{N_r}{I_Z}\frac{L_\alpha}{mV}\frac{Y_\beta}{mV}+\frac{L_\alpha}{mV}\frac{Y_\beta}{mV}\left(\frac{I_X-I_Y}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2$$

In reference 1, C_{L_α} and C_{Y_β} were assumed to be equal to zero; this assumption is representative of the condition in which the center of gravity is moving in a straight line. In this analysis the case where $C_{L_\alpha}=C_{Y_\beta}=0$ (referred to as case (a)) is considered, as well as the case where the values of C_{L_α} and C_{Y_β} are finite (referred to as case (b)).

ANALYSIS AND DISCUSSION

DIVERGENCE BOUNDARIES

The conditions necessary for the system described by equations (1) to be stable are that the coefficients of the characteristic equation (eq. (2)) must be positive and that Routh's discriminant, $BCD-AD^2-B^2E$, must be greater than zero. From an examination of the characteristic equation of this system, it can be shown that, for aircraft designed with positive static stability and for conditions where each of the damping derivatives C_{n_r}, C_{m_q}, C_{L_α}, and C_{Y_β} adds damping to the system, the oscillatory modes will be stable for all values of the steady rolling velocity. Thus, the only type of instability that could be encountered is an aperiodic mode which occurs when the constant term of the characteristic equation, the E coefficient, is negative. As shown in reference 1, divergence boundaries, obtained by setting $E=0$,

can be plotted as a function of the squares of the natural frequencies in pitch and yaw nondimensionalized to the square of the rolling velocity, ω_θ^2 and ω_ψ^2, respectively. These divergence boundaries are shown in figure 1 for cases (a) and (b) for an airplane whose mass and aerodynamic characteristics are presented in table I. The nondimensional pitch and yaw frequencies of the airplane described in table I fall along the straight line, with the slope equal to $\frac{-C_{m_\alpha}}{C_{n_\beta}} \frac{I_Z}{I_Y} \frac{\bar{c}}{b}$, shown in figure 1. Each point on this line corresponds to a particular value of p_0 and, as p_0 increases, the point moves along the line toward the origin. For case (a), the airplane line intersects the divergence boundaries at two points and thus defines the critical range of rolling velocities where a divergent mode exists, namely, $1.86 < |p_0| < 2.33$. For case (b) the airplane line lies in the stable region and the motion is therefore stable for all values of p_0.

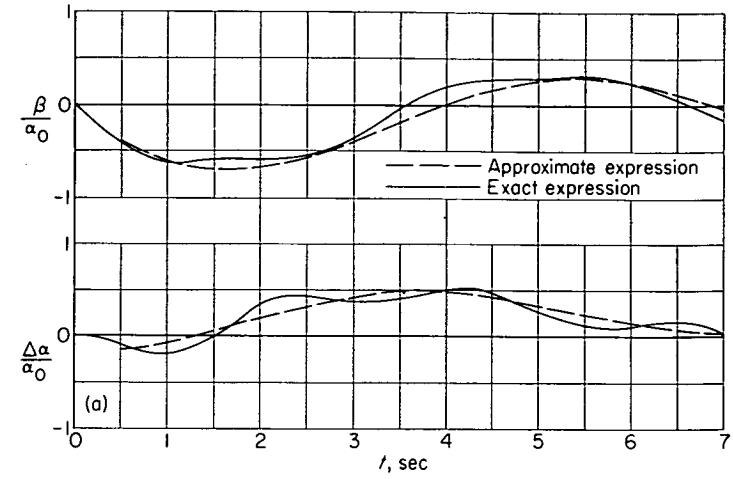
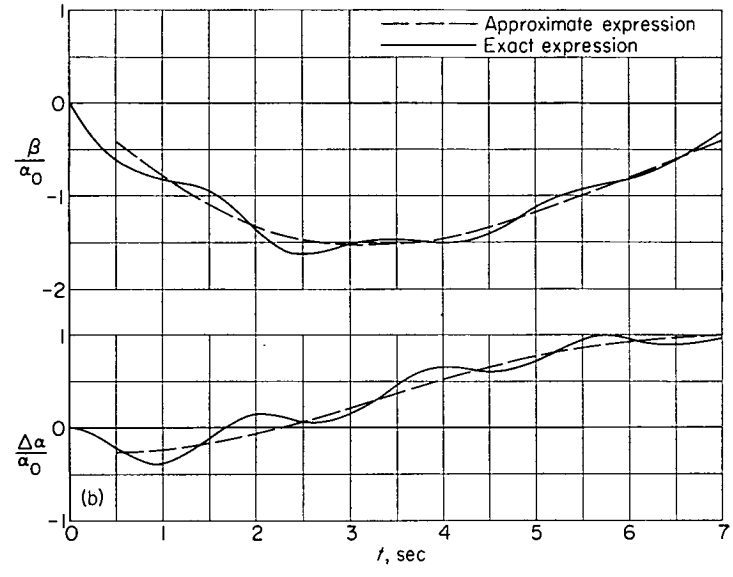
respectively. A method of approximating the roots of the characteristic equation is presented in the appendix. The roots for $p_0=0$ which correspond to the condition where no coupling exists between the lateral and longitudinal modes are also given in the table. If the roots are complex, $\lambda=a\pm i\omega$, $P=\frac{2\pi}{\omega}$, and $T_{1/2}=\frac{-0.693}{a}$; whereas, for a real root λ_1, $T_{1/2}=\frac{-0.693}{\lambda_1}$ or $T_2=\frac{0.693}{\lambda_1}$.

The roots for $p_0=0$, for both cases (a) and (b), indicate that the motion consists of two independent oscillatory modes, a longitudinal and lateral oscillation with periods of 2.74 seconds and 4.08 seconds, respectively. The damping of the oscillation for case (b) is greater than that for case (a) because the damping derivatives C_{Y_β} and C_{L_α} were assumed equal to zero in case (a). The values of $T_{1/2}$ in seconds are given in the following table:



Case	$T_{1/2}$	
	Longitudinal oscillation	Lateral oscillation
(a)	3.3	13.2
(b)	1.4	9.5

For values of $|p_0|$ other than zero, the lateral variables β and r are coupled with the longitudinal variables α and q and the system now has the characteristic modes shown in table II for each of the variables β, r, α, and q. It should be noted that as $|p_0|$ increases, the frequency of the high frequency mode continues to increase and the damping decreases. However, the frequency of the other oscillation decreases until $|p_0|$ reaches approximately 1.86 when the oscillation breaks down into two aperiodic modes. In case (a) at this value of $|p_0|$, a zero root is obtained and the unstable region begins. The system remains unstable, with one aperiodic divergent mode, until $|p_0|$ becomes equal to 2.33. In case (b), the system is stable although two aperiodic modes occur for $1.86<|p_0|<2.33$. For $|p_0|>2.33$, the oscillation reappears in cases (a) and (b) and the frequency and damping increase as $|p_0|$ increases.

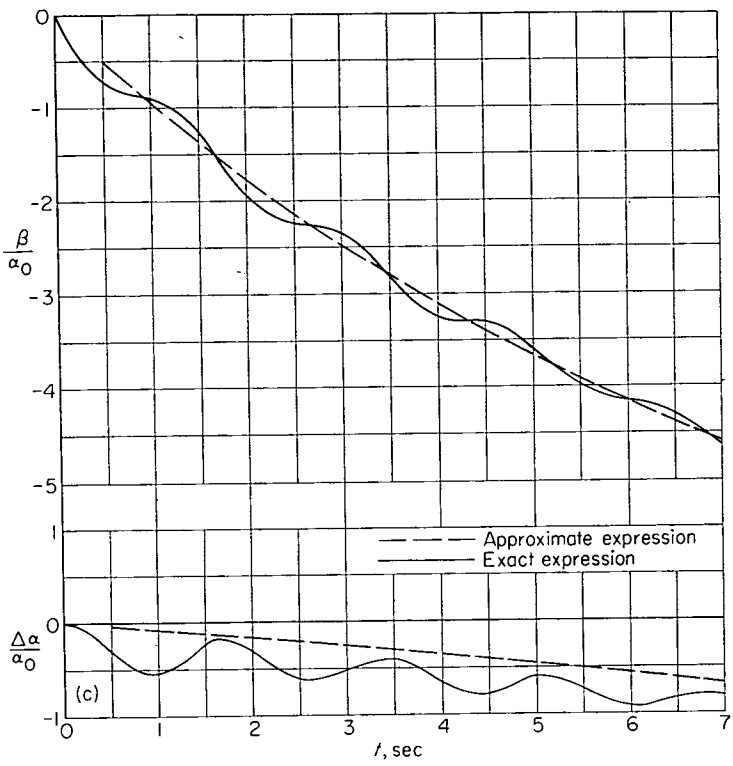


From the contour lines of constant oscillation frequencies presented in reference 1, it appears that, in general, the frequency of one of the oscillatory modes will always decrease and probably break down into two aperiodic modes as $|p_0|$ increases.

MOTIONS IN $\beta(t)$ AND $\Delta\alpha(t)$

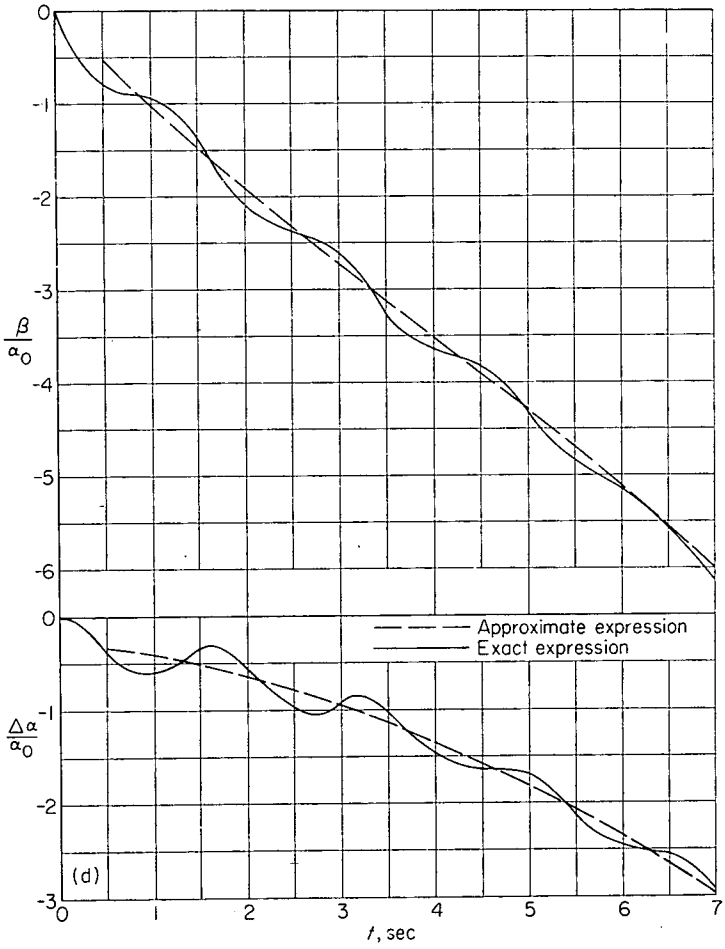
Time histories were calculated by the method of Laplace transform (ref. 2) of the motions in β and $\Delta\alpha$ for the several values of p_0 shown in figure 1. The disturbance acting on the airplane is represented by the term $p_0\alpha_0$ in the side-force equation while the airplane is rolling in a negative direction. The motions in $\frac{\beta(t)}{\alpha_0}$ and $\frac{\Delta\alpha(t)}{\alpha_0}$ are presented in figures 2 and 3 for cases (a) and (b), respectively. A comparison of figures 2 and 3 shows that the inclusion of C_{L_α} and C_{Y_β} modifies

(a) $p_0=-1.0$.



(b) $p_0=-1.5$.

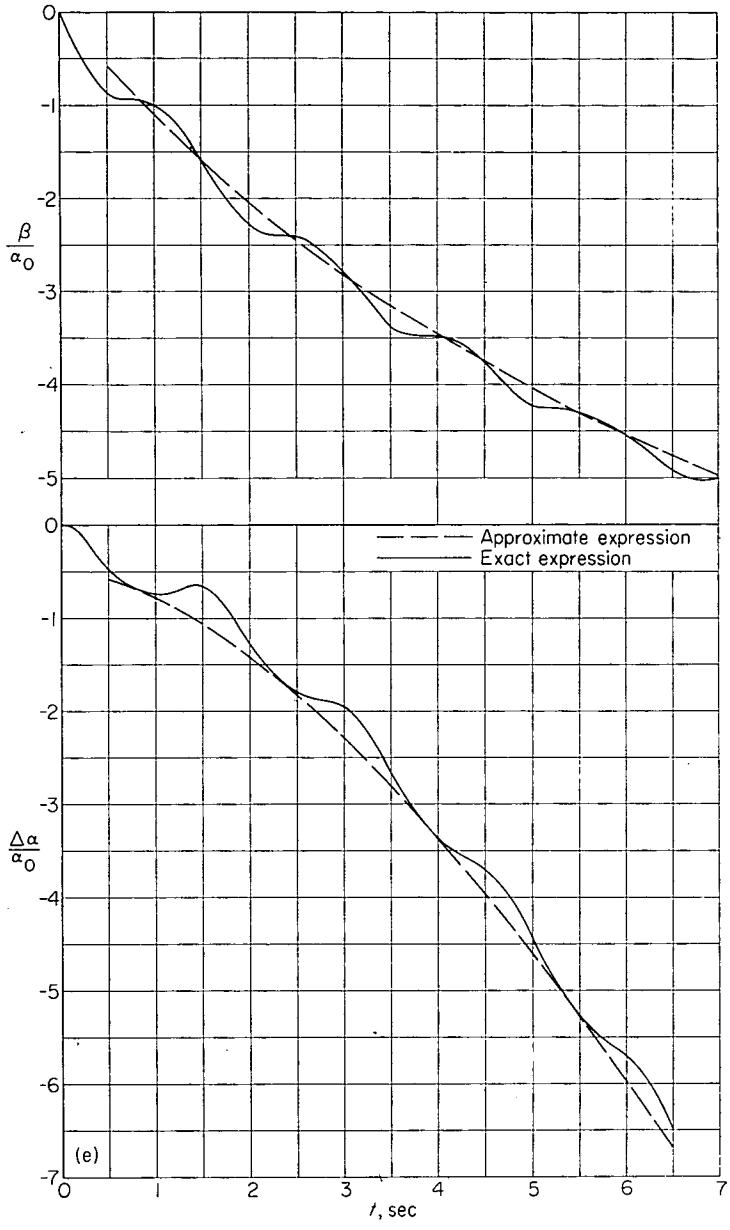
FIGURE 2.—Time histories of β/α_0 and $\Delta\alpha/\alpha_0$ for case (a).



the motions slightly. Additional time histories were made and are presented in figure 4 for the same airplane but with the following assumed values of the derivatives: $C_{m_\alpha}=-0.09$, $C_{n_\beta}=0.114$, and $C_{Y_\beta}=C_{L_\alpha}=0$. For $p_0=-1.0$, the airplane would be located in figure 1 at the point $\omega_\theta^2=1.32$ and $\omega_\psi^2=4.77$.

Although the modes of motion involved in the transient behavior of the airplane will be stable for points along the airplane line located in the stable region, that is, $2.33<|p_0|<1.86$ in case (a) and for all values of $|p_0|$ in case (b), the magnitudes of $\Delta\alpha$ and β developed during the transient motion may be large enough to cause severe loads on the airplane. For example, in the particular flight condition for which the motions were calculated, where $\alpha_0=5°$, the airplane develops a sideslip angle of about $-8°$ at $p_0=-1.5$ and $\Delta\alpha$ is about $-20°$ at $p_0=-3.0$. These values are reached in about 3 seconds.

In all the motions the high-frequency mode is clearly evident, although the amplitude of this mode is relatively small. Hence, the high-frequency mode modifies the shape of the motion only slightly. Thus, for $p_0=-1.0$, -1.5, -2.5,



(c) $p_0=-1.86$.

(d) $p_0=-2.0$.

FIGURE 2.—Continued.

(e) $p_0=-2.33$.

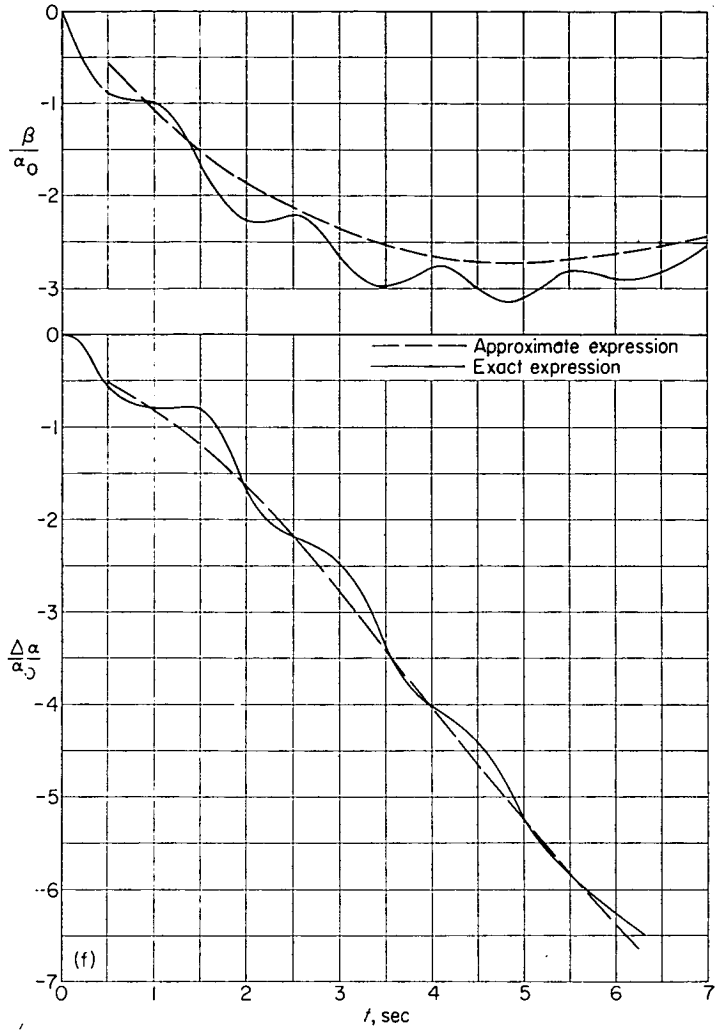


FIGURE 2.—Continued.

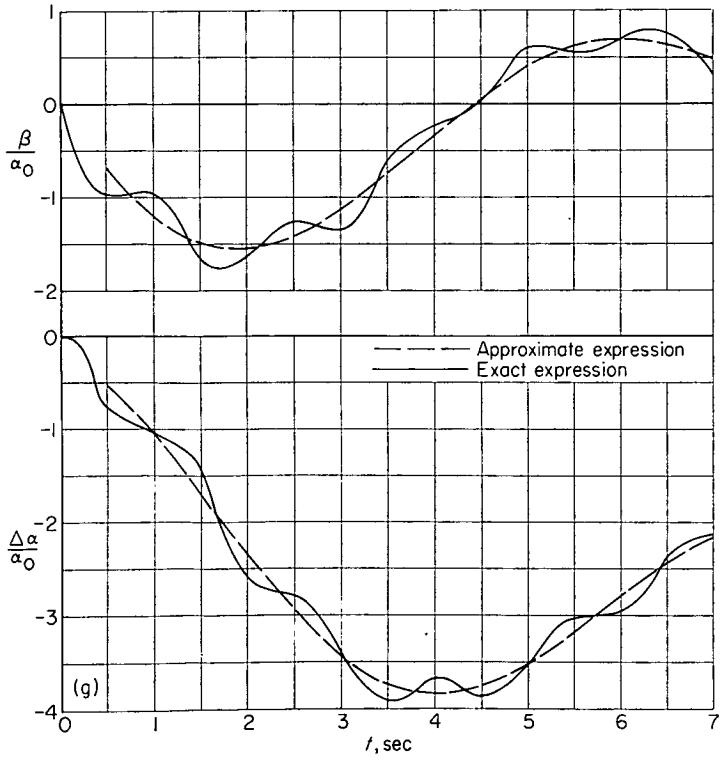
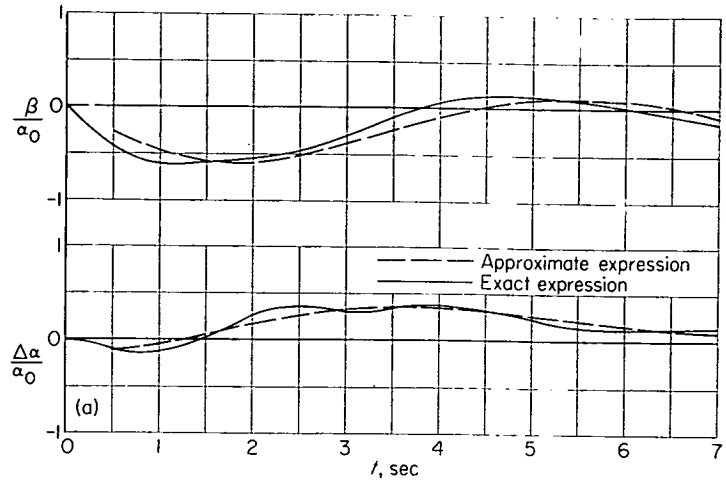
and -3.0, the low-frequency mode is of primary importance in the motions, whereas for $p_0=-1.86$, -2.0, and -2.33, the aperiodic modes are of primary importance. In addition, the analytical expressions for the motions would also contain a constant term which represents the steady-state value of β and $\Delta\alpha$ if the system is stable. A good approximation to the time history could therefore be expressed in general form for $p_0=-1.0$, -1.5, -2.5, and -3.0 as



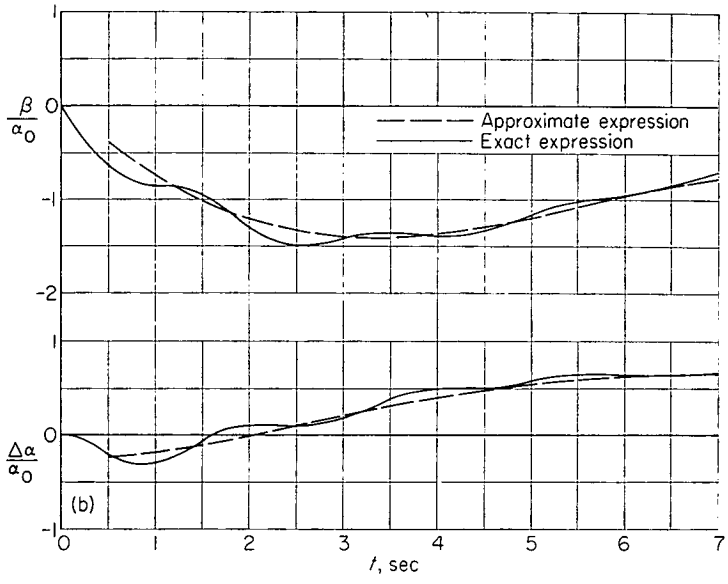
$$\frac{\beta(t)}{\alpha_0} \text{ or } \frac{\Delta\alpha(t)}{\alpha_0}=K_0+K_1e^{at}\sin(\omega t+\epsilon) \tag{3}$$

For case (b) when $p_0=-1.86$, -2.0, and -2.33 and for case (a) when $p_0=-2.0$, the following equation is obtained:

$$\frac{\beta(t)}{\alpha_0} \text{ or } \frac{\Delta\alpha(t)}{\alpha_0}=K_0+K_2e^{\lambda_1 t}+K_3e^{\lambda_2 t} \tag{4}$$



(f) $p_0 = -2.5$.



(g) $p_0 = -3.0$.

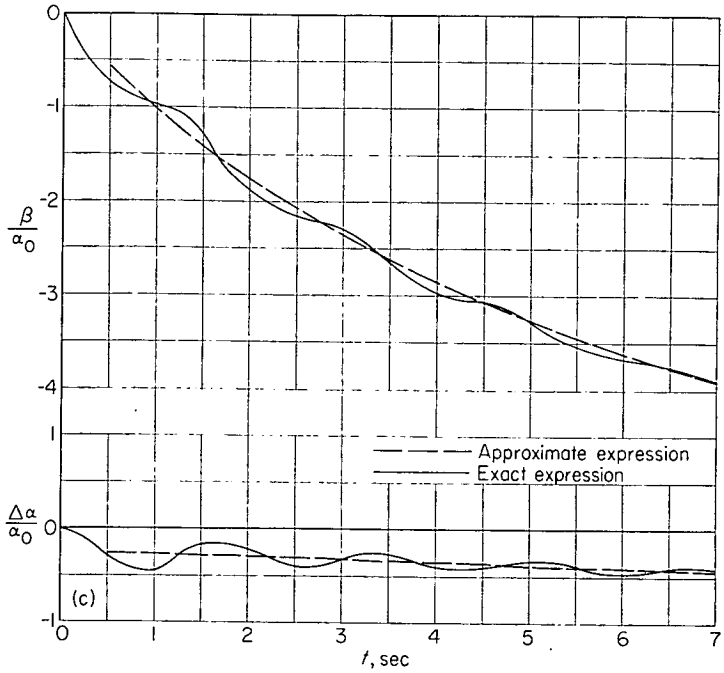


FIGURE 2.—Concluded.

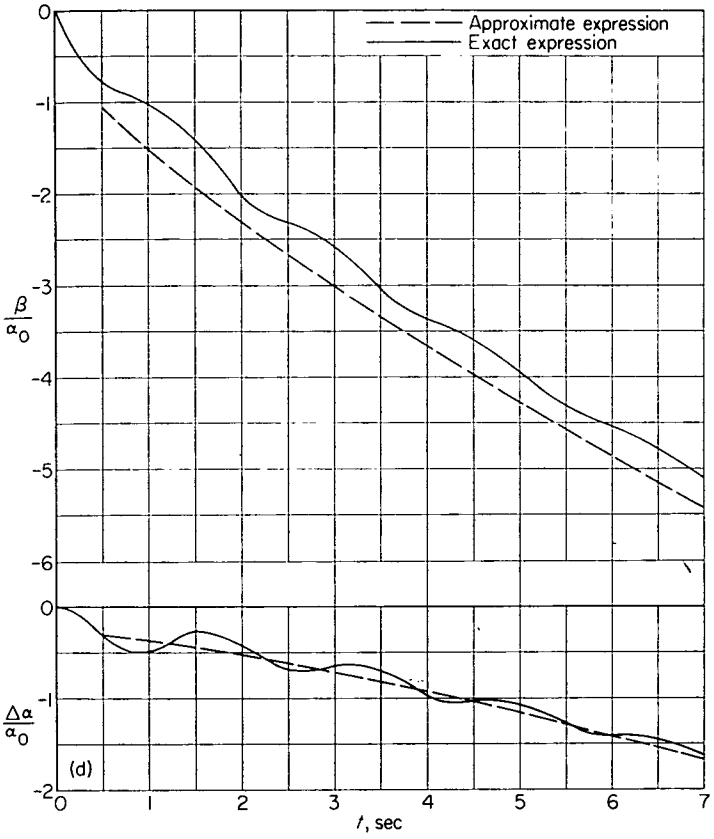
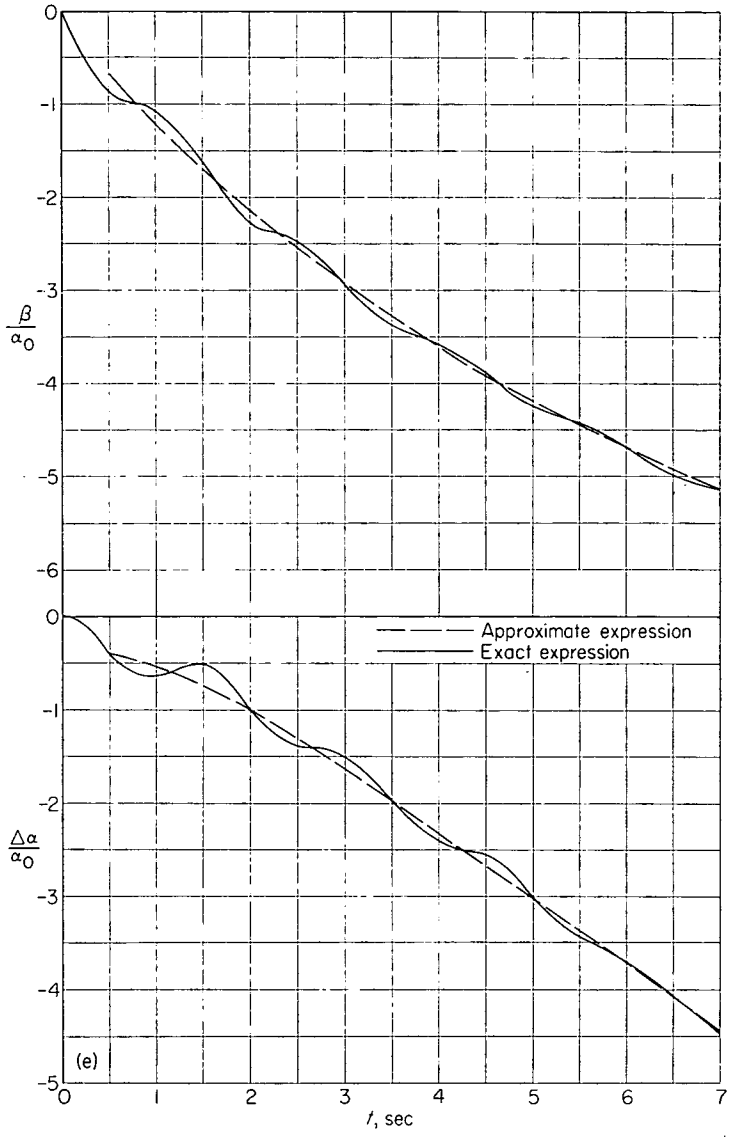
(a) $p_0 = -1.0$.



(b) $p_0 = -1.5$.

(c) $p_0 = -1.86$.

FIGURE 3.—Time histories of β/α_0 and $\Delta\alpha/\alpha_0$ for case (b).



(d) $p_0=-2.0$.

FIGURE 3.—Continued.

and for case (a) when $p_0=-1.86$ and -2.33,

$$\frac{\beta(t)}{\alpha_0} \text{ or } \frac{\Delta\alpha(t)}{\alpha_0}=K_4t+K_5(e^{\lambda t}-1) \tag{5}$$

Since the high-frequency mode is omitted from expressions (3), (4), and (5), the values of $\frac{\beta(t)}{\alpha_0}$ and $\frac{\Delta\alpha(t)}{\alpha_0}$ will not satisfy the initial condition of being zero at $t=0$.

(e) $p_0=-2.33$.

FIGURE 3.—Continued.

By differentiating expressions (3), (4), and (5) and setting them equal to zero, the maximum values of β and $\Delta\alpha$ and the time at which they occur could be easily determined. In these calculations, β and $\Delta\alpha$ occurred at about ¼ and ½ of the period, respectively.

APPROXIMATION OF THE AMPLITUDE COEFFICIENTS AND PHASE ANGLE

The amplitude coefficients K_0, K_1, K_2, K_3, K_4, and K_5 and the phase angle ϵ in expressions (3), (4), and (5) can be calculated directly by using the Heaviside expansion formula given on page 45 of reference 2. A detailed examination of the exact expressions for the amplitude coefficients and phase angle indicated that many of the terms appearing in the expressions had a negligible effect on the resultant magnitudes. Thus the following simplified expressions were derived which result in good agreement with the exact values.

In the expressions for $\frac{\beta(t)}{\alpha_0}$,

$$K_0=\frac{p_0}{E}\left\{\frac{M_\alpha}{I_Y}\frac{N_r}{I_Z}+\frac{L_\alpha}{mV}\left[\frac{M_q}{I_Y}\frac{N_r}{I_Z}+p_0^2\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)\right]\right\}$$

$$K_1=\frac{p_0}{(a^2+\omega^2)(C-2\omega^2)}\sqrt{\omega^2\left[-\omega^2-\frac{M_\alpha}{I_Y}+p_0^2\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)\right]^2+\left[\frac{M_\alpha}{I_Y}\frac{N_r}{I_Z}+\omega^2\left(-2a+\frac{N_r}{I_Z}+\frac{M_q}{I_Y}\right)+\frac{L_\alpha}{mV}\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2\right]^2}$$

$$\epsilon=\tan^{-1}\frac{1}{\omega}\frac{-\frac{M_\alpha}{I_Y}\frac{N_r}{I_Z}-\omega^2\left(-2a+\frac{N_r}{I_Z}+\frac{M_q}{I_Y}\right)-\frac{L_\alpha}{mV}\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2}{\left[-\omega^2-\frac{M_\alpha}{I_Y}+p_0^2\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)\right]}$$

$$K_2, K_3, \text{ and } K_5=\frac{p_0\left[\frac{M_\alpha}{I_Y}\left(\frac{N_r}{I_Z}\frac{1}{\lambda}-1\right)+p_0^2\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)\left(1+\frac{L_\alpha}{mV}\frac{1}{\lambda}\right)\right]}{2C\lambda+D}$$

$$K_4=\frac{p_0}{D}\left\{\frac{M_\alpha}{I_Y}\frac{N_r}{I_Z}+\frac{L_\alpha}{mV}\left[\frac{M_q}{I_Y}\frac{N_r}{I_Z}+p_0^2\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)\right]\right\}$$

In the expressions for $\frac{\Delta\alpha(t)}{\alpha_0}$,

$$K_0=-\frac{p_0^2}{E}\left[\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2-\frac{N_\beta}{I_Z}\left(\frac{I_Z-I_X}{I_Y}\right)+\frac{M_q}{I_Y}\frac{N_r}{I_Z}\right]$$

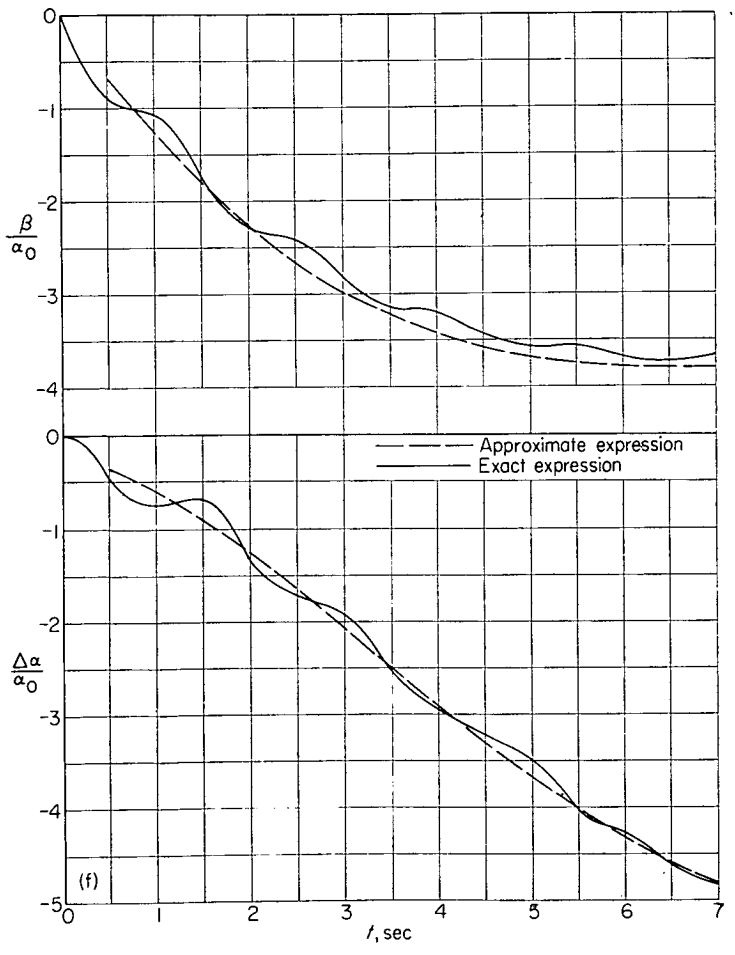
$$K_1=\sqrt{C_2^2+C_1^2}$$

$$K_2, K_3, \text{ and } K_5=-\frac{p_0^2\left[\lambda^2-\left(\frac{M_q}{I_Y}+\frac{N_r}{I_Z}\right)\lambda+p_0^2\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)-\frac{N_\beta}{I_Z}\left(\frac{I_Z-I_X}{I_Y}\right)+\frac{M_q}{I_Y}\frac{N_r}{I_Z}\right]}{\lambda\,(2C\lambda+D)}$$

$$K_4=-\frac{p_0^2}{D}\left[\left(\frac{I_Y-I_X}{I_Z}\right)\left(\frac{I_Z-I_X}{I_Y}\right)p_0^2-\frac{N_\beta}{I_Z}\left(\frac{I_Z-I_X}{I_Y}\right)+\frac{M_q}{I_Y}\frac{N_r}{I_Z}\right]$$

$$\epsilon=\tan^{-1}\frac{C_2}{C_1}$$

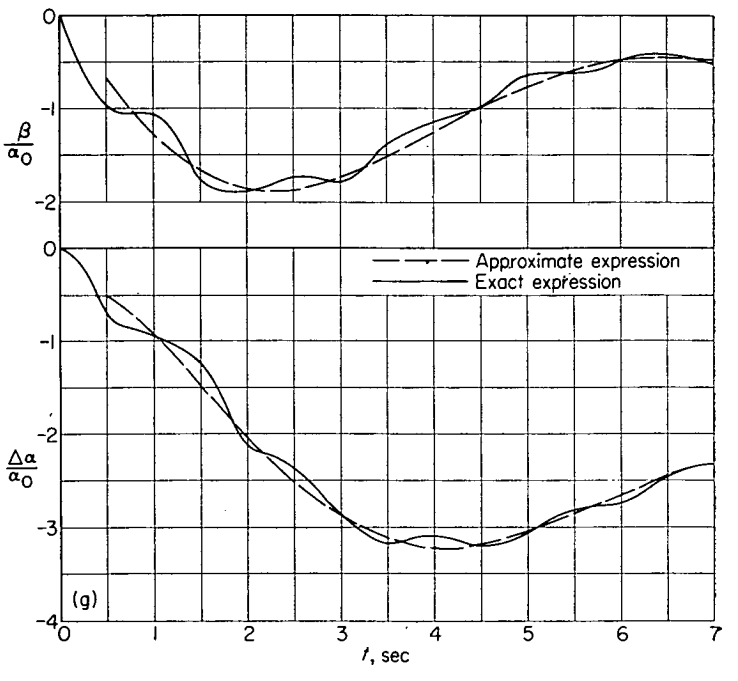
where



$$C_2=-\frac{p_0^2}{\omega^2\,(C-2\omega^2)}\left[\omega^2+\left(\frac{I_Z-I_X}{I_Y}\right)\frac{N_\beta}{I_Z}-p_0^2\left(\frac{I_Z-I_X}{I_Y}\right)\left(\frac{I_Y-I_X}{I_Z}\right)\right]$$

$$C_1=-C_2\left(\frac{a}{\omega}\right)-\frac{2a-p_0^2\left(\frac{M_q}{I_Y}+\frac{N_r}{I_Z}\right)}{\omega\,(C-2\omega^2)}$$

The C, D, and E appearing in the preceding expressions are the coefficients of the characteristic equation. A comparison of the motions obtained by using the exact and approximate coefficients is shown in figures 2 to 4 to be very good.



EFFECT OF ASSUMING p_0 CONSTANT AT $t=0$

In general, the rolling velocity builds up exponentially in response to an aileron input instead of being constant at $t=0$ as assumed in this analysis. In order to determine the effect of the assumption on the motions in β and $\Delta\alpha$, an analog study was conducted with the assumption that the rolling velocity reaches its steady-state value exponentially. The resultant motions in β and $\Delta\alpha$ were compared with the

(f) $p_0=-2.5$.

FIGURE 3.—Continued.

(g) $p_0=-3.0$.

FIGURE 3.—Concluded.

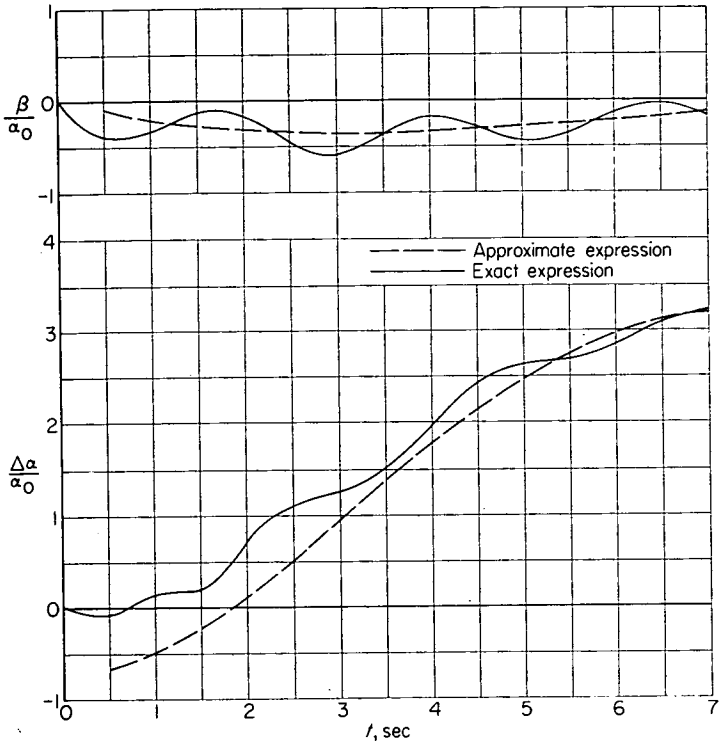


FIGURE 4.—Time histories of β/α_0 and $\Delta\alpha/\alpha_0$ for $C_{m_\alpha}=-0.09$, $C_{n_\beta}=0.114$, $p_0=-1.0$, and $C_{Y_\beta}=C_{L_\alpha}=0$.

motions in β and $\Delta\alpha$ obtained on the assumption that p_0 is constant at $t=0$. Equations (1) were used in the analog study and, in addition, a simplified roll equation $\dot{p}-\frac{qSb^2}{2VI_X}C_{l_p}p=\frac{M_X}{I_X}$ was introduced. This equation states that p reaches its steady-state value, p_0, according to the expression $p=p_0(e^{\lambda t}-1)$. In general, the resultant motions obtained in the analog study were very similar to the motions shown in figures 2 and 3. The only significant difference noted was that different peak values of $\frac{\Delta\alpha}{\alpha_0}$ and $\frac{\beta}{\alpha_0}$ were encountered. Table III presents a comparison between the maximum values of $\frac{\Delta\alpha}{\alpha_0}$ and $\frac{\beta}{\alpha_0}$ obtained from the analog study and from figures 2 and 3 for $p_0=-1.0$, -1.5, and -3.0. It is seen from the values presented in table III that higher maximum values occur for $p_0=-1.0$ and -1.5 for the condition of constant p_0 at $t=0$ whereas the opposite is true for $p_0=-3.0$. These results can be explained by the fact that, during the first several seconds of the transient motion, the average value of p_0 in the analog study is smaller than under the assumption of constant p_0. Hence in the analog study for $p_0=-1.0$ and -1.5 the airplane may be considered to be located farther away from the stability boundary, but for $p_0=-3.0$ the airplane is located closer to the stability boundary.

CALCULATIONS OF MOTIONS FOR AN AIRPLANE PERFORMING A 360° ROLL

The analysis presented thus far is applicable to the condition of the airplane performing a continuous rolling motion. Of particular interest are the motions of the airplane when the pilot performs a 360° roll. These motions can be approximated by first determining the values of β, r, α, and q at the time the airplane has rolled through 360°, that is, at $t=\frac{2\pi}{p_0}$. At this value of t, the constant rolling velocity is returned to $p_0=0$ and the motion originally described by four degrees of freedom is now separable into its lateral and longitudinal values, the former represented by the yawing and sideslipping equations and the latter represented by the pitching-moment and normal-force equations. Thus, the values of β, r, α, and q at $t=\frac{2\pi}{p_0}$ are the initial conditions required to calculate the motions subsequent to $t=\frac{2\pi}{p_0}$. The values of β and α can be determined from equation (3), (4), or (5). From equations (1c) and (1d), the following equations are obtained:

$$r=\frac{Y_\beta}{mV}\beta+p_0\alpha_0+p_0\,\Delta\alpha-\dot{\beta} \tag{6}$$

and

$$q=\frac{L_\alpha}{mV}\Delta\alpha+p_0\beta+\dot{\alpha} \tag{7}$$

A good approximation of r and q at $t=\frac{2\pi}{p_0}$ is obtained by neglecting the terms $\dot{\beta}$ and $\dot{\alpha}$ in equations (6) and (7). The following table compares the values of r and q at $t=\frac{2\pi}{p_0}$ for $p_0=-1.5$, -1.7, and -3.0 when $\dot{\beta}$ and $\dot{\alpha}$ are included in

TABLE III
COMPARISON OF MAXIMUM VALUES OF $\frac{\beta}{\alpha_0}$ AND $\frac{\Delta\alpha}{\alpha_0}$

EFFECT OF GRAVITY TERMS ON THE β AND $\Delta\alpha$ MOTIONS

The effect of the gravity components which would appear in the side force (eq. (1c)) and normal force (eq. (1d)) equations have been neglected in this analysis. In order to determine the effect of the gravity terms on the β and $\Delta\alpha$ motions, an analog study was conducted using equations (1c) and (1d) with the gravity terms included and then deleted from the equations. The airplane was assumed to be performing a 360° roll for rolling velocities of $p_0=-1.5$, -1.7, and -3.0. A comparison of the maximum values of $\frac{\beta}{\alpha_0}$ and $\frac{\Delta\alpha}{\alpha_0}$ obtained with and without the gravity terms is presented in table IV. The two values given for $\frac{\Delta\alpha}{\alpha_0}$, that is, $\frac{\Delta\alpha_1}{\alpha_0}$ and $\frac{\Delta\alpha_2}{\alpha_0}$, correspond to the maximum values of $\frac{\Delta\alpha}{\alpha_0}$ obtained during the initial part of the transient motion (p_0=constant) and during the recovery part of the motion ($p_0=0$), respectively. The comparison shows that with the gravity terms included the maximum values of β are about 2° greater and the maximum values of $\Delta\alpha$ increase by about 1° for an initial α_0 of 5°.

TABLE IV

COMPARISON OF MAXIMUM VALUES OF $\frac{\beta}{\alpha_0}$ AND $\frac{\Delta\alpha}{\alpha_0}$

−3.0	−3.0	−2.4	1.5	−2.7	−2.2	1.6

CONCLUDING REMARKS

From the analysis presented in this paper it appears that the transient motion in angles of attack and sideslip during a constant rolling maneuver consists chiefly of either an oscillatory mode or two aperiodic modes. Approximate expressions are derived for the determination of these modes as well as the modal coefficient corresponding to each mode. Inclusion of the derivatives C_{Y_β} (side force due to sideslip) and C_{L_α} (lift-curve slope) increases the total damping of the system but does not markedly affect the transient motions.

The sole input considered in this paper is the term $p_0\alpha_0$ (the product of rolling velocity and trim angle of attack) in the side-force equation.

APPENDIX

METHOD OF APPROXIMATING THE ROOTS OF THE CHARACTERISTIC EQUATION

The fourth-degree characteristic equation

$$A\lambda^4+B\lambda^3+C\lambda^2+D\lambda+E=0$$

may be factored as follows:

$$(\lambda^2+a_1\lambda+b_1)(\lambda^2+a_2\lambda+b_2)=0$$

where

$$A=1$$

$$B=a_1+a_2$$

$$C=b_1+b_2+a_1a_2$$

$$D=a_2b_1+a_1b_2$$

$$E=b_1b_2$$

An examination of the quadratic equations from which the exact roots presented in tables II (a) and II (b) were obtained indicated that $b_1 \gg b_2$ and that a_1 and a_2 are of the same order of magnitude and much smaller than b_1. Thus, one may write

$$A=1$$

$$B=a_1+a_2$$

$$C=b_1$$

$$D=a_2b_1$$

$$E=b_1b_2$$

The solution of these equations yields

$$a_1=\frac{BC-D}{C}$$

$$b_1=C$$

$$a_2=\frac{D}{C}$$

$$b_2=\frac{E}{C}$$

The roots of $\lambda^2+a_1\lambda+b_1=0$ approximate the high-frequency mode whereas the roots of $\lambda^2+a_2\lambda+b_2=0$ approximate the remaining two roots of primary importance in the motion calculations presented herein. A comparison between the exact roots and the approximate roots presented in tables II (a) and II (b) indicates that the agreement is excellent.

REPORT 1345

THE RESPONSE OF AN AIRPLANE TO RANDOM ATMOSPHERIC DISTURBANCES[1]

By Franklin W. Diederich

SUMMARY

The statistical approach to the gust-load problem which consists in considering flight through turbulent air to be a stationary random process is extended by including the effect of lateral variation of the instantaneous gust intensity on the aerodynamic forces. The forces obtained in this manner are used in dynamic analyses of rigid and flexible airplanes free to move vertically, in pitch, and in roll. The effect of the interaction of longitudinal, normal, and lateral gusts on the wing stresses is also considered.

The method of analyzing the rigid-body motions is similar to that used for analyses of the dynamic stability of airplanes, in that the equations of motion are referred to stability axes and expressed in terms of conventional stability derivatives. The method of analyzing the dynamic effects of structural flexibility consists in an extension of a numerical-integration approach to the static aeroelastic problem and is in a form which offers the possibility of calculating divergence and flutter speeds with relatively little additional effort.

The mean-square values, correlation functions, and power spectra of some of the aerodynamic forces required in this type of analysis are calculated for one special correlation function of the atmospheric turbulence. It is shown, for instance, that if the span is relatively large compared with the integral scale of turbulence, the mean-square lift and root bending moment directly due to the gust are substantially reduced when the differences in instantaneous intensity of the turbulence along the span are taken into account. However, if the motions of the airplane are taken into account the mean-square root bending moment may be increased as a result of these differences. Also, the mean-square pitching moment is shown to be substantially increased if the tail length is relatively large compared with the scale of turbulence. Finally, the wing stresses due to longitudinal, normal, and lateral gusts are shown to be statistically independent under certain conditions.

INTRODUCTION

The local velocity fluctuations acting on an airplane flying through atmospheric turbulence are functions of time defined only in a statistical sense and, hence, constitute a stochastic or random process. Consequently, the responses of the airplane, whether they are motions (linear or angular displacement, velocities, or accelerations), forces (lift, pitching moment, bending moment, and so on), stresses, or any other phenomena determined by the turbulence, can also be known as functions of time in only a statistical sense.

This report is concerned with the statistical characteristics of those responses which have a bearing on the loads and stresses experienced by the airplane; although other problems such as those relating to passenger comfort or to the stability of the airplane as a gun platform can be treated in the same manner, they will not be considered here.

The first approaches to the gust-load problem which use the statistical techniques developed for stationary random processes appear to be those of references 1, 2, and 3. (An earlier investigation concerned with the motions of an airplane in turbulent air is reported in ref. 4.) The fundamentals of these approaches are discussed in some detail in reference 1, and mention is made therein of investigations in other fields of engineering and physics that have dealt with the problem of deducing the statistical characteristics of the output or response of a dynamic system from those of its input. The mean-square normal acceleration of a rigid airplane free to move in one degree of freedom, namely, vertical motion, is calculated in reference 2. In addition to being rigid, the airplane is implicitly assumed to be small enough for all its components to experience the same gust velocity at any instant of time. This means that the span of the airplane must be small compared with the integral scale of atmospheric turbulence, which on the basis of the available knowledge concerning the properties of the atmosphere (ref. 4, for instance) appears to be in the order of several hundred to 1,000 or 2,000 feet; that is, the span of the airplane must be less than about 100 feet.

The purpose of the present report is to extend this approach to large flexible airplanes free to move in all directions. As used herein, the terms "small" and "large" airplane refer to airplanes which are very small and not very small, respectively, compared with the integral scale of turbulence; thus, an airplane flying in a wide variety of atmospheric conditions may be "small" under certain conditions and "large" under others. Similarly, the terms "rigid" airplane and "flexible" airplane are used to designate airplanes flying, respectively, at speeds far below those at which dynamic and aeroelastic effects become important, and at speeds at which these effects have to be taken into account; the same airplane can thus be "rigid" under some conditions and "flexible" under others.

[1] Supersedes NACA Technical Note 3910 by Franklin W. Diederich, 1957. This report represents, except for some minor changes, a thesis submitted in May 1954 in partial fulfillment of the requirements for the degree of Doctor of Philosophy at the California Institute of Technology, Pasadena, Calif.

Several fundamental assumptions are inherent in the analysis contained in this report. In the first place, all atmospheric disturbances, motions, and structural deformations are assumed to be small enough to produce forces that are linear and, hence, superposable. Also, the turbulent "input" to the airplane is assumed to be stationary in a statistical sense; that is, the turbulence in the plane of the flight path is homogeneous. For the large airplane, the additional assumption is made that the turbulence is axisymmetric with respect to vertical axes, a condition less severe than complete isotropy. The statistical characteristics of the turbulence are thus assumed to be invariant under a translation of the space origin within the horizontal plane and under a rotation of the coordinates about the vertical axis. Finally, Taylor's hypothesis to the effect that time displacements are equivalent to longitudinal space displacements is assumed to be valid.

The aerodynamic forces directly due to atmospheric turbulence, which constitute the input forces for the dynamic system represented by the airplane, are calculated in the first part of this report for the large airplane, that is, for the case where the spanwise distribution of the intensity of turbulence has to be taken into account. (The effect of spanwise variation of gust intensity on the lift has been treated by a slightly different method in ref. 5.)

The dynamics of the rigid airplane are considered in the second part. The dynamic system is now represented by a set of three simultaneous ordinary differential equations, rather than one as in reference 2; nonetheless, the problem of calculating the required transfer functions is still one of simple algebra.

The next part is concerned with the small flexible airplane and thus has direct application to fighter-type airplanes and guided missiles operating at relatively high speeds, in addition to serving as a preliminary to the last part of the report. The dynamic system is now represented by a partial differential equation, and the calculation of the transfer functions requires the solution of ordinary differential equations. Once these functions are calculated, however, the statistical techniques are the same as before, as a result of the fact that the lateral variation in gust intensity is ignored. Either modal or numerical-integration approaches may be used to analyze the dynamics of a swept-wing airplane with arbitrary stiffness and mass distribution. Although modal approaches have usually been preferred in the past for similar problems, it was believed that, in view of the highly complex nature of modern aircraft structures and the advanced type of computing machinery required and generally available for their analysis, the numerical-integration approach would be preferable and it has, therefore, been used.

The last part contains the analysis of the large flexible airplane. The statistical problem is now that of a system which is characterized by a partial differential equation with time and a space coordinate as independent variables and which is subjected to a random input that varies in time and space, so that more is required than the transfer functions from the gust intensity at one point on the wing to the stresses at another. The particular statistical problem presented by this case is considered in some detail, and the appropriate transfer functions are then obtained by using the numerical-integration approach presented in the preceding part to solve, in effect, the ordinary differential equations which describe the wing deformations at any given frequency.

AERODYNAMIC FORCES RESULTING DIRECTLY FROM ATMOSPHERIC TURBULENCE

The motions of a rigid airplane depend on the overall forces and moments, whereas the stresses of a rigid airplane and the motions and stresses of a flexible airplane depend on the distribution of these forces, as well. This part of the report is concerned with the calculation of the integrated and distributed forces and moments directly due to atmospheric turbulence when the spanwise variation of gust intensity has to be taken into account. (The forces and moments caused by the motions which result from the forces treated in this part can be calculated by conventional methods and will not be considered here, although the combined forces will be considered in the following parts.) Thus, this part serves as a basis for all the material presented in the later parts pertaining to the large airplane, and, hence, the fundamental notions required for an analysis of the large airplane are introduced here and discussed in some detail.

The basic approach is as follows: First, the instantaneous value of the quantity of interest, such as the lift, is expressed in terms of the instantaneous gust intensity at a point and a suitable influence function. For the lift this influence function can and will be identified with a certain lift distribution on the given wing in reverse flow; the same procedure may and, in the case of the rolling moment, will be followed for other integrated forces. On the other hand, for the local lift the influence function is the Green's function for the three-dimensional unsteady-lift problem and cannot be identified with an easily calculated lift distribution on the wing in reverse flow. Inasmuch as no knowledge concerning this function appears to be available, a method of calculating an approximate Green's function for this problem is outlined herein. The required influence functions for integrated effects can be synthesized from this function, and if the associated lift distribution in reverse flow cannot be calculated conveniently this approach may be preferable. This technique is illustrated here by means of the bending moment.

The next step consists in using the expression for the instantaneous value of the given quantity to calculate a correlation function for this quantity in terms of a correlation function of the normal component of the atmospheric turbulence. The power spectrum for the given quantity can then be obtained by taking the Fourier transform of its correlation function. This power spectrum is considered herein to be the desired end result, because the mean-square values of the quantity and its derivatives can be obtained from it, and other statistical parameters of interest can be obtained from these mean-square values. Several alternative approaches for calculating the aforementioned spectrum, either from the correlation function or directly from the spectrum of atmospheric turbulence, are given in connection with the lift and are directly applicable to other quantities as well.

In this part of the report the assumption is made that the influence functions of concern can be written as products of a function of time alone and a function of distance along

the span alone, and advantage is taken of this simplification in calculating the desired spectra. This restriction is removed in the last part of the report, where the influence functions considered cannot be separated into space-dependent and time-dependent constituents, and so the approaches outlined there are generalizations of those presented in this part; they may also be used for the calculation of the spectra of the quantities considered in this part if the assumption concerning the influence functions is not valid.

DEFINITIONS OF STATISTICAL PARAMETERS

As pointed out in the introduction, the intensity of the vertical component of turbulence $w(t)$ is a random process, so that the resulting forces can also be known only in a statistical sense. The purpose of this part is to calculate certain statistical properties of these forces, namely, their mean-square values, their correlation functions, and their power spectra. The fundamental principles involved in statistical analyses of the type considered herein are expounded in some detail, and citations of the literature on the subject are given in references 1 and 2. These fundamentals will therefore not be repeated here. However, both for the sake of ready reference and inasmuch as the statistical terms are not always defined in the same manner, the forms that are used herein are indicated in the succeeding paragraphs.

The time average of a time-dependent quantity is designated by a bar placed over the symbol,[2] and is defined as follows:

$$\bar{\xi} \equiv \lim_{T\to\infty} \frac{1}{2T}\int_{-T}^{T} \xi(t)dt$$

The assumption will always be made that this limit exists and is invariant under a translation of the origin of time. This assumption implies that the processes considered here are stationary in a statistical sense.

The mean of a random process $f(t)$ is defined as its time average, and is always assumed to be zero. In dealing with processes with nonzero mean this analysis is thus pertinent only to the process which consists of the difference between the original process and its mean value. Similarly, the mean-square value of a random process $f(t)$ is defined as the time average of the square of the process, so that

$$\overline{f^2} \equiv \lim_{T\to\infty} \frac{1}{2T}\int_{-T}^{T} f^2(t)\,dt$$

The time-correlation function of $f(t)$ is defined as

$$\psi_f(\tau) \equiv \overline{f(t)f(t+\tau)}$$

so that

$$\overline{f^2} = \psi_f(0)$$

and the power spectrum of $f(t)$ is defined as the Fourier transform of the correlation function:

$$\varphi_f(\omega) = \frac{1}{\pi}\int_{-\infty}^{\infty} e^{-i\omega\tau}\psi_f(\tau)\,d\tau$$

$$= \frac{1}{\pi U}\int_{-\infty}^{\infty} e^{-i\frac{\omega}{U}r}\psi_f\left(\frac{r}{U}\right)dr$$

The second form is the more convenient one when ψ_f represents more nearly a space correlation than a time correlation, so that it depends directly on a space displacement $r \equiv U\tau$ rather than on a time displacement τ. For the purposes of the analysis presented herein, the gust or input correlation functions have this property, so that, for instance, ψ_w may be defined as

$$\psi_w(r) = \overline{w(t)w\left(t+\frac{r}{U}\right)}$$

By virtue of the reciprocal properties of Fourier transforms and the symmetry of $\psi_f(\tau)$, which is a direct consequence of the assumed stationarity of $f(t)$, $\overline{f^2}$ may be expressed in terms of the spectrum of f as

$$\overline{f^2} = \int_0^{\infty} \varphi_f(\omega)\,d\omega \tag{1}$$

If $f(t)$ is the input of a linear system, the power spectrum of the response $x(t)$ of the system is related to the power spectrum of $f(t)$ by

$$\varphi_x(\omega) = |H(\omega)|^2\varphi_f(\omega) \tag{2}$$

where $H(\omega)$ is the transfer function of the system, that is, the complex amplitude of the response of the system to unit sinusoidal input. Hence, $H(\omega)$ is also the Fourier transform of the indicial response $h(t)$ of the system, which is defined herein as the response of the system to a unit impulsive input:

$$H(\omega) = \int_{-\infty}^{\infty} e^{-i\omega t}h(t)dt \tag{3}$$

where the lower limit could be taken as zero, since $h(t)$ is zero for $t<0$. Conversely, $h(t)$ can be obtained from $H(\omega)$ by means of the inverse of equation (3):

$$h(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{i\omega t}H(\omega)\,d\omega \tag{3a}$$

The mean-square value of the response can then be obtained by integrating its spectrum. Similarly, the mean-square values of the nth time derivative of the response can be obtained from the $(2n)$th moment of the output spectrum. For instance,

$$\overline{\left(\frac{dx}{dt}\right)^2} = \int_0^{\infty} \varphi_x(\omega)\,\omega^2\,d\omega$$

From the mean-square values of these derivatives other statistical quantities of interest, such as the expected number of peaks of the response per unit time, can then be calculated.

[2] When no possibility of confusion exists, a bar is also used to designate a space average, as in the case of $\bar{c}$ and $\bar{y}$. Also, for the components of turbulence the correlation functions depend primarily on space displacements and can be defined by space averages. For the sake of consistency, however, they are considered to be defined by time averages.

LIFT-INFLUENCE FUNCTIONS IN UNSTEADY FLOW

At any time the lift on a wing which results directly from atmospheric disturbances can be expressed for an unswept wing as

$$L(t)=\int_{-\infty}^{\infty} dt_1 \int_{-b/2}^{b/2} h(t_1,y)w(U(t-t_1),y)\,dy \qquad (4)$$

where $h(t,y)dy$ is a lift-influence function which represents the lift caused by an impulsive vertical gust of width dy which at time $t=0$ impinges on the wing at station y.

The influence functions required in equation (4) are difficult to calculate directly; methods for obtaining lift distributions on wings of finite span in unsteady flow usually require numerical solutions which do not lend themselves readily to the analysis of angle-of-attack distributions represented by delta functions. However, by virtue of the reciprocity theorems of linearized lifting-surface theory (ref. 6, for instance) the lift influence function for a twisted wing in indicial motion is equal to the lift distribution on that wing during indicial motion in the reverse direction with uniform unit angle of attack. The lift distribution in indicial motion with uniform angle of attack can be calculated relatively easily.

For the few cases for which calculations have been made (namely, some unswept wings), this lift distribution tends to be substantially invariant in time, except for overall magnitude. For instance, the calculations of reference 7 indicate that the lift distribution of an oscillating rectangular or elliptic wing in incompressible flow is substantially independent of frequency, so that in indicial motion it is substantially independent of time. This simplification may not be valid for swept wings.

The lift influence function can then be written as

$$h(t,y)=\frac{1}{b}h_L(t)\,\gamma(y) \qquad (5)$$

where $\gamma(y)$ defines the steady-state lift distribution for uniform unit angle of attack:

$$\gamma(y)\equiv\frac{cc_l}{\bar{c}C_L}$$

and where $h_L(t)$ describes the variation of the overall magnitude of the lift as a function of time after entry into a sharp-edge gust and may be written as

$$h_L(t)=\frac{C_{L_\alpha}qS}{U}\frac{d}{dt}k_2\left(\frac{Ut}{\bar{c}/2}\right)$$

In turn, k_2 is the lift response to a unit sharp-edge gust normalized to a steady-state value of unity and is, as in the preceding equation, usually expressed in terms of semichord lengths traveled $\frac{Ut}{\bar{c}/2}$. The time derivative is taken here because the response wanted is the one to a unit impulsive gust rather than a sharp-edge gust.

The Fourier transform $H_L(\omega)$ of this function $h_L(t)$ is proportional to a function $\phi(k)$, which may be termed the generalized Sears function because for two-dimensional incompressible flow it is the Sears function:

$$H_L(\omega)=\frac{C_{L_\alpha}qS}{U}\phi(k) \qquad (6)$$

where

$$k\equiv\frac{\omega\bar{c}}{2U}$$

The function $H_L(\omega)$ represents the complex amplitude of the lift due to sinusoidal gusts of unit amplitude and is thus the transfer function from the gust to the lift.

Actually, only the absolute square of $\phi(k)$ will be required. For two-dimensional incompressible flow the following approximation is given in reference 1:

$$|\phi(k)|^2\approx\frac{1}{1+2\pi k} \qquad (7)$$

This expression has the advantage of simplicity, although it is somewhat in error compared with the absolute square of the Sears function at very low frequencies, a fact which could be remedied by using the approximation

$$|\phi(k)|^2\approx\frac{1+ak}{1+ak(1+2\pi k)}$$

where a is about 15 for a good overall fit to the exact expression. However, the behavior of the Sears function itself at very high frequencies is unrealistic, because its absolute square goes to zero as $1/k$, whereas for any nonzero Mach number and any finite span the absolute square of the generalized Sears function can be shown to tend to zero at least as rapidly as $1/k^2$. As a result of these discrepancies, the approximation given by equation (7) and, for the same reason, the absolute square of the exact Sears function, cannot be used to obtain moments of the lift spectrum, that is, values of the mean-square derivatives of the lift, although they may be adequate for calculating the mean-square value of the lift itself in many cases, particularly when absolute accuracy is not required. Whenever possible the values of $|\phi(k)|^2$ given in reference 8 for the plan form and Mach number of interest should be used.

MEAN-SQUARE LIFT AND ITS SPECTRAL RESOLUTION FOR THE UNSWEPT WING

Basic equations.—The correlation function of the lift can be expressed, by virtue of equation (4), as

$$\psi_L(\tau)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2} h(t_1,y_1)h(t_2,y_2)\,\overline{w(U(t-t_1),y_1)w(U(t+\tau-t_2),y_2)}\,dy_1dy_2dt_1dt_2 \qquad (8)$$

where the averaged product on the right side represents a velocity correlation function. This function depends in general on both space and time displacements. However, if Taylor's hypothesis is made, the time displacements are equivalent to

longitudinal space displacements. The velocity correlation functions are then functions only of longitudinal and lateral space displacements. Thus, for homogeneous turbulence,

$$\overline{w(x+Ut,y)w(x+\xi+U(t+\tau),y+\eta)}=\tilde{\psi}_w(\xi+U\tau,\eta) \tag{9}$$

In addition to Taylor's hypothesis and the assumption of homogeneity, the turbulence is assumed to be axisymmetric with respect to vertical axes, so that $\tilde{\psi}_w(\xi,\eta)$ is a function only of $\sqrt{\xi^2+\eta^2}$. This function is the ordinary space-correlation function ψ_w, so that

$$\tilde{\psi}_w(U\tau+\xi,\eta)=\psi_w\left(\sqrt{(U\tau+\xi)^2+\eta^2}\right)$$

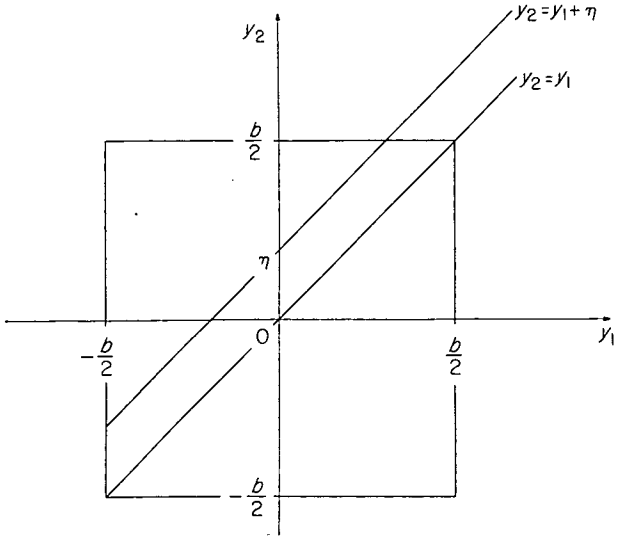
and, hence,

$$\psi_L(\tau)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}h(t_1,y_1)h(t_2,y_2)\psi_w\left(\sqrt{U^2(\tau+t_1-t_2)^2+(y_2-y_1)^2}\right)dy_1dy_2dt_1dt_2$$

If the assumption implicit in equation (5) is now made, the preceding equation can be written as

$$\psi_L(\tau)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}h_L(t_1)\,h_L(t_2)\,\psi_{w_e}(U(\tau+t_1-t_2))\,dt_1\,dt_2 \tag{10}$$

where



$$\psi_{w_e}(U\tau)=\frac{1}{b^2}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}\psi_w\left(\sqrt{U^2\tau^2+(y_2-y_1)^2}\right)\gamma(y_1)\,\gamma(y_2)\,dy_1\,dy_2$$

$$=\frac{1}{b}\int_0^b\Gamma(\eta)\,\psi_w\left(\sqrt{U^2\tau^2+\eta^2}\right)d\eta \tag{11}$$

where, in turn, $\Gamma(\eta)$ is an autoconvolution of $\gamma(y)$ defined by

$$\Gamma(\eta)=\frac{2}{b}\int_{-b/2}^{\frac{b}{2}-\eta}\gamma(y)\,\gamma(y+\eta)\,dy \tag{12}$$

The validity of equation (11) can be demonstrated by performing the integration in the y_1,y_2 plane as indicated in the following sketch:

That is, integration is performed first over y_1, with a variable $\eta\equiv y_2-y_1$ held constant. For this integration ψ_w is constant, so that only $\gamma(y_1)$ and $\gamma(y_1+\eta)$ are involved, and the result is a function of η which is one-half of the function $\Gamma(\eta)$ defined by equation (12). The second integration is then performed over η, yielding equation (11) except for a factor of ½. In this process, only the part of the square above the line $y_2=y_1$ is covered. However, by a similar process, the part of the integral corresponding to the part of the plane below this line can be evaluated and shown to be equal to the first part, so that by defining Γ as in equation (12), both parts are taken into account simultaneously in equation (11).

The quantity

$$w_e^2\equiv\psi_{w_e}(0)$$

$$=\frac{1}{b}\int_0^b\Gamma(\eta)\,\psi_w(\eta)\,d\eta$$

may be considered an averaged mean-square vertical component of turbulence; $\psi_{w_e}(U\tau)$ is then the corresponding correlation function, and the Fourier transform of the latter,

$$\varphi_{w_e}(\omega)=\frac{1}{\pi U}\int_{-\infty}^{\infty}e^{-i\frac{\omega}{U}(U\tau)}\psi_{w_e}(U\tau)\,d(U\tau) \tag{13}$$

is the corresponding power spectrum.

Once $\varphi_{w_e}(\omega)$ has been obtained, the power spectrum of the lift can be obtained by taking the Fourier transforms of both sides of equation (10). The result is

$$\varphi_L(\omega)=|H_L(\omega)|^2\varphi_{w_e}(\omega) \tag{14}$$

where $H_L(\omega)$ is the transfer function defined in the preceding section. The mean square of the lift can then be obtained by integrating its spectrum, as indicated in equation (1).

Equation (14) has the same form as the corresponding equation for the case where spanwise averaging of the effects of turbulence is not taken into account (see eq. (2) and ref. 1), except that $\varphi_w(\omega)$ is now replaced by $\varphi_{w_e}(\omega)$. Thus, the spectrum of the averaged turbulence must approach that of the unaveraged turbulence when the span approaches zero, as may be seen to be the case from equation (11) and the definitions of $\gamma(y)$ and $\Gamma(\eta)$.

Two alternative approaches.—The defining relations for $\varphi_{w_e}(\omega)$, equations (11) and (13), do not necessarily represent the best method of calculating it in any given case. A slightly different expression appears to be more convenient in general. It consists in substituting equation (11) into equation (13) and inverting the order of integration to yield

$$\varphi_{w_e}(\omega)=\frac{1}{b}\int_0^b\Gamma(\eta)\tilde{\varphi}_w(\omega,\eta)\,d\eta \tag{15}$$

where

$$\tilde{\varphi}_w(\omega,\eta)=\frac{1}{\pi U}\int_{-\infty}^{\infty} e^{-i\frac{\omega}{U}(U\tau)}\psi_w\left(\sqrt{U^2\tau^2+\eta^2}\right)d(U\tau) \tag{16}$$

so that

$$\tilde{\varphi}_w(\omega,0)=\varphi_w(\omega)$$

A third approach, which has certain advantages over the others, is similar to the one that has been used in reference 5. In this approach the assumption of axisymmetry is not made initially, and use is made of the spectrum

$$\tilde{\Phi}_w(\lambda_1,\lambda_2)=\frac{1}{\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{-i(\lambda_1\xi+\lambda_2\eta)}\tilde{\psi}_w(\xi,\eta)\,d\xi\,d\eta \tag{17a}$$

The correlation function $\psi_{w_e}(U\tau)$ can then be written as

$$\psi_{w_e}(U\tau)=\frac{1}{b^2}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}\gamma(y_1)\,\gamma(y_2)\,dy_1\,dy_2\,\frac{1}{4}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{i[\lambda_1 U\tau+\lambda_2(y_2-y_1)]}\,\tilde{\Phi}_w(\lambda_1,\lambda_2)\,d\lambda_1\,d\lambda_2$$

Substitution of this expression into equation (13) and then interchanging the order of integration yields:

$$\varphi_{w_e}(\omega)=\frac{1}{2U}\int_{-\infty}^{\infty}\tilde{\Phi}_w\left(\frac{\omega}{U},\lambda_2\right)\left|\tilde{\Gamma}(\lambda_2)\right|^2 d\lambda_2$$

where

$$\tilde{\Gamma}(\lambda)=\frac{1}{b}\int_{-b/2}^{b/2}\gamma(y)\,e^{-i\lambda y}\,dy$$

and is, as a result of the symmetry of $\gamma(y)$, real and symmetric in λ.

Now, if the turbulence is axisymmetric, $\tilde{\Phi}_w$ depends only on $\lambda\equiv\sqrt{\lambda_1^2+\lambda_2^2}$, that is,

$$\tilde{\Phi}_w(\lambda_1,\lambda_2)=\Phi_w\left(\sqrt{\lambda_1^2+\lambda_2^2}\right) \tag{17b}$$

so that the expression for $\varphi_{w_e}(\omega)$ becomes

$$\varphi_{w_e}(\omega)=\frac{1}{U}\int_0^{\infty}\Phi_w\left(\sqrt{\left(\frac{\omega}{U}\right)^2+\lambda^2}\right)\tilde{\Gamma}^2(\lambda)\,d\lambda \tag{18}$$

where $\Phi_w(\lambda)$ is related to $\psi_w(r)$ by

$$\Phi_w(\lambda)=\frac{2}{\pi}\int_0^{\infty} r\,J_0(\lambda r)\,\psi_w(r)\,dr$$

Although the spectra used in the last two approaches have been defined by expressions involving the point correlation function $\psi_w(r)$, they can be expressed equally well in terms of the point spectrum $\varphi_w(\omega)$, so that if, say, an experimentally obtained point spectrum is to be used, it need not be transformed into a correlation function before it can be used in these calculations. The required relations are

$$\tilde{\varphi}_w(\omega,\eta)=\varphi_w(\omega)-\frac{|\eta|}{U}\int_{|\omega|}^{\infty}\varphi_w(\omega_1)\,\frac{\omega_1}{\sqrt{\omega_1^2-\omega^2}}\,J_1\left(\frac{|\eta|\sqrt{\omega_1^2-\omega^2}}{U}\right)d\omega_1 \tag{19}$$

and

$$\Phi_w(\lambda)=-\frac{2U^2}{\pi}\left[\int_{\lambda U}^{\infty}\varphi(\omega)\,\frac{\omega}{(\omega^2-\lambda^2U^2)^{3/2}}\,d\omega \right. \tag{20}$$

where the notation $\lceil\ \rceil$ is used to specify that the finite part of the integral is to be taken, an operation which may be performed by integrating by parts and ignoring the infinite part, so that, in terms of a proper integral,

$$\Phi_w(\lambda)=-\frac{2U^2}{\pi}\int_{\lambda U}^{\infty}\frac{d\varphi_w(\omega)}{d\omega}\,\frac{d\omega}{\sqrt{\omega^2-\lambda^2U^2}}$$

Also, the function $\Phi_w(\lambda)$ can be obtained from $\tilde{\varphi}_w(\omega,\eta)$ by means of either of the relations

$$\Phi_w(\lambda)=\frac{1}{\pi U}\int_{-\infty}^{\infty}e^{-i\lambda\eta}\tilde{\varphi}_w(0,\eta)\,d\eta$$

$$=\frac{2}{\pi U}\int_0^{\infty}\tilde{\varphi}_w(\lambda U,\eta)\,d\eta$$

Results of calculations.—In order to illustrate the magnitude of the effects under consideration, calculations have been made for a uniform loading $\gamma(y)=1$ and a point correlation function which has been used in references 1 and 2 and appears to fit experimental data (ref. 4) fairly well over a large portion of the significant frequency range, namely,

$$\psi_w(r)=\overline{w^2}\left(1-\frac{|r|}{2L^*}\right)e^{-|r|/L^*}$$

so that

$$\varphi_w(\omega)=\frac{\overline{w^2}L^*}{\pi U}\,\frac{1+3k'^2}{(1+k'^2)^2}$$

where L^* is the integral scale of turbulence, which is here defined as

$$L^*=\frac{2}{\overline{w^2}}\int_0^{\infty}\psi_w(r)\,dr$$

and where

$$k'\equiv\frac{\omega L^*}{U}$$

This correlation function has the drawback that the moments of the spectrum associated with it are infinite, so that

it implies a process with infinite mean-square derivatives, but it is quite useful if only the mean-square value of the process itself is of interest.

For uniform loading,

$$\Gamma(\eta)=2\left(1-\frac{\eta}{b}\right)$$

and

$$\tilde{\Gamma}(\lambda)=\frac{\sin\frac{\lambda b}{2}}{\frac{\lambda b}{2}}$$

and for the given correlation function,

$$\tilde{\varphi}_w(\omega,y)=\frac{\overline{w^2}L^*}{\pi U}\left[\frac{y}{L^*}\frac{1+3k'^2}{(1+k'^2)^{3/2}}K_1\left(\frac{y}{L^*}\sqrt{1+k'^2}\right)-\left(\frac{y}{L^*}\right)^2\frac{1}{1+k'^2}K_0\left(\frac{y}{L^*}\sqrt{1+k'^2}\right)\right]$$

where K_0 and K_1 are modified Bessel functions of the second kind, and

$$\Phi_w(\lambda)=\frac{3\overline{w^2}L^{*2}}{\pi U^2}\frac{k'^2}{(1+k'^2)^{5/2}}$$

The mean-square average gust intensity for this case is given by

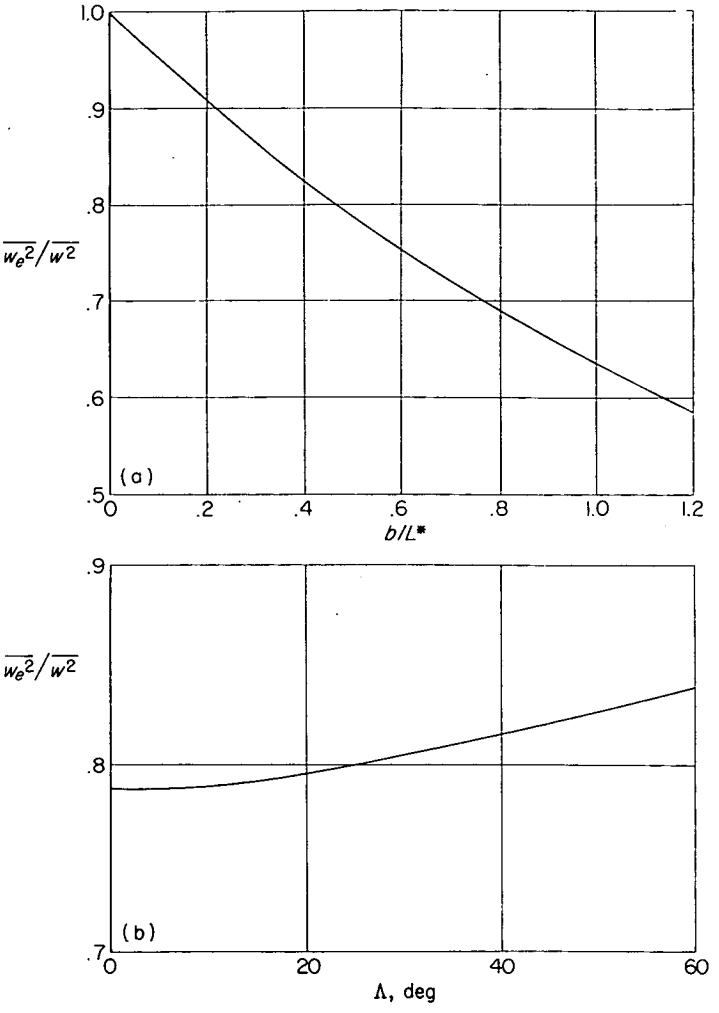
$$\overline{w_e^2}=\overline{w^2}\,\frac{1-e^{-\beta}}{\beta}$$

where $\beta\equiv b/L^*$, and is shown in figure 1 (a). The correlation function ψ_{w_e} is given by

$$\psi_{w_e}(r)=\frac{\overline{w^2}}{\beta}\left[\sigma\tilde{K}_1\left(\sigma;\ \sinh^{-1}\frac{\beta}{\sigma}\right)-\sigma^2\tilde{K}_0\left(\sigma;\ \sinh^{-1}\frac{\beta}{\sigma}\right)+\frac{\sigma^2}{\beta}\left(e^{-\sigma}-e^{-\sqrt{\sigma^2+\beta^2}}\right)\right]$$

where $\sigma\equiv r/L^*$, and where $\tilde{K}_0(\sigma;\vartheta)$ and $\tilde{K}_1(\sigma;\vartheta)$ are incomplete modified Bessel functions of the second kind defined by

$$\tilde{K}_n(\sigma;\vartheta)\equiv\int_0^{\vartheta}\cosh n\vartheta\ e^{-\sigma\cosh\vartheta}\,d\vartheta$$



The spectrum $\varphi_{w_e}(\omega)$ is given by

$$\varphi_{w_e}(\omega)=\frac{\overline{w^2}}{\beta^2}\frac{2L^*}{\pi U}\frac{1}{(1+k'^2)^3}\{3k'^2\beta\sqrt{1+k'^2}\,[Ki_0(\beta\sqrt{1+k'^2})-\beta\sqrt{1+k'^2}K_0(\beta\sqrt{1+k'^2})]+(1-3k'^2)[2-2\beta\sqrt{1+k'^2}K_1(\beta\sqrt{1+k'^2})-\beta^2(1+k'^2)K_0(\beta\sqrt{1+k'^2})]\}$$

where $Ki_0(x)$ is the integral of $K_0(x)$:

$$Ki_0(x)=\int_0^x K_0(x_1)dx_1$$

The functions ψ_{w_e} and φ_{w_e} (normalized with the averaged mean-square turbulent velocity) are shown in figures 2 and 3, respectively. The effect of the span ratio on the normalized correlation function of the averaged turbulence may be seen to be relatively small, so that the effect on the unnormalized correlation function is primarily the decrease in overall level given by the ratio of $\overline{w_e^2}$ to $\overline{w^2}$. A similar statement may be made for the power spectrum. If the power spectrum were not normalized the averaging effect of the span would tend to reduce the intensity of the spectrum at all frequencies, but the high frequencies would be attenuated much more than the low ones, as might be expected. In fact, although the unaveraged spectrum decreases as ω^{-2} at high frequencies, the averaged spectrum decreases as ω^{-3}.

(a) Unswept wings.

(b) Swept wings, $\frac{b}{L^*\cos\Lambda}=0.5$.

FIGURE 1.—The mean-square averaged vertical component of turbulence.

The asymptotic values for $b/L^*\to\infty$ are shown in figures 2 and 3 in order to indicate the nature of the functions considered here when the scale of turbulence is small compared with the span, as may be the case for a wind-tunnel model responding to natural or artificial tunnel turbulence, or for a buffeting wing or tail surface, although this condition is not of practical concern for the gust-load problem.

The power spectrum of the lift is equal to the product of the power spectrum $\varphi_{w_e}(\omega)$ and the absolute square of the transfer function $H_L(\omega)$, as indicated in equation (14).

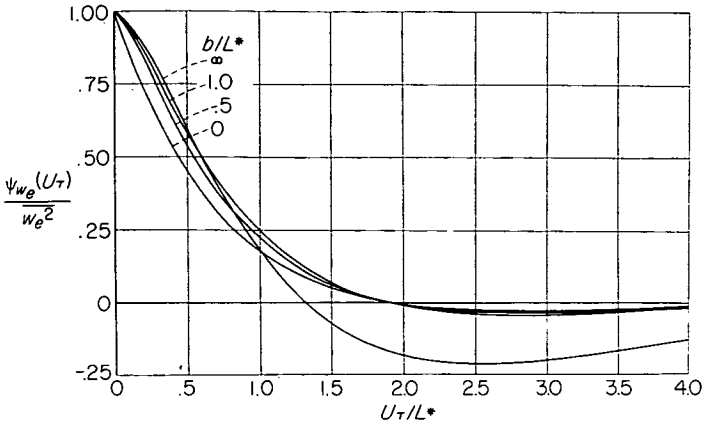


FIGURE 2.—The correlation function of the averaged vertical component of turbulence.

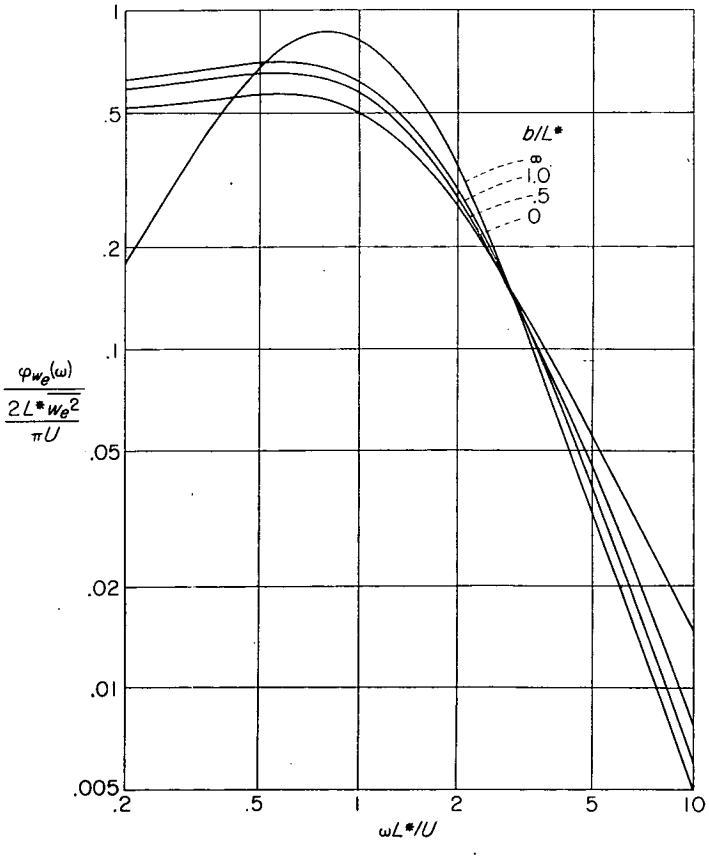

FIGURE 3.—The power spectrum of the averaged vertical component of turbulence.

Inasmuch as this lift is not an end in itself but only one of the parameters that enter into the calculations of the motion of the airplane, its mean-square intensity is of little practical significance; its spectrum is the quantity needed in further calculations. However, if the mean-square intensity is wanted for any reason it can be obtained by integrating the spectrum. Thus, for instance, the approximate expression for $|\phi(k)|^2$ given by equation (7) and the spectrum $\varphi_w(\omega)$ used for the preceding calculation yields the mean-square lift:

$$(\overline{L^2})_{\beta\to 0}=\left(\frac{C_{L_\alpha}qS}{U}\right)^2\overline{w^2}\,\frac{s}{2\pi^2}\left\{\frac{1+3\left(\frac{s}{2\pi}\right)^2}{\left[1+\left(\frac{s}{2\pi}\right)^2\right]^2}\left(\frac{s}{4}-\log\frac{s}{2\pi}\right)-\frac{\frac{s}{4}-1}{1+\left(\frac{s}{2\pi}\right)^2}\right\}$$

where

$$s\equiv\frac{L^*}{\overline{c}/2}$$

and, in view of the observation that much of the turbulent energy is contained in a region for which the span has a very small effect on the (normalized) spectrum, this equation should serve to furnish an approximation to the mean-square lift for nonvanishing span, provided $\overline{w_e^2}$ is used instead of $\overline{w^2}$. However, the mean-square values of the derivatives of the lift cannot be calculated in this simple manner, because the deviation of the normalized averaged spectrum from the point spectrum at high frequencies cannot be ignored in calculating the moments of the lift spectrum.

MEAN-SQUARE LIFT OF THE SWEPT WING

For the yawed or sideslipping unswept wing, equations (10) and (14) for the lift-correlation function and spectrum are still valid if an appropriate lift-influence function is used, and if the correlation function for the averaged turbulence is defined by

$$\psi_{w_e}(U\tau)=\frac{1}{b\cos\Lambda}\int_0^{b\cos\Lambda}\Gamma(\eta)\,\psi_w\left(\sqrt{(U\tau+\eta\tan\Lambda)^2+\eta^2}\right)d\eta$$

where $\Gamma(\eta)$ now pertains to a lift-distribution function $\gamma(y)$ which is appropriate for yawed motion and is defined for $-\frac{b}{2}\cos\Lambda\leqq y\leqq\frac{b}{2}\cos\Lambda$. The mean-square averaged intensity of the vertical component of turbulence is then

$$\overline{w_e^2}=\frac{1}{b\cos\Lambda}\int_0^{b\cos\Lambda}\Gamma(\eta)\,\psi_w\left(\frac{\eta}{\cos\Lambda}\right)d\eta$$

$$=\frac{1}{b}\int_0^b\Gamma(\eta'\cos\Lambda)\,\psi_w(\eta')\,d\eta'$$

where $\eta'\equiv\frac{\eta}{\cos\Lambda}$. Thus, this mean-square intensity is unaffected by the yawing process, except for the slight change which results from the change in $\Gamma(\eta)$, although the spectral resolution of the averaged intensity changes in the process.

For the swept wing both y_2-y_1 and $|y_2|-|y_1|$ occur in the integral, so that the reduction of the double integral for $\psi_{w_e}(U\tau)$ to a single integral (see eq. (11)) cannot be affected so simply. The double integral for the swept wing is

$$\psi_{w_e}(U\tau)=\frac{1}{b^2}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}\gamma(y_1)\,\gamma(y_2)\,\psi_w\left(\sqrt{[U\tau+(|y_2|-|y_1|)\tan\Lambda]^2+(y_2-y_1)^2}\right)dy_1\,dy_2 \qquad (21)$$

From this integral, by using rectangular lift distributions and the aforementioned point correlation function, the mean square of the averaged turbulence as well as the corresponding correlation function and power spectrum have been calculated by numerical integration for various sweep angles Λ, the ratio $\frac{\beta}{\cos\Lambda}$ being maintained at 0.5. (The decision to hold $\frac{\beta}{\cos\Lambda}$ rather than β constant was reached as a result of the foregoing analysis of the yawed unswept wing, which indicated that the effects of sweep should be minimized in this manner.) The results for $\overline{w_e^2}$ are shown in figure 1, and the effect of sweep on $\overline{w_e^2}$ is seen to be small for this comparison. The calculated correlation functions and spectra (normalized with respect to $\overline{w_e^2}$) are not shown because they agreed with those for $\Lambda=0$ within less than 1 percent for most values of $U\tau$ and k', respectively.

MEAN-SQUARE ROLLING MOMENT

In the preceding sections the averaging effect of the span has been shown to consist, essentially, in reducing the effective intensity of the turbulence sensed by the wing; thus, it only modifies the forces present on a wing of small span. If the analysis is extended to the rolling moment, however, a new phenomenon appears. When a wing is so small relative to the scale of turbulence that at any instant all of its points experience the same turbulent velocity, the wing experiences no rolling moment as the result of the direct action of turbulence (although it may experience a rolling moment indirectly as a result of the rolling and yawing motion caused by the lateral component of the turbulence). On the other hand, on a large wing the different intensities of the turbulence at different points on the span give rise directly to a net rolling moment, which then results in rolling motion. In this section the mean-square value of this moment is calculated.

At any instant t the rolling moment $L'(t)$ can be written in the same form as the lift $L(t)$ in equation (4); however, according to the previously mentioned reciprocity theorem, the lift-influence function $h(t,y)$ is now the lift distribution for an indicial roll with unit helix angle at the wing tip. If the assumption of invariance of this distribution with time is made, as for the symmetric case (see eq. (5)), then the required lift-influence function can be written as

$$h(t,y)=\frac{1}{b}h'(t)\gamma'(y)$$

where $h'(t)=\frac{C_{l_p}(t)qSb}{2U}$, and where the steady-state lift distribution $\gamma'(y)\equiv\frac{cc_l}{\bar{c}C_l}$ now pertains to a unit linear antisymmetric angle of attack.

The correlation function for the moment can then be written as

$$\psi_{L'}(\tau)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}h'(t_1)h'(t_2)\psi_{w_e'}(U(\tau+t_1-t_2))dt_1dt_2 \quad (22)$$

where

$$\psi_{w_e'}(U\tau)=\frac{1}{b^2}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}\gamma'(y_1)\gamma'(y_2)\psi_w(\sqrt{U^2\tau^2+(y_2-y_1)^2})dy_1dy_2$$

$$=\frac{1}{b}\int_0^b\Gamma'(\eta)\psi_w(\sqrt{U^2\tau^2+\eta^2})d\eta \quad (23)$$

where, in turn, in analogy with equation (12),

$$\Gamma'(\eta)=\frac{2}{b}\int_{-b/2}^{(b/2)-\eta}\gamma'(y)\gamma'(y+\eta)dy$$

Hence, the second and third approaches indicated in the section concerned with the mean-square lift (see eqs. (15) and (16)) can be used to obtain

$$\varphi_{w_e'}(\omega)=\frac{1}{b}\int_0^b\Gamma'(\eta)\tilde{\varphi}_w(\omega,\eta)d\eta \quad (24)$$

and

$$\varphi_{w_e'}(\omega)=\frac{1}{U}\int_0^\infty\Phi_w\left(\sqrt{\left(\frac{\omega}{U}\right)^2+\lambda^2}\right)|\tilde{\Gamma}'(\lambda)|^2d\lambda$$

where

$$\tilde{\Gamma}'(\lambda)=\frac{1}{b}\int_{-b/2}^{b/2}\gamma'(y)e^{-i\lambda y}dy$$

and

$$\varphi_{L'}(\omega)=\left(\frac{C_{l_p}qSb}{2U}\right)^2|\phi(k)|^2\varphi_{w_e'}(\omega) \quad (25)$$

so that the mean-square rolling moment can be obtained by integrating this spectrum.

A qualitative indication of the effect of span on the mean-square rolling moment sensed by an airplane may be obtained from the quantity $\psi_{w_e'}(0)$, which represents the integral of the spectrum $\varphi_{w_e'}$. For a linear loading, $\gamma'=6\frac{y}{b/2}$ and

$$\Gamma'(\eta)=6\left[4-6\frac{\eta}{b/2}+\left(\frac{\eta}{b/2}\right)^3\right]$$

$$\tilde{\Gamma}'(\lambda)=6i\frac{\frac{\lambda b}{2}\cos\frac{\lambda b}{2}-\sin\frac{\lambda b}{2}}{\left(\frac{\lambda b}{2}\right)^2}$$

Hence, using the aforementioned expression for the point correlation function yields

$$\varphi_{w_e'}(\omega)=\frac{L^*\overline{w^2}}{\pi U}\frac{18}{\beta'^4(1+k'^2)^4}\{[-32+2\beta'^2+(16\beta'^2+\beta'^4)K_0(\beta')+$$
$$(32\beta'+6\beta'^3)K_1(\beta')]+k'^2[32-6\beta'^2-16\beta'^2K_0(\beta')-$$
$$(32\beta'+2\beta'^3)K_1(\beta')+\beta'^3Ki_0(\beta')]\}$$

where

$$\beta'\equiv\beta\sqrt{1+k'^2}$$

and

$$\psi_{w_e'}(0)=\frac{12\overline{w^2}}{\beta^4}\left[\frac{\beta^3}{4}-6+e^{-\beta}\left(6+6\beta+3\beta^2+\frac{3}{4}\beta^3\right)\right]$$

This spectrum and its integral approach zero linearly as β tends to zero.

GENERALIZED AERODYNAMIC INFLUENCE FUNCTIONS IN UNSTEADY FLOW

The aerodynamic influence functions used in the preceding sections define the contribution of a given station of a wing to the total lift and rolling moment. In the analysis of a flexible wing, and even in the calculation of certain properties of a rigid wing, generalized aerodynamic influence functions are required, which define the contribution of one station on the wing to the lift at another station and thus represent a Green's function for the unsteady spanwise lift distribution. No work appears to have been done on such functions. For steady flow, apart from some calculations for supersonic speeds which are based on the subdivision of a given wing into a number of squares, the only available results appear to be those given in references 9 and 10.

The analysis in this section is based on reference 8 and consists in a generalization of the method presented therein to unsteady flow. This method constitutes an attempt to predict the lift distribution for any given twist on the basis of knowledge concerning a few definite angle-of-attack distributions, and may therefore be termed a function-interpolation method. For the present purpose, the presumably known lift distributions are the ones for uniform angle of attack in direct and reverse flow in a dimensionless form, namely, $cc_l/\overline{c}C_L$; they will be referred to as $\gamma_D(y)$ and $\gamma_R(y)$, respectively. (The function $\gamma(y)$ used previously is the one now designated by $\gamma_R(y)$.) Also required is the coefficient of damping in roll C_{l_p}. (The lift-curve slope and the coefficient of damping in roll are the same in direct and reverse flow by virtue of the reciprocity theorem, so that no distinction will be made.)

The approach of reference 9 then yields the following approximate expression for the lift distribution due to any angle-of-attack distribution:

$$\frac{cc_l}{\overline{c}}=C_{L_\alpha}\{\overline{\alpha}\,\gamma_D(y)+K[\alpha(y)-\overline{\alpha}]\,\gamma_R(y)\} \tag{26}$$

where

$$\overline{\alpha}=\frac{1}{b}\int_{-b/2}^{b/2}\gamma_R(y)\,\alpha(y)\,dy$$

$$K=\frac{C_{l_p}}{C_{L_\alpha}}\frac{b^3}{4\int_0^{b/2}\gamma_R(y)\,y^2dy} \tag{27}$$

Values of K may be obtained from the information given in references 9 and 10. As the aspect ratio tends to zero, K approaches ½, whereas for aspect ratios approaching infinity, K tends to 1. The following relations can be obtained from elementary definitions and from the aforementioned reciprocity theorem:

$$C_L=\frac{1}{b}\int_{-b/2}^{b/2}\frac{cc_l}{\overline{c}}\,dy$$

$$=\frac{C_{L_\alpha}}{b}\int_{-b/2}^{b/2}\gamma_R(y)\,\alpha(y)\,dy$$

$$\frac{1}{b}\int_{-b/2}^{b/2}\gamma_D(y)\,dy=\frac{1}{b}\int_{-b/2}^{b/2}\gamma_R(y)\,dy=1$$

$$C_l=\frac{1}{b^2}\int_{-b/2}^{b/2}\frac{cc_l}{\overline{c}}\,y\,dy$$

$$C_{l_p}=\frac{1}{b^2}\int_{-b/2}^{b/2}\left(\frac{cc_l}{\overline{c}}\right)_{\alpha=\frac{y}{b/2}}y\,dy$$

With the aid of these relations the lift distributions given by equation (26) may readily be seen to have the correct lift and rolling moment for all angle-of-attack distributions, and to reduce to the exact lift distributions for angle-of-attack distributions which vary linearly along the span. A lift distribution which possesses these properties could readily be obtained by approximating any given angle-of-attack distribution by a suitably chosen linear one. However, this procedure would yield poorer approximations than the ones furnished by equation (26); for a parabolic angle-of-attack distribution on a wing of very small aspect ratio, for instance, this procedure would yield the lift distribution

$$\frac{cc_l}{\overline{c}}=\frac{A}{2}\sqrt{1-\left(\frac{y}{b/2}\right)^2}$$

with a bending moment too low by 17 percent compared with the one of the exact lift distribution,

$$\frac{cc_l}{\overline{c}}=\frac{A}{3}\sqrt{1-\left(\frac{y}{b/2}\right)^2}\left[1+2\left(\frac{y}{b/2}\right)^2\right]$$

whereas equation (26) yields

$$\frac{cc_l}{\overline{c}}=\frac{A}{4}\sqrt{1-\left(\frac{y}{b/2}\right)^2}\left[1+4\left(\frac{y}{b/2}\right)^2\right]$$

with a bending moment 8 percent too high. For very large aspect ratios, γ_D and γ_R both tend to the chord distribution $c/\overline{c}$, so that the lift distributions given by equation (26) tend to the correct limiting value,

$$\left(\frac{cc_l}{\overline{c}}\right)_{A\to\infty}=C_{l_\alpha}\frac{c}{\overline{c}}\alpha \tag{28}$$

Therefore the accuracy of the results furnished by equation (26) may be expected to increase as the aspect ratio increases, whereas the accuracy of the other approximation is independent of aspect ratio.

In this connection, it may be mentioned that "strip theory" consists in using equation (28) for all aspect ratios and, hence, is not very satisfactory for wings with medium and low aspect ratios. For instance, for the case discussed in the preceding paragraph, it furnishes a bending moment which is too low by 25 percent for a delta wing, and too high by 25 to 100

percent for tapered wings. (The two figures pertain to taper ratios of ¼ and 1, respectively.)

Substituting the value for $\bar{\alpha}$ from equation (27) into equation (26) gives the following expression for $cc_l/\bar{c}$:

$$\frac{cc_l}{\bar{c}}=\frac{C_{L_\alpha}}{b}\int_{-b/2}^{b/2}\{[\gamma_D(y)-K\gamma_R(y)+bK\,\delta(y-\eta)]\,\gamma_R(\eta)\}\alpha(\eta)\,d\eta$$

The expression in braces in the integrand is the desired generalized aerodynamic influence function and will be designated by $G(y,\eta)$, so that

$$G(y,\eta)=[\gamma_D(y)-K\gamma_R(y)+bK\,\delta(y-\eta)]\,\gamma_R(\eta) \tag{29}$$

and

$$\frac{cc_l}{\bar{c}}=\frac{C_{L_\alpha}}{b}\int_{-b/2}^{b/2}G(y,\eta)\,\alpha(\eta)\,d\eta \tag{30}$$

In the limiting cases of wings of very low or very high aspect ratio, γ_D and γ_R approach a common value, say γ. Thus, for wings of very low aspect ratio,

$$G(y,\eta)=\frac{1}{2}[\gamma(y)+b\,\delta(y-\eta)]\,\gamma(\eta) \tag{31a}$$

where δ is the Dirac delta (unit-impulse) function, and for wings of very high aspect ratio,

$$G(y,\eta)=b\,\delta(y-\eta)\,\gamma(\eta) \tag{31b}$$

which is the Green's function associated with strip theory. Thus, on wings of very high aspect ratio all the lift produced by the local angle of attack at a given station is carried in the immediate vicinity of that station, whereas on wings of very low aspect ratio much of the lift is carried elsewhere. This tendency for a given station to affect a greater portion of the wing as the span decreases is, of course, to be expected.

The preceding analysis can be applied to the oscillatory case at a given reduced frequency k, as well as to the steady case. If the assumption of invariance of normalized distributions with time or frequency is made, as before, then $\gamma_D(y)$, $\gamma_R(y)$, and K are independent of frequency, so that equation (30) can be written as

$$l(y;k)=\frac{C_{L_\alpha}(k)qS}{b^2}\int_{-b/2}^{b/2}G(y,\eta)\alpha(\eta)d\eta \tag{32a}$$

where $G(y,\eta)$, defined as before, is independent of k. By applying a Fourier transformation to both sides of this equation the following relation is then obtained for flight through continuously varying turbulence (cf. eq. (4)), as modified by the assumption stated in equation (5):

$$l(y,t)=\frac{1}{b}\int_{-\infty}^{\infty}h_L(t_1)dt_1\frac{1}{b}\int_{-b/2}^{b/2}G(y,\eta)w(U(t-t_1),\eta)d\eta \tag{32b}$$

where $l(y,t)$ is the lift per unit span at station y and time t, and where the function $h_L(t)$ is the one used previously.

The correlation function for this lift can then be written as

$$\psi_{l(y)}(\tau)=\frac{1}{b^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}h_L(t_1)h_L(t_2)\,dt_1dt_2\,\frac{1}{b^2}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}G(y,\eta_1)G(y,\eta_2)\psi_w\left(\sqrt{U^2(\tau+t_1-t_2)^2+(\eta_2-\eta_1)^2}\right)d\eta_1d\eta_2$$

$$=\frac{1}{b^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}h_L(t_1)h_L(t_2)dt_1dt_2\psi_{w_\epsilon}(U(\tau+t_1-t_2),y) \tag{33a}$$

where the function

$$\psi_{w_\epsilon}(U\tau,y)\equiv\frac{1}{b^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}G(y,\eta_1)\,G(y,\eta_2)\,\psi_w\left(\sqrt{U^2\tau^2+(\eta_2-\eta_1)^2}\right)d\eta_1d\eta_2$$

represents an effective correlation function, which when transformed into the equivalent power spectrum $\varphi_{w_\epsilon}(\omega,y)$ can be used to obtain the power spectrum for $l(y,t)$ and hence its mean-square value. Thus

$$\varphi_{l(y)}(\omega)=\frac{1}{b^2}\left(\frac{C_{L_\alpha}qS}{U}\right)^2|\phi(k)|^2\varphi_{w_\epsilon}(\omega,y) \tag{33b}$$

Before the calculation of $\varphi_{w_\epsilon}(\omega,y)$ is discussed, the function $\psi_{w_\epsilon}(U\tau,y)$ will be defined in a somewhat more general form than in the preceding paragraph in order to anticipate future needs, namely

$$\psi_{w_\epsilon}(U\tau,y_1,y_2)$$

$$\equiv\frac{1}{b^2}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}G(y_1,\eta_1)\;G(y_2,\eta_2)\;\psi_w\left(\sqrt{U^2\tau^2+(\eta_2-\eta_1)^2}\right)d\eta_1\,d\eta_2$$

If the assumption is now made that $\gamma_R(y)$ and $\gamma_D(y)$ are the same, as is the case for all unswept wings and for wings of very low or very high aspect ratio, they can both be identified with the function $\gamma(y)$ used previously, so that

$$G(y,\eta)=[(1-K)\,\gamma(y)+bK\,\delta(y-\eta)]\,\gamma(\eta) \tag{34}$$

and

$$\psi_{w_\epsilon}(U\tau,y_1,y_2)=\{(1-K)^2\psi_{w_e}(U\tau)+K(1-K)[\psi_{w_e}{}^*(U\tau,y_1)+$$

$$\psi_{w_e}{}^*(U\tau,y_2)]+K^2\psi_w\left(\sqrt{U^2\tau^2+(y_2-y_1)^2}\right)\}\,\gamma(y_1)\;\gamma(y_2)$$

where $\psi_{w_e}(U\tau)$ is the correlation function calculated previously for the averaged vertical component of turbulence, and where

$$\psi_{w_e}{}^*(U\tau,y)=\frac{1}{b}\int_{-b/2}^{b/2}\gamma(\eta)\;\psi_w\left(\sqrt{U^2\tau^2+(y-\eta)^2}\right)d\eta$$

Similarly, then,

$$\varphi_{w_\epsilon}(\omega,y_1,y_2)=\{(1-K)^2\varphi_{w_e}(\omega)+K(1-K)[\varphi_{w_e}{}^*(\omega,y_1)+\varphi_{w_e}{}^*(\omega,y_2)]+K^2\tilde{\varphi}_w(\omega,y_2-y_1)\}\gamma(y_1)\gamma(y_2) \quad (35)$$

where $\varphi_{w_e}{}^*(\omega,y)$ is the Fourier transform of $\psi_{w_e}{}^*(U\tau,y)$, so that

$$\varphi_{w_e}{}^*(\omega,y)=\frac{1}{b}\int_{-b/2}^{b/2}\gamma(\eta)\tilde{\varphi}_w(\omega,|y-\eta|)d\eta \quad (36)$$

and thus represents an averaged form of the spectrum $\tilde{\varphi}_w$ introduced previously. (See eqs. (16) and (19).) For uniform spanwise loading and the point correlation function used previously, this function is

$$\varphi_{w_e}{}^*(\omega,y)=\frac{L^*\overline{w^2}}{\pi U}\frac{1}{\beta}\frac{1}{(1+k'^2)^{5/2}}\{3k'^2[Ki_0(a_1)+Ki_0(a_2)-a_1K_0(a_1)-a_2K_0(a_2)]+[a_1{}^2K_1(a_1)+a_2{}^2K_1(a_2)]\}$$

where

$$a_1,a_2\equiv\frac{\frac{b}{2}\pm y}{L^*}\sqrt{1+k'^2}$$

and is shown in figure 4 for several values of $\frac{|y|}{b/2}$.

The more restricted form of φ_{w_ϵ} required in equation (33b) can now be obtained from the more general form given in

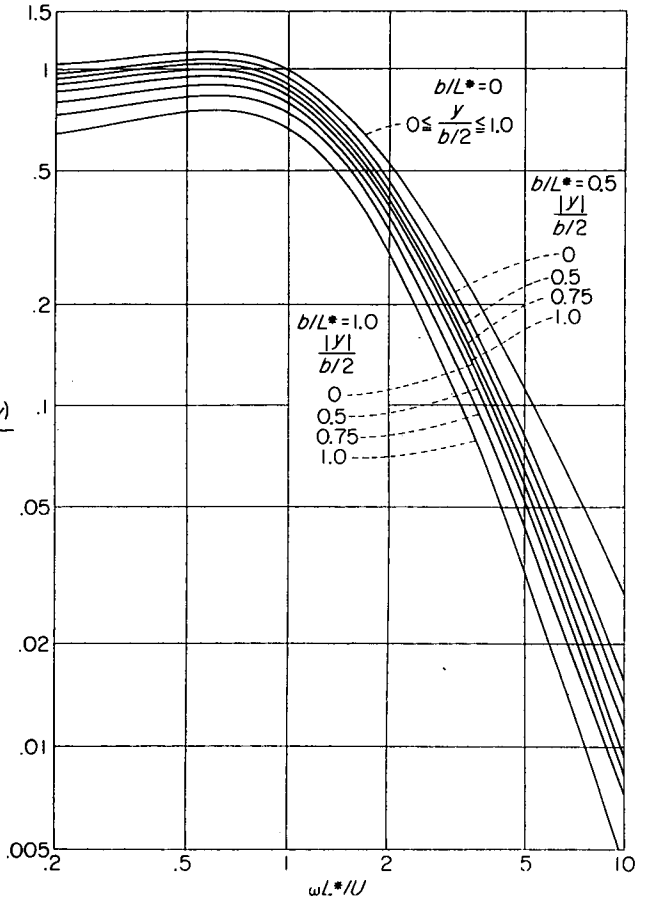

FIGURE 4.—The power spectrum $\varphi_{w_e}{}^*(\omega, y)$.

equation (35) by setting $y_2=y_1=y$ in the latter, to yield

$$\varphi_{w_\epsilon}(\omega)=[(1-K)^2\varphi_{w_e}(\omega)+2K(1-K)\varphi_{w_e}{}^*(\omega,y)+K^2\varphi_w(\omega)]\gamma^2(y) \quad (37)$$

MEAN-SQUARE BENDING AND PITCHING MOMENTS

When the variation of the gust intensity along the span is taken into account, the mean-square lift $\overline{L^2}$ is not an adequate index of the stresses in the wing, nor can the stresses be obtained from the mean-square lift distribution $\overline{l^2(y)}$. Instead, the mean-square bending and twisting moments, as well as the mean-square vertical shear, must be calculated directly.

In a manner analogous to that employed for the lift and rolling moment, each of these quantities can be expressed in terms of a certain influence function which, by means of the reciprocity theorem, can be related to a lift distribution on the wing in reverse flow. For instance, for the root bending moment the desired lift distribution is the one for an angle of attack which is zero on one wing and proportional to y on the other, as may be seen from the fact that the bending moment can be expressed as

$$M_B=\int_{-b/2}^{b/2}[l(y)]_{\alpha(y)}f(y)dy$$

where

$$f(y)\equiv 0 \qquad (y<0)$$

$$f(y)\equiv y \qquad (y\geq 0)$$

so that, according to the reciprocity theory for unswept wings in steady or indicial flow,

$$M_B=\int_{-b/2}^{b/2}[l(y)]_{f(y)\alpha(y)}dy$$

Similarly, for the root shear the required lift distribution corresponds to an angle of attack which is zero on one wing and uniform on the other.

Such lift distributions can be calculated readily. For instance, for subsonic flow and unswept wings they can be obtained from those given in reference 10; the lift distribution for the root bending moment is one-half the sum of a linear symmetric and linear antisymmetric lift distribution, and the lift distribution for the root shear is one-half the sum of a lift distribution due to a uniform angle of attack and a lift distribution due to deflection of a full-span aileron.

However, in some cases such calculations may be time-consuming, and an alternative approach may be desirable. One such approach consists in synthesizing the desired influence function from the generalized lift-influence (Green's) function discussed in the preceding section. In order to illustrate the use of this approach, it is adopted in this section.

The bending moment at any station $y\left(0\leq y\leq\frac{b}{2}\right)$ and at

any time t can be obtained from the lift distribution considered in the preceding section as

$$M_B(y,t)=\int_y^{b/2}(y'-y)l(y',t)\,dy'$$

$$=\frac{1}{b}\int_y^{b/2}(y'-y)\,dy'\int_{-\infty}^{\infty}h_L(t_1)\,dt_1\,\frac{1}{b}\int_{-b/2}^{b/2}G(y',\eta)w(U(t-t_1),\eta)\,d\eta$$

$$=\frac{1}{b}\int_{-\infty}^{\infty}h_L(t_1)\,dt_1\int_{-b/2}^{b/2}\tilde{M}(y,\eta)w(U(t-t_1),\eta)d\eta \tag{38}$$

where the influence function for the bending moment is

$$\tilde{M}(y,\eta)=\frac{1}{b}\int_y^{b/2}(y'-y)G(y',\eta)\,dy' \tag{39a}$$

so that, upon introducing the previously used function for $G(y,\eta)$

$$\tilde{M}(y,\eta)=[(1-K)M_1(y)+KM_2(y,\eta)]\gamma(\eta) \tag{39b}$$

where

$$M_1(y)=\frac{1}{b}\int_y^{b/2}(y'-y)\gamma(y')\,dy'$$

$$M_2(y,\eta)=\eta-y \quad (\eta>y)$$

$$M_2(y,\eta)=0 \quad (\eta\leqq y)$$

and, hence, for the root bending moment,

$$M_1(0)=\frac{1}{b}\int_0^{b/2}y'\gamma(y')\,dy'$$

$$M_2(0,\eta)=\eta \quad (\eta>0)$$

$$M_2(0,\eta)=0 \quad (\eta\leqq 0)$$

Hence, the correlation function for the root bending moment is

$$\psi_{M_B}(\tau)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}h_L(t_1)h_L(t_2)dt_1dt_2\frac{1}{b^2}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}\{(1-K)^2M_1^2(y)+K(1-K)M_1(0)[M_2(0,\eta_1)+$$

$$M_2(0,\eta_2)]+K^2M_2(0,\eta_1)M_2(0,\eta_2)\}\gamma(\eta_1)\gamma(\eta_2)\psi_w(\sqrt{U^2(\tau+t_1-t_2)^2+(\eta_2-\eta_1)^2})d\eta_1d\eta_2 \tag{40}$$

The approach used in the preceding sections can now be used to obtain the power spectrum of the root bending moment by evaluating the inner pair of integrals of equation (40), taking the Fourier transform of the result with respect to τ, and multiplying the power spectrum obtained in this manner by $\left(\frac{C_{L_\alpha}qS}{U}\right)^2|\phi(k)|^2$ or by using one of the alternative approaches indicated for the lift.

The spectrum corresponding to the inner pair of integrals is, for $K=1$ and uniform loading,

$$\varphi_{w_e''}(\omega)=\frac{L^*\overline{w^2}}{\pi U\beta^4(1+k'^2)^4}\left\{\left[(-64+2\beta'^2)+8\beta'^2K_0\left(\frac{\beta'}{2}\right)+\right.\right.$$

$$(32\beta'+\beta'^3)K_1\left(\frac{\beta'}{2}\right)\Big]+k'^2\Big[\beta'^3Ki_0\left(\frac{\beta'}{2}\right)+(64-6\beta'^2)-$$

$$\left.\left.8\beta'^2K_0\left(\frac{\beta'}{2}\right)-(32\beta'-\beta'^3)K_t\left(\frac{\beta'}{2}\right)\Big]\right]\right\}$$

where $\beta'\equiv\beta\sqrt{1+k'^2}$, as before.

The integral of this spectrum is

$$\psi_{w_e''}(0)=\frac{\overline{w^2}}{3\beta^4}\left[\left(-24+\frac{\beta^3}{2}\right)+e^{-\beta/2}(24+12\beta+3\beta^2)\right]$$

Examination of $\psi_{w_e''}(0)$ indicates that, although the mean-square bending moment tends to decrease as the span increases, it decreases less rapidly than the mean-square lift, with the result that the effective lateral center of pressure moves outboard. Quantitatively, the distance from the plane of symmetry to the effective lateral center of pressure can be defined as the square root of the ratio of the mean-square root bending moment to the mean square of the lift on one wing, that is, of the root shear. Although these mean squares have not been calculated, the square root of the ratio of $\psi_{w_e''}(0)$ to the corresponding value for the root shear increases by 15.5 percent as β increases from 0 to infinity, with much of the increase realized at fairly small values of β.

For a swept wing the variation of the gust intensity along the span results in a pitching moment which must be taken

into account in calculations of the dynamic response of the airplane to continuous turbulence. This pitching moment can be obtained in substantially the same manner as the bending moment. Thus, if $\bar{y}$ is the station of the mean aerodynamic chord,

$$M(t)=\tan\Lambda\int_{-b/2}^{b/2}(\bar{y}-|y|)\,l\,(y,t)\,dy$$

$$=\tan\Lambda\,\frac{1}{b}\int_{-\infty}^{\infty}h_L(t_1)\,dt_1\int_{-b/2}^{b/2}M_3(\eta)w(U(t-t_1),\eta)\,d\eta \qquad (41)$$

where

$$M_3(\eta)=\frac{1}{b}\int_{-b/2}^{b/2}(\bar{y}-|y|)\,G(y,\eta)\,dy$$

so that, with the previously used approximation to the Green's function,

$$M_3(\eta)=\{(1-K)[\bar{y}-2M_1(0)]+K(\bar{y}-|\eta|)\}\gamma(\eta)$$

The correlation function, spectrum, and mean-square value of the pitching moment can then be obtained in the manner used in the preceding sections.

WING-TAIL CORRELATION EFFECTS

The tail strikes a given gust some time after the wing does; as a result, a pitching moment arises which does not exist in steady or quasi-steady motion, nor if the airplane is very small, because then the time lag is insignificant. This pitching moment can, for the purpose of the present paper, be analyzed either in terms of the correlation between the gusts at the wing and those at the tail or, if a time-lag term is included in the indicial-response function of the tail, in terms of the correlation between the wing and tail response functions. The first point of view serves to exhibit the effect under consideration more clearly and is adopted first; the second is more convenient and is adopted in the subsequent parts of this report.

In the somewhat artificial case of a small wing and tail separated by a relatively large distance, only the distribution of turbulence along a line (the flight path) rather than in a portion of a plane is needed. The pitching moment due to the vertical component of atmospheric turbulence can then be written as

$$M(t)=\int_{-\infty}^{\infty}h_w(t_1)w(U(t-t_1))dt_1+\int_{-\infty}^{\infty}h_t(t_1)w(x_t+U(t-t_1))dt_1$$

where x_t is the tail length, and where $h_w(t)$ and $h_t(t)$ are the pitching-moment responses to indicial gusts hitting the wing and tail, respectively, at $t=0$; both may include unsteady-lift effects, and, if downwash effects are to be considered, $h_w(t)$ should include the contribution to the pitching moment of the tail lift caused by the downwash at the tail associated with the lift on the wing which results from the indicial gust.

The spectrum of this moment can then be written as

$$\varphi_M(\omega)=\left[|H_w(\omega)+H_t(\omega)|^2-2\mathrm{R}\left\{\left(1-e^{i\frac{\omega}{U}x_t}\right)H_w^*(\omega)H_t(\omega)\right\}\right]\varphi_w(\omega)$$

where the symbols R{ } and * designate, respectively, the real part and the complex conjugate of a complex number. Obviously, when x_t approaches 0 the second term in the bracket in this equation vanishes, so that the first term represents the perfect-correlation effect, and the second represents the correction for imperfect correlation.

In order to furnish an estimate of the magnitude of the effects under consideration, some calculations have been made on the basis of the assumption that a real coefficient μ exists such that

$$H_w(\omega)=\mu H_t(\omega)$$

which implies that the attenuation with frequency of the contributions of the wing lift and tail lift, respectively, to the pitching moment is the same. The ratio μ is -1 for neutral stability, and $\mu>-1$ for stable flight; it is positive when the aerodynamic-center location (tail off) is behind the center of gravity, so that positive values of μ are not likely to be incurred with normal configurations and flight conditions.

For this case,

$$\varphi_M(\omega)=|H_t(\omega)|^2\left[(1+\mu)^2-2\mu\left(1-\cos\frac{\omega x_t}{U}\right)\right]\varphi_w(\omega)$$

and

$$\frac{\overline{M^2}}{(\overline{M^2})_{(tail\ alone)}}=(1+\mu)^2-2\mu\Psi\left(\frac{x_t}{L^*},\frac{x_t}{\bar{c}/2}\right)$$

where

$$\Psi\left(\frac{x_t}{L^*},\frac{x_t}{\bar{c}/2}\right)\equiv\frac{\int_0^{\infty}|H_t(\omega)|^2\varphi_w(\omega)\left(1-\cos\frac{\omega x_t}{U}\right)d\omega}{\int_0^{\infty}|H_t(\omega)|^2\varphi_w(\omega)d\omega}$$

The function Ψ has been calculated for several values of its arguments by means of the lift-attenuation function given in equation (7) and the point spectrum used in the preceding sections, and is shown in figure 5. Also shown is the ratio of the mean-square moments as a function of the factor μ which in figure 5 is referred to as M_w/M_t. The effect of imperfect correlation is seen to be very large as the condition of neutral stability is approached; the entire pitching moment is then the result of instantaneous differences in gust intensities at the wing and tail.

In general, however, the tail length and the span are of the same order of magnitude, so that an analysis of the effect of imperfect correlation between the wing and tail must take into account the averaging effect of the wing span. The pitching moment at any instant is then

$$M(t)=\frac{1}{b}\int_{-\infty}^{\infty}h_w(t_1)dt_1\int_{-b/2}^{b/2}\gamma(y)\,w(U(t-t_1),y)dy+$$

$$\int_{-\infty}^{\infty}h_t(t_1)w(x_t+U(t-t_1),0)\,dt_1 \qquad (42a)$$

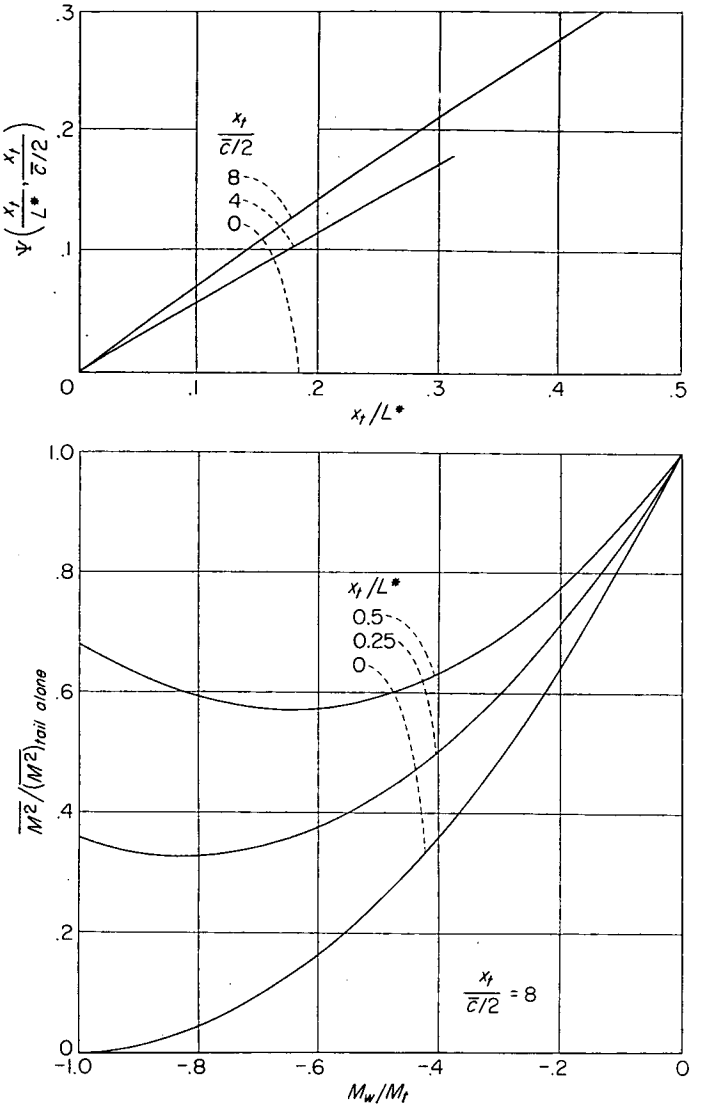

FIGURE 5.—Effect of tail length x_t on the mean-square pitching moment.

Hence, the power spectrum of this moment is

$$\varphi_M(\omega)=|H_w(\omega)|^2\varphi_{w_e}(\omega)+|H_t(\omega)|^2\varphi_w(\omega)+2\mathrm{R}\left\{e^{i\frac{\omega}{U}x_t}H_t(\omega)H_w{}^*(\omega)\right\}\varphi_{w_e{}^*}(\omega,0) \qquad (42b)$$

where $\varphi_{w_e}(\omega)$ is the averaged spectrum of equations (11) and (13), and $\varphi_{w_e{}^*}(\omega,0)$ is the spectrum of equation (36) for $y=0$. (It should be noted that $h_t(t)$ is the response to an indicial response which strikes the tail at $t=0$; if it were the indicial response to a gust which strikes the wing at $t=0$, the factor $e^{i\frac{\omega}{U}x_t}$ in the preceding equation would not be required.)

DYNAMICS OF THE RIGID AIRPLANE

In this part of the report the motions of a rigid airplane subjected to atmospheric disturbances are considered. This part thus applies directly to those airplanes which fly at relatively low speeds and do not experience any significant structural deformations, and also serves as a preliminary to the treatment of the flexible airplane in the later parts.

The assumption is made that the motions are small enough to permit the use of linear approximations to the resulting aerodynamic forces and to permit the linear superposition of these forces. The longitudinal degrees of freedom (pitching, vertical, and horizontal motion) and the lateral degrees of freedom (yaw, sideslip, and roll) can therefore be considered separately. The first two sections of this part are concerned with the longitudinal motions of a small airplane. The material presented here is thus a generalization of the single-degree-of-freedom analysis presented in reference 2. Mathematically, the dynamic system is now described by a set of simultaneous ordinary differential equations rather than a single one, but the problem of calculating the pertinent transfer functions is still one of simple algebra. The extension of these results to the large airplane is effected in the third section, using the techniques developed in the first part of this report. The lateral motions of a large airplane are considered briefly in the fourth section, and the combination of the stresses due to longitudinal and lateral motion of a large airplane is discussed in the fifth section.

EQUATIONS OF LONGITUDINAL MOTION

The equations of motion of an airplane can be expressed in several coordinate systems. The system which is generally the most convenient one for analyses of airplane stability and is generally referred to as stability axes, consists of body-centered axes which are normal and parallel to the relative air velocity and rotate with the airplane as it pitches or yaws. (See ref. 11, for instance.) The aerodynamic forces related to this axis system can be measured more readily in wind tunnels than those related to other axis systems. In view of the very close relation of a stability analysis to the problem considered here, these axes will be used in this part of the paper, but in the analysis of the flexible airplane in the subsequent parts of the report space-centered axes will be used, because they are slightly more convenient for that purpose.

The airplane will be considered to be in steady level flight prior to disturbance. The motions studied will be the deviations from their mean values; for instance, the angle θ considered here will be the difference between the disturbed and the initial value of the angle of pitch. Hence, the motions and forces calculated by the method indicated here must be added to their mean values to obtain the total motions and forces.

Inasmuch as, for the purpose of a statistical analysis, the dynamic characteristics of the airplane are represented most conveniently by its transfer functions, attention will be confined in this section to sinusoidal gusts and motions.

For this case the linearized equations of longitudinal motion can be written as follows (see eqs. II–193 of ref. 11, for instance):

$$\begin{bmatrix} i\omega-Z_w & -Z_u & -i\omega U \\ -X_w & i\omega-X_u & g \\ -i\omega M_{\dot{w}}-M_w & -M_u & -\omega^2-i\omega M_q \end{bmatrix}\begin{Bmatrix} w_p \\ u_p \\ \theta \end{Bmatrix} = \phi(k)\begin{bmatrix} Z_w & Z_u \\ X_w & X_u \\ M_w & M_u \end{bmatrix}\begin{Bmatrix} w \\ u \end{Bmatrix} \qquad (43)$$

The stability derivatives which appear in these equations are defined in table 1 in terms of conventional aerodynamic coefficients, and the numerical values are given for the example used in reference 11. (The value of the mean chord is not given in ref. 11 but it is assumed herein to be 10 feet on the basis of other information given in ref. 11.)

In analyses of the stability of a rigid airplane the quasi-steady approximation to unsteady-lift effects is usually made, in which, in effect, the forces corresponding to a steady attitude, to constant disturbance velocities, and to constant accelerations are considered. This approximation is justified because the motions of concern are generally sufficiently slow. For the same reason this approximation can also be made in analyzing the response of an airplane to atmospheric turbulence.

However, in this problem another type of unsteady-lift effect occurs, namely, that related to the forces directly attributable to the turbulence. This effect is here taken into account by multiplying the quasi-steady values of the forces due to gusts on the right side of equation (43) by the attenuation function $\phi(k)$. This procedure implies the assumption that the airplane is small relative to the scale of turbulence, inasmuch as no averaging effects have been taken into account; these effects will be discussed presently. Also, this attenuation function is strictly applicable only to the normal forces.

The unsteady effects on the drag are not known because of the relatively complicated nature of the mechanism which gives rise to drag. If, however, the assumption is made that upon entry into a sharp-edge gust the drag rises linearly and attains its steady-state value in the time required to travel

TABLE 1.—DEFINITIONS AND NUMERICAL VALUES OF STABILITY DERIVATIVES

Derivative	Definition	Numerical value for the example
Z_w	$-\frac{qS}{mU}(C_{L_\alpha}+C_D)$	−1. 430
Z_u	$-\frac{2qS}{mU}(C_{L_u}+C_L)$	−0. 0955
X_w	$\frac{qS}{mU}(C_L-C_{D_\alpha})$	0. 0016
X_u	$-\frac{2qS}{mU}(C_{D_u}+C_D)$	−0. 0097
M_w	$\frac{qS\bar{c}}{I_{yy}U}C_{m_\alpha}$	−0. 0235
$M_{\dot{w}}$	$\frac{qS\bar{c}^2}{2I_{yy}U^2}C_{m_{\dot{\alpha}}}$	−0. 0013
M_u	$\frac{2qS\bar{c}}{I_{yy}U}(C_{m_u}+C_m)$	0
M_q	$\frac{qS\bar{c}^2}{2I_{yy}U}C_{m_q}$	−1. 920

W, lb	30, 500

526597—60——12

N chord lengths, the drag equivalent of $|\phi(k)|^2$ is the function

$$\frac{1-\cos 2Nk}{2N^2k^2}$$

which, for N equal to about 5 or 6, agrees fairly well with $|\phi(k)|^2$ in the region of main interest ($k>1$).

The unsteady moment is also difficult to predict because of the paucity of knowledge concerning unsteady downwash effects for wings of finite span. However, inasmuch as the wing lift contributes part of the moment and, through the mechanism of downwash, determines to a large extent the moment contributed by the tail, the use of the lift attenuation function for the moment appears reasonable for a first approximation, and the use of the same function for the lift, drag, and moment facilitates the analysis.

For a more refined analysis, the time lag between the instants at which the gust hits the wing and the tail must be taken into account, not only for large airplanes, but even for small airplanes if phugoid motions are important. (See ref. 12.) Also, the lag in downwash should be taken into account for large airplanes and possibly also for small airplanes in some cases. One way of achieving this result is indicated in the next part of the present paper; another is discussed in reference 12.

In equation (43) the unknown quantities w_p and u_p are the normal and axial components of the disturbance velocities of the airplane relative to the free stream. Inasmuch as the coordinate axes rotate during the motion, the time derivatives of these quantities do not represent the actual airplane accelerations, which are required in analyses of the loads experienced by the airplane and the degree of passenger discomfort. If the deviations from a mean flight path are assumed to be small, the accelerations normal and parallel to the chord or longitudinal axis of the airplane are substantially the same as the absolute vertical and horizontal accelerations $\ddot{z}$ and $\ddot{x}$, which can be obtained from the relations

$$\ddot{z}=-\dot{w}_p+U\dot{\theta}$$

$$x=-\dot{u}_p-g\theta$$

The transfer functions for these quantities can then be obtained by introducing these relations into equation (43).

In studies of the longitudinal stability of airplanes, equation (43) is rarely solved in the form given here. It is usually reduced to two equations with two unknowns, either u_p and θ (the phugoid case) or w_p and θ (the short-period case), the short-period case being usually the one of primary interest. The part of the turbulent energy contained in the frequency range near the phugoid frequency is relatively small, so that the phugoid case has no significance for the analysis of loads and accelerations resulting from atmospheric turbulence. Hence, the short-period case, which ignores the phugoid oscillations, furnishes an excellent approximation to the loads and accelerations associated with the longitudinal motions of an airplane in turbulent air. However, another two-degree-of-freedom case, the one involving w_p and u_p, is useful in certain studies of the effects related to the interaction of horizontal and vertical components of turbulence.

Both of these two-degree cases can be reduced to the single-degree-of-freedom case involving only z (or w_p). For airplanes which have a large moment of inertia in pitch this simple case furnishes a good approximation. It has been studied in reference 2, where substantially the same approximations to the unsteady-lift effects were made as are made here, except that in reference 2 apparent-mass effects were included. (These effects are not included in the stability derivatives used in equation (43) because they are usually small—less than 1 percent of the mass of the airplane—and are different for each degree of freedom. However, if desired, the apparent mass pertaining to a given degree of freedom can easily be added to the airplane mass in calculating the stability derivatives.) However, this approximation is more nearly valid for calculating peak loads pursuant to an entry into a sharp-edge gust than for calculating the response due to random turbulence. Consequently, in the following sections, attention will be confined to the short-period case, although the analysis is equally applicable to the other case and easily extended to the case of three degrees of freedom.

SOLUTION OF THE EQUATIONS OF LONGITUDINAL MOTION

Transfer functions.—If the degree of freedom pertaining to x (or u_p) is ignored, the solution of equation (43) can be written as

$$\begin{Bmatrix} \ddot{z} \\ \ddot{\theta} \end{Bmatrix} = \begin{bmatrix} H_{\ddot{z}}^{w}(\omega) & H_{\ddot{z}}^{u}(\omega) \\ H_{\ddot{\theta}}^{w}(\omega) & H_{\ddot{\theta}}^{u}(\omega) \end{bmatrix} \begin{Bmatrix} w \\ u \end{Bmatrix} \tag{44}$$

where the transfer function $H_{\ddot{z}}^{w}(\omega)$ is defined by

$$H_{\ddot{z}}^{w}(\omega) = \phi(k)\frac{-A_{\ddot{z}}^{w}\omega^2 + B_{\ddot{z}}^{w} i\omega + C_{\ddot{z}}^{w}}{-A_0\omega^2 + B_0 i\omega + C_0} \tag{45}$$

where, in turn, the coefficients are defined in terms of the stability derivatives (see table 1) by

$$A_0 = 1 \qquad A_{\ddot{z}}^{w} = -Z_{w'}$$

$$B_0 = -(Z_w + M_q + UM_{\dot{w}}) \qquad B_{\ddot{z}}^{w} = Z_{w'}(UM_{\dot{w}} + M_q)$$

$$C_0 = M_q Z_w - UM_w \qquad C_{\ddot{z}}^{w} = -U(M_{w'}Z_w - M_w Z_{w'})$$

The transfer function $H_{\ddot{\theta}}^{w}(\omega)$ can be defined similarly in terms of the coefficients

$$A_{\ddot{\theta}}^{w} = M_{w'} + Z_{w'}M_{\dot{w}}$$

$$B_{\ddot{\theta}}^{w} = -(M_{w'}Z_w - M_w Z_{w'})$$

$$C_{\ddot{\theta}}^{w} = 0$$

In these equations a distinction has been made between the values of Z_w and M_w which occur on the right side of equation (43) and are here designated by a prime mark, and those on the left side of that equation. The primed derivatives pertain to the lift and moment directly due to gusts, whereas the unprimed derivatives pertain to the lift and moment due to airplane motion; the reason for this distinction is discussed in a later section. Furthermore, the coefficients $A_{\ddot{z}}^{u}$, $B_{\ddot{z}}^{u}$, $C_{\ddot{z}}^{u}$, $A_{\ddot{\theta}}^{u}$, $B_{\ddot{\theta}}^{u}$, and $C_{\ddot{\theta}}^{u}$ are the same as the coefficients $A_{\ddot{z}}^{w}$, $B_{\ddot{z}}^{w}$, . . . except that Z_w, $Z_{w'}$, M_w, and $M_{w'}$ are replaced by Z_u, $Z_{u'}$, M_u, and $M_{u'}$.

With these transfer functions the mean-square values of $\ddot{z}$ and $\ddot{\theta}$ can be calculated from the spectra of w and u by using equation (1), provided that the simultaneous action of w and u is taken into account. In order to analyze this effect the vertical acceleration $\ddot{z}$ will be considered, but the analysis will be applicable to $\ddot{\theta}$ or any other characteristic of the airplane which responds to w and u. Furthermore, the transfer functions need not be those considered in equation (44), but can be those calculated for the three-degree-of-freedom system or for a flexible airplane.

Normal-acceleration spectrum and mean-square value.—For the present purpose the indicial-response functions $h_{\ddot{z}}^{w}(t)$ and $h_{\ddot{z}}^{u}(t)$, which are the Fourier transforms of the transfer functions (see eq. (3a)), are more convenient. In terms of these indicial-response functions,

$$\ddot{z}(t) = \int_{-\infty}^{\infty} h_{\ddot{z}}^{w}(t_1) w(U(t-t_1))\, dt_1 + \int_{-\infty}^{\infty} h_{\ddot{z}}^{u}(t_1)\, u(U(t-t_1))\, dt_1$$

Then, if $w(t)$ and $u(t)$ are stationary in a statistical sense, the correlation function for $\ddot{z}(t)$ can be written as

$$\begin{aligned}\psi_{\ddot{z}}(\tau) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} [&h_{\ddot{z}}^{w}(t_1)\, h_{\ddot{z}}^{w}(t_2)\, \psi_w(U(\tau + t_1 - t_2)) + \\ &h_{\ddot{z}}^{u}(t_1)\, h_{\ddot{z}}^{u}(t_2)\, \psi_u(U(\tau + t_1 - t_2)) + \\ &h_{\ddot{z}}^{w}(t_1)\, h_{\ddot{z}}^{u}(t_2)\, \psi_{wu}(U(\tau + t_1 - t_2)) + \\ &h_{\ddot{z}}^{u}(t_1)\, h_{\ddot{z}}^{w}(t_2)\, \psi_{wu}(U(-\tau + t_1 - t_2))]\, dt_1\, dt_2\end{aligned} \tag{46}$$

where $\psi_{wu}(U\tau)$ is a cross correlation of w and u defined by

$$\psi_{wu}(U\tau) = \overline{w(x + Ut)\, u(x + U(t+\tau))}$$

Now, if the turbulence is isotropic, the mutually perpendicular velocity components u and w at points in the XY-plane are statistically independent, and their cross correlation is zero. Therefore, the two terms in equation (46) involving $\psi_{wu}(U\tau)$ vanish, and the power spectrum of $\ddot{z}$ is

$$\varphi_{\ddot{z}}(\omega) = |H_{\ddot{z}}^{w}(\omega)|^2 \varphi_w(\omega) + |H_{\ddot{z}}^{u}(\omega)|^2 \varphi_u(\omega) \tag{47}$$

so that, generally speaking, the power spectrum of a response which depends on both the horizontal and the vertical component of turbulence is simply the sum of the power spectra of the two contributions, provided the turbulence is isotropic. (This statement can be shown to be true even if the distribution of the gusts over the span is taken into account.)

For the short-period two-degree-of-freedom case, then, the contribution due to w is

$$\overline{\ddot{z}^2} = \int_0^{\infty} |\phi(k)|^2 \frac{(A_{\ddot{z}}^{w})^2\omega^4 - [2A_{\ddot{z}}^{w}C_{\ddot{z}}^{w} - (B_{\ddot{z}}^{w})^2]\omega^2 + (C_{\ddot{z}}^{w})^2}{\omega^4 - (2C_0 - B_0^2)\omega^2 + C_0^2} \varphi_w(\omega)\, d\omega$$

and the contribution due to u can be obtained from the same expression, but with the subscript and superscript w replaced by u. However, the ratio of the two contributions is in the

order of $4\alpha^2$, where α is the trim angle of attack in radians, measured from the zero-lift conditions. Consequently, except at very high lift coefficients, such as those used in landing, the contribution due to u is usually negligible compared with the one due to w and is disregarded in subsequent sections.

By means of the lift-attenuation function given in equation (7) and the point spectrum used in the first part of the report, the integral for $\overline{\ddot{z}^2}$ has been evaluated (by using the technique of partial fractions for the integrand) for the example of reference 11. (The lift-attenuation function of equation (7) has been used despite its shortcomings in order to facilitate the analytic integration of the spectra.) The results are shown in figure 6, as are the results calculated similarly for the three-degree-of-freedom case, the other two-degree-of-freedom case (horizontal and vertical motion; referred to in the figure as the zero-pitch approximation), and the single-degree-of-freedom case (vertical motion). An examination of this figure indicates that, at least for this airplane, inclusion of horizontal motions does not affect the mean-square normal-acceleration response to any significant extent. These calculations pertain to a "small" airplane, and no distinction has been made between the primed and unprimed values of Z_w and M_w.

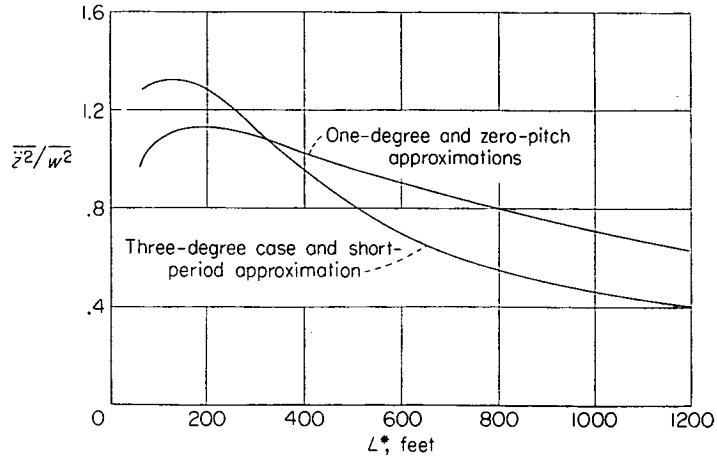

FIGURE 6.—Effect of scale of turbulence on the mean-square acceleration of the example airplane.

The preceding treatment of the short-period case has the advantage of using readily available information concerning the characteristics of any given airplane. For the purpose of trend studies a dimensionless form of the transfer functions is preferable. The preceding equation for $\overline{\ddot{z}^2}$ can be written in dimensionless form (the contribution of horizontal gusts again being neglected) as

$$\frac{\overline{\ddot{z}^2}}{g^2}=\left(\frac{U^2}{g\bar{c}/2}\right)^2\frac{\overline{w^2}}{U^2}\frac{4}{\kappa^2}\int_0^\infty|\phi(k)|^2\frac{k^4+4\left(\nu-\frac{1}{\kappa}\right)^2k^2}{k^4-2(k_o^2-\nu^2)k^2+(k_o^2+\nu^2)^2}\frac{U\varphi_w(\omega)}{L^*\overline{w^2}}dk' \tag{48a}$$

and, similarly,

$$\frac{\overline{\ddot{\theta}^2}}{(2g/\bar{c})^2}=\left(\frac{U^2}{g\bar{c}/2}\right)^2\frac{\overline{w^2}}{U^2}\left[\left(\nu-\frac{2}{\kappa}\right)^2+k_o^2\right]^2\int_0^\infty|\phi(k)|^2\frac{k^4}{k^4-2(k_o^2-\nu^2)k^2+(k_o^2+\nu^2)^2}\frac{U\varphi_w(\omega)}{L^*\overline{w^2}}dk' \tag{48b}$$

where κ is the mass parameter

$$\kappa\equiv\frac{8m}{C_{L_\alpha}\rho S\bar{c}}$$

ν is the dimensionless damping coefficient

$$\nu\equiv\frac{c}{2U}\frac{\log_e 2}{T_{1/2}}$$

$T_{1/2}$ is the time to damp to one-half amplitude, which is given by

$$\frac{\log_e 2}{T_{1/2}}=-\frac{1}{2}(Z_w+M_q+UM_{\dot{w}})$$

so that

$$\nu=\frac{1}{\kappa}\left(1-\frac{1}{2}\frac{m\bar{c}^2}{I_y}\frac{C_{m_q}+C_{m_{\dot{\alpha}}}}{C_{L_\alpha}}\right)$$

and k_o is the dimensionless frequency of the short-period oscillations,

$$k_o\equiv\frac{\omega_o\bar{c}}{2U}$$

with

$$\omega_o=\sqrt{M_qZ_w-UM_w-\frac{1}{4}\left(Z_w+M_q+UM_{\dot{w}}\right)^2}$$

so that

$$k_o=\frac{1}{\kappa}\sqrt{-\frac{m\bar{c}^2}{I_y}\left(\kappa\frac{C_{m_\alpha}}{C_{L_\alpha}}+2\frac{C_{m_q}}{C_{L_\alpha}}\right)-\left(1-\frac{1}{2}\frac{m\bar{c}^2C_{m_q}+C_{m_{\dot{\alpha}}}}{I_y}\frac{}{C_{L_\alpha}}\right)^2}$$

Thus, for this two-degree-of-freedom case the dimensionless mean-square responses are functions of only two additional parameters, which are dimensionless forms of the main characteristics of the short-period case (the short-period frequency and the time to damp to one-half amplitude), beyond those encountered in the single-degree-of-freedom case, namely, the mass parameter κ and the scale parameter $s\equiv\frac{L^*}{\bar{c}/2}$.

Bending-moment spectrum and mean-square value.—For a small airplane the instantaneous bending moments at various points on the span are proportional to the instantaneous normal acceleration. For instance, the root bending moment can be written as

$$M_B=\frac{L_w}{2}\bar{y}-\frac{m_w}{2}\bar{\bar{y}}\ddot{z} \tag{49a}$$

where L_w and m_w are, respectively, the lift on and the mass of the wing, and where $\overline{y}$ and $\overline{\overline{y}}$ are the lateral distances to the center of pressure of the lift on one wing and the center of gravity of the mass of one wing. However, L_w is proportional to the lift L on the entire airplane, which in turn is proportional to the normal acceleration, so that

$$L_w=\frac{L_w}{L}m\ddot{z}$$

and

$$M_B=\left[\frac{m}{2}\left(\frac{L_w}{L}\overline{y}-\frac{m_w}{m}\overline{\overline{y}}\right)\right]\ddot{z} \tag{49b}$$

Hence, the spectrum and mean-square value of M_B are proportional to the spectrum and mean-square value of $\ddot{z}$, respectively, the constant of proportionality being the square of the quantity in the brackets of equation (49b).

SPECIAL PROBLEMS RELATED TO THE LONGITUDINAL MOTION OF LARGE AIRPLANES

Single-degree-of-freedom case.—In the preceding sections the airplane has been assumed to be small in the sense of this report, and neither the instantaneous lateral variation of the intensity of turbulence nor the difference between instantaneous intensities at the wing and the tail has been taken into account. In this section this restriction is removed by introducing the aerodynamic forces calculated in the first part of this report into the dynamic analysis of the preceding sections. The arguments advanced in the preceding section for ignoring horizontal gusts and horizontal motions are equally valid for the large airplane; therefore these gusts and motions will not be considered here.

For the single-degree-of-freedom case involving only vertical motion the required modification for the normal acceleration is very simple. For this case the transfer function is

$$H_{\ddot{z}}^{w}(\omega)=-\phi(k)\frac{Z_w'}{i\omega-Z_w} \tag{50}$$

where Z_w', attenuated by $\phi(k)$, is the stability derivative for vertical gusts and, hence, represents the lift per unit gust intensity. Therefore, if the result for the lift calculated in the first part of this report is used, the mean-square normal acceleration becomes

$$\overline{\ddot{z}^2}=\int_0^\infty |\phi(k)|^2\frac{Z_w{}^2\omega^2}{\omega^2+Z_w{}^2}\varphi_{w_e}(\omega)\,d\omega$$

(The function $\varphi_{w_e}(\omega)$ is defined in the first part of this report.) This expression differs from the result obtained in reference 2 only in that $\varphi_w(\omega)$ is here replaced by $\varphi_{w_e}(\omega)$.

However, even for the single-degree case the calculation of the bending moment now becomes a considerably more complicated problem, because the lateral centers of pressure of the lifts due to the motion of the airplane and directly due to turbulence no longer coincide. Equation (49a) now becomes

$$M_B=-\frac{\overline{y}}{2}\frac{L_w}{L}\frac{C_{L_\alpha}qS}{U}\frac{\dot{z}}{U}-\frac{m_w}{2}\overline{\overline{y}}\,\ddot{z}+\frac{1}{b}\int_{-\infty}^{\infty}h_L(t_1)\,dt_1\int_{-b/2}^{b/2}\gamma_M(y)\,w(U(t-t_1),y)\,dy \tag{51}$$

where C_{L_α} is the lift-curve slope for the entire airplane, $h_L(t)$ is the response function used in equation (38), and $\gamma_M(y)$ is the function $\tilde{M}(y,\eta)$ used in equation (38), with $y=0$. In the first two terms on the right side of equation (51), $\dot{z}$ and $\ddot{z}$ can be related to w by means of $h_{\dot{z}}^{w}$ (the Fourier transform of the function $H_{\dot{z}}^{w}$ presented in eq. (50)) and the lift directly due to turbulence obtained in the first part of this report, so that these two terms can be written in the form

$$\frac{1}{b}\int_{-\infty}^{\infty}h_M(t_1)\,dt_1\int_{-b/2}^{b/2}\gamma(y)\,w(U(t-t_1),y)\,dy$$

and, hence, equation (51) becomes

$$M_B(t)=\frac{1}{b}\int_{-\infty}^{\infty}dt_1\int_{-b/2}^{b/2}[h_L(t_1)\gamma_M(y)+h_M(t_1)\gamma(y)]\,w(U(t-t_1),y)\,dy \tag{52}$$

The required influence function for the bending moment is, thus,

$$h_{M_B}(y,t)=\frac{1}{b}[h_L(t)\gamma_M(y)+h_M(t)\gamma(y)] \tag{53}$$

Although the two terms of this function are products of a time-dependent and a space-dependent constituent, as in equation (5), their sum cannot be split up in this manner. Hence, the techniques used in the first part of this paper are not directly applicable. The general treatment of problems involving influence functions for which the assumption of equation (5) is not valid will be considered in the last part of this paper. However, in this section a special technique will be used that applies to cases for which the influence function can be expressed as a sum of several terms (two in this case), each of which can be expressed as a product of two functions, which depend, respectively, on time alone and distance along the span alone. (See also ref. 13.) This approach is more convenient than the general approach of the last part of this report when the number of terms is two or, possibly, three. (Although in this section only two terms will be considered, the generalization to three or more terms is straightforward.) When the number of terms is greater than three, the general approach becomes more covenient.

If the value of M_B given by equation (52) for $t+\tau$ is multiplied by the value for t and the result is averaged, and if the Fourier transform of the resultant correlation function is then taken, the following expression is obtained for the spectrum of the bending moment:

$$\varphi_{M_B}(\omega)=|H_L(\omega)|^2\varphi_{w_{e_2}}(\omega)+|H_M(\omega)|^2\varphi_{w_e}(\omega)+2\mathrm{R}\{H_L(\omega)H_M{}^*(\omega)\}\varphi_{w_{e_1}}(\omega) \tag{54}$$

where the symbols R{ } and * designate, respectively, the real part and the complex conjugate of a complex number. In this equation $H_M(\omega)$ and $H_L(\omega)$ are the Fourier transforms of $h_M(t)$ and $h_L(t)$, $\varphi_{w_e}(\omega)$ is the previously defined averaged spectrum for the lift, and $\varphi_{w_{e_1}}$ and $\varphi_{w_{e_2}}$ are averaged

spectra obtained in a similar manner but with the value of Γ given by equation (12) replaced by

$$\left.\begin{aligned}\Gamma_1(\eta)&=\frac{2}{b}\int_{-b/2}^{(b/2)-\eta}\gamma(y)\,\gamma_{M_s}(y+\eta)\,dy\\ \Gamma_2(\eta)&=\frac{2}{b}\int_{-b/2}^{(b/2)-\eta}[\gamma_{M_s}(y)\,\gamma_{M_s}(y+\eta)+\gamma_{M_a}(y)\,\gamma_{M_a}(y+\eta)]\,dy\end{aligned}\right\}\quad(55)$$

where the subscripts s and a refer to the symmetric and antisymmetric parts of γ_M, respectively.

The contribution of the antisymmetric part of γ_M to Γ_2 and, hence, to the spectrum for the bending moment stems basically from the asymmetry of the instantaneous distribution of gust intensity over the span. This asymmetry gives rise to a rolling moment (which was considered in the first part of this report) and, hence, to rolling motions, which contribute additional bending moments due to the aerodynamic and inertia loads associated with these motions. If, for the purpose of calculating the bending moment due to symmetric flight through turbulent air alone, these motions are disregarded, then the contribution of γ_M to Γ_2 should be disregarded as well. The problem of combined symmetric and antisymmetric motion will be considered presently.

As pointed out in reference 13, the mean-square bending moment calculated in this manner may be smaller or greater than the value calculated by ignoring spanwise variations in gust intensity. If the mass of the airplane is almost entirely contained in the fuselage, the decrease in the lift which results from taking these variations into account causes a decrease in bending moment. However, if most of the mass is in the wing, the net bending moments (aerodynamic less inertia) for a uniform spanwise gust are very small, and the effect of taking spanwise variations of gust intensity into account is to increase the mean-square bending moments.

Two-degree-of-freedom case.—For the two-degree-of-freedom (short-period) case the analysis given for the normal acceleration in the preceding section can be extended as follows: As indicated in equation (44) the transfer function for $\ddot{z}$ is now

$$H_{\ddot{z}}^{w}(\omega)=\left[-\frac{1}{m}\frac{\omega^2+(UM_{\dot{w}}+M_q)i\omega+UM_w}{-\omega^2+B_0 i\omega+C_0}\right]m(-Z_{w'})\,\phi(k)+\left[\frac{1}{I_y}\frac{U(-Z_w)}{-\omega^2+B_0 i\omega+C_0}\right]I_y M_{w'}\,\phi(k)\quad(56)$$

(The following analysis can be applied equally well to $\ddot{\theta}$ by using $H_{\ddot{\theta}}^{w}(\omega)$ instead of $H_{\ddot{z}}^{w}(\omega)$.)

If the expressions inside the brackets of equation (56) are designated, respectively, by $H_1(\omega)$ and $H_2(\omega)$, and their Fourier transforms by $h_1(t)$ and $h_2(t)$, then, as a result of the definitions of $Z_{w'}$ and $M_{w'}$,

$$\ddot{z}(t)=\int_{-\infty}^{\infty}h_1(t_1)\,L(t-t_1)\,dt_1+\int_{-\infty}^{\infty}h_2(t_1)\,M(t-t_1)\,dt_1\quad(57)$$

where $L(t)$ and $M(t)$ are the instantaneous lift and pitching moment due to the vertical component of atmospheric turbulence, which have been obtained in the first part of this report. The calculation of $\varphi_{\ddot{z}}(\omega)$ or of $\overline{\ddot{z}^2}$ thus requires not only the spectra of L and M, the calculation of which has been discussed, but also the cross spectrum of L and M, which has to be calculated directly from equations (4) and (42a). The result is

$$\varphi_{\ddot{z}}(\omega)=|H_1(\omega)|^2\,|H(\omega)|^2\,\varphi_{w_e}(\omega)+|H_2(\omega)|^2\Big[|H_w(\omega)|^2\,\varphi_{w_e}(\omega)+|H_t(\omega)|^2\,\varphi_w(\omega)+2\mathrm{R}\left\{e^{i\frac{\omega}{U}x_t}H_t(\omega)\,H_w^*(\omega)\right\}\varphi_{w_e^*}(\omega,0)\Big]+2\left[\mathrm{R}\{H_1(\omega)\,H_2^*(\omega)\,H(\omega)\,H_w^*(\omega)\}\varphi_{w_e}(\omega)+\mathrm{R}\{H_1(\omega)\,H_2^*(\omega)\,H(\omega)\,H_t^*(\omega)\}\varphi_{w_e^*}(\omega,0)\right]\quad(58)$$

where the first two terms represent the contributions of the spectra of L and M, respectively (see eqs. (14) and (42b)), and the third represents the contribution of the cross spectrum of L and M. For the present purpose the functions $H(\omega)$, $H_w(\omega)$, and $H_t(\omega)$ can be expressed as

$$H(\omega)=m(-Z_w)\,\phi(k)$$
$$H_w(\omega)=m\,\Delta x_a\,(-Z_w)\,\phi(k)$$
$$H_t(\omega)=[I_{yy}M_w-m\,\Delta x_a\,(-Z_w)]\,\phi(k)$$

where Δx_a is the distance from the aerodynamic center (tail off) to the airplane center of gravity. This definition of the contributions of the wing and tail to the pitching moment is based on the considerations that the direct contribution of the wing can be estimated with good accuracy and the total pitching moment is likely to be known from experiments, so that the contribution of the tail (which includes the effect of the wing lift on the downwash at the tail) can be determined as the difference of the two. The functions $\varphi_{w_e}(\omega)$ and $\varphi_{w_e^*}(\omega,0)$ have been defined in the first part of this report. In view of the fact that the function $\phi(k)$ contained in some of the terms of equation (58) always appears in terms multiplied by others which contain $\phi^*(k)$, only the absolute square of this function is required, as before.

SPECIAL PROBLEMS RELATED TO THE LATERAL MOTION OF LARGE AIRPLANES

The equations of motion in the lateral degrees of freedom (roll, yaw, sideslip) have the same form and can be solved in the same way as the equations for the longitudinal motion. (See pp. III–53 to III–67 of ref. 11.) Again it is convenient to cast the problem in the form used in a stability analysis in order to take advantage of the results of such an analysis. For a small airplane it is necessary only to replace the terms due to rudder deflection by corresponding terms involving side gusts, namely,

$$Y_{\dot{\delta}_R}\dot{\delta}_R \text{ by } Y_v\frac{v}{U}\phi'(k)$$

$$L_{\dot{\delta}_R}\dot{\delta}_R \text{ by } L_\beta\frac{v}{U}\phi'(k)$$

$$N_{\dot{\delta}_R}\dot{\delta}_R \text{ by } N_\beta\frac{v}{U}\phi'(k)$$

where $\phi'(k)$ is a suitable side-force attenuation function for side gusts and the notation of reference 11 is used for the other terms. The terms corresponding to aileron deflection can be disregarded for the small airplane. In the lateral degrees of freedom the small airplane thus reacts only to side gusts. On the other hand, the large airplane also reacts in the lateral degrees of freedom to vertical gusts through the rolling moment calculated in the first part of the present report. If this rolling moment is to be included, it replaces the term $L_{\delta_A}\,\delta_A$ used in reference 11.

Instead of treating all three degrees of freedom simultaneously, in stability analyses two one-degree-of-freedom cases are often considered, namely, the one of sideslip alone, with angle of yaw equal and opposite to angle of sideslip (the Dutch roll case), and the one of rolling alone.

The Dutch roll case may be used for gust-load purposes in connection with yawing and sideslipping motion due to lateral gusts, provided the phase of the motion is not important. (As may be noted from the preceding sections, the phase of a transfer function is important only in terms involving cross spectra.) Also, the Dutch roll case may prove useful in calculating the vertical-tail loads resulting from flight through turbulent air, particularly if the human or automatic pilot holds the wings substantially level by means of the ailerons. However, in general it does not appear to be as satisfactory an approximation as the one- and two-degree-of-freedom approximations for longitudinal motion.

For rolling motions due to rolling moments, the single-degree case of rolling alone appears to furnish a very good approximation. Although the rolling motion causes yawing and sideslipping motions, these motions do not appear to reflect on the rolling motion. Thus, the rolling motion which results from the rolling moment can probably be calculated fairly accurately without regard to the other lateral degrees of freedom. Furthermore, within the assumption of small motions, the stresses associated with these other lateral degrees of freedom do not generally contribute appreciably to those associated with the longitudinal degrees of freedom in the parts of the structure for which the latter are critical, such as the wing (although they may be critical for other parts of the structure, such as the vertical tail). Therefore these degrees of freedom (yaw and sideslip) will be ignored in the treatment of the large flexible airplane in the last part of this paper. However, if chordwise bending effects (deformations parallel to the chord) are important, as they may be in some cases at speeds close to the flutter speed, these other lateral degrees of freedom may have to be included in the analysis.

For the large airplane, which responds in the lateral degrees of freedom both to vertical gusts and to side gusts, the superposition of the resulting responses, such as stresses, may be effected in the way indicated for the interaction of horizontal and vertical gusts. If the turbulence is isotropic, the vertical and lateral gusts are statistically independent for points in the XY-plane, so that the spectrum of a given response is equal to the sum of the spectrum of that part of the given response which is due to vertical gusts and the spectrum of that part of the response which is due to lateral gusts.

COMBINATION OF THE RESULTS OBTAINED FROM ANALYSES OF THE LONGITUDINAL AND LATERAL DEGREES OF FREEDOM

The instantaneous wing stresses depend both on the motions in the longitudinal degrees of freedom (primarily vertical motion and pitching) and on those in the lateral degrees of freedom (primarily rolling). The purpose of this section is to indicate how the stresses associated with vertical motion and pitching can be combined with those associated with rolling due to vertical gusts, particularly in the case of a large rigid airplane. (A small airplane, flexible or rigid, does not roll as a result of the action of vertical gusts, and for the large flexible airplane it is more convenient to consider rolling motion simultaneously with the other motions, so that the superposition is effected automatically in the process of obtaining the required transfer functions.) For all airplanes the effect of side gusts can then be taken into account, if isotropy is assumed, by adding the stress spectra directly.

In this section the instantaneous stress at a given part of the wing will be assumed to be proportional to the instantaneous bending moment at that section of the wing, so that consideration can be confined to this bending moment; also, the airplane will be considered to be free to move in only two degrees of freedom, namely, vertical motion and rolling. The extension of the following arguments to stresses which depend on the vertical shear and the torque as well, and the inclusion of pitching as an additional degree of freedom, can be effected readily and will not alter the conclusion reached here.

When rolling motions of the airplane are taken into account, the bending moment due to the aerodynamic forces associated with rate of roll and to the inertia load associated with rolling acceleration can be expressed in terms of the rolling moment by a superposition integral. In turn, the rolling moment can be expressed in terms of a superposition integral involving the instantaneous gust intensities along the span, the influence function $\gamma'(y)$ used in the first part of the report, and an associated response function $h'_M(t)$. Hence, equation (52) is modified by the inclusion of a third term and becomes

$$M_B(t)=\int_{-\infty}^{\infty} dt_1 \int_{-b/2}^{b/2} [h_L(t_1)\gamma_M(y)+h_M(t_1)\gamma(y)+ h'_M(t_1)\gamma'(y)]w(U(t-t_1),y)\,dy$$

If the spectrum for M_B is now calculated in the manner used previously, the following result is obtained:

$$\varphi_{M_B}(\omega)=|H_L(\omega)|^2\varphi_{w_{e_2}}(\omega)+|H_M(\omega)|^2\varphi_{w_e}(\omega)+ 2\mathrm{R}\{H_L(\omega)H_M^*(\omega)\}\varphi_{w_{e_1}}(\omega)+|H'_M(\omega)|^2\varphi_{w_{e_3}}(\omega)+ 2\mathrm{R}\{H_L(\omega)H'^*_M(\omega)\}\varphi_{w_{e_4}}(\omega) \quad (59)$$

where $H'_M(\omega)$ is the Fourier transform of $h'_M(t)$, and where

$\varphi_{w_{e_3}}(\omega)$ and $\varphi_{w_{e_4}}(\omega)$ can be obtained from equation (12) with the following values of Γ_3 and Γ_4, respectively:

$$\Gamma_3(\eta)=\frac{2}{b}\int_{-b/2}^{(b/2)-\eta}\gamma'(y)\gamma'(y+\eta)\,dy$$

$$\Gamma_4(\eta)=\frac{2}{b}\int_{-b/2}^{(b/2)-\eta}\gamma'(y)\gamma_{M_a}(y+\eta)\,dy$$

(The function $\Gamma_3(\eta)$ is four times the function $\Gamma'(\eta)$ considered previously in connection with the rolling moment. This factor of four must be taken into account in $h'_M(t)$.)

The spectrum φ_{M_B} may be considered to consist of two parts: The first three terms listed in equation (59), but excluding the contribution of γ_{M_a} to $\varphi_{w_{e_2}}$ (see eq. (55)), represent the contribution of the symmetric parts of the instantaneous gust distributions or the contribution associated with symmetric motion; the last two terms and the contribution of γ_{M_a} to $\varphi_{w_{e_2}}$ represent the contribution of the antisymmetric parts of the instantaneous gust distributions or the contribution associated with rolling motion. Therefore, the power spectrum of the stress due to gusts and combined symmetric and rolling motion resulting from the gusts is the sum of the two power spectra (that for the gusts and symmetric motion alone and that for the gusts and rolling motion alone), provided the direct contribution of the gusts is split up into a symmetric and antisymmetric part and each is taken into account only once, in connection with the appropriate type of motion. The cross-correlation terms between the symmetric and antisymmetric contributions to the stress can be shown to involve integrals which contain products of symmetric and antisymmetric influence functions and, hence, vanish, so that the cross correlations are zero; hence, the two parts of the combined spectrum are statistically independent and, therefore, directly additive.

DYNAMICS OF THE SMALL FLEXIBLE AIRPLANE

The purpose of this part of the report is to consider the transfer functions relating the stresses at various points of a small flexible airplane to the vertical gusts which cause them. The longitudinal and lateral degrees of freedom are still separable, and only the longitudinal degrees will be considered; the lateral degrees, which are involved in analysis of the response to side gusts acting on the vertical tail, can be analyzed in the same way. Therefore, for this case only one-half of the wing need be considered as a result of the symmetry (or antisymmetry, in the case of the lateral degrees of freedom) of the problem.

The method which is outlined in this part consists in an extension of the numerical-integration method of aeroelastic analysis described in reference 14 to sinusoidal motions of the airplane. This extension takes into account the facts that the aerodynamic forces now have out-of-phase as well as in-phase parts and that vertical deflections must now be calculated separately because the structural deformations can no longer be characterized by angle-of-attack changes. Also, the "rigid-body" degrees of freedom (vertical and pitching motion of the airplane as a whole and structural deformations of the tail) are now taken into account.

The result is a set of linear algebraic equations (which serve as an approximation to the ordinary differential equations that characterize the problem) for the airplane motions and deformations in terms of the applied aerodynamic forces directly due to gusts. The desired transfer functions can then be obtained from solutions of these equations at various frequencies, and the power spectra of the stresses are given by the product of the absolute square of these transfer functions and the point power spectrum of the vertical component of turbulence. The same equations may be used to calculate with little additional effort certain aeroelastic effects, such as the static aeroelastic deformations and the flutter speed, which are usually obtained in separate analyses.

LOADS APPLIED TO THE WING

The loads applied to the wing stem from three sources: The aerodynamic loads directly due to the action of the gusts, the aerodynamic loads due to the motions of the airplane, and the inertia loads.

The lift and pitching moment (about the elastic axis) per unit span on a two-dimensional airfoil undergoing sinusoidal angle-of-attack changes and vertical motions in incompressible flow are (see ref. 15)

$$\left.\begin{aligned} l_a=2\pi qc\Bigg\{C(k)\left[(1+2e_4ik)\alpha-ik\frac{z}{c/2}\right]+\\ \left(\frac{ik}{2}-e_3k^2\right)\alpha+\frac{k^2}{2}\frac{z}{c/2}\Bigg\}\\ m_a=2\pi qc^2\Bigg\{C(k)e_1\left[(1+2e_4ik)\alpha-ik\frac{z}{c/2}\right]-\\ \left[\frac{e_4}{2}ik-\left(\frac{1}{32}+e_3^2\right)k^2\right]\alpha-\frac{e_3}{2}k^2\frac{z}{c/2}\Bigg\}\end{aligned}\right\} \tag{60}$$

The terms multiplied by $C(k)$ are referred to as the circulatory terms because they are calculated from the bound and shed vorticity, and the others are referred to as the potential terms. The potential terms are in the nature of additional-apparent-mass effects, and all those that involve k^2 are usually treated together with the inertia forces rather than with the aerodynamic forces. For compressible flow, however, the forces are calculated in a different manner, and the division of the forces into circulatory and potential parts then has little meaning. Consequently, in order to facilitate the extension of this analysis to compressible flow, this distinction will not be made herein.

The aerodynamic forces are therefore written as

$$\left.\begin{aligned} l_a=2\pi qc\left[\tilde{C}_1(k)\alpha+\tilde{C}_2(k)\frac{z}{c/2}\right]\\ m_a=2\pi qc^2\left[\tilde{C}_3(k)\alpha+\tilde{C}_4(k)\frac{z}{c/2}\right]\end{aligned}\right\} \tag{61}$$

so that for incompressible flow

$$\tilde{C}_1(k)=(1+2e_4ik)C(k)+\frac{ik}{2}-e_3k^2$$

$$\tilde{C}_2(k)=-ikC(k)+\frac{k^2}{2}$$

$$\tilde{C}_3(k)=(1+2e_4ik)e_1C(k)-\frac{e_4}{2}ik+\left(\frac{1}{32}+e_3^2\right)k^2$$

$$\tilde{C}_4(k)=-ike_1C(k)-\frac{e_3}{2}k^2$$

In order to calculate the lift at a given point of a wing of finite span an appropriate Green's function is required. An approximation to this function based on a reciprocity theorem of linearized lifting-surface theory, is given in the first part of this report; as used for the computations of that part, this function implies the assumptions that the spanwise distribution of the lift for oscillations of the wing as a whole is substantially invariant with frequency and that this distribution is the same in direct as in reverse flow. Neither of these assumptions is essential to the analysis but both, and particularly the first, simplify it considerably. With these assumptions, the desired lift distribution is then given by expressions of the form of equations (32a) and (34).

For the present purpose, however, a set of aerodynamic influence coefficients is required, rather than influence functions. Such a set of coefficients, based on the same ideas, can be obtained readily by the techniques used in references 9 and 10. The result may be expressed as follows:

$$\{l\}_a=C_{L_\alpha}\bar{c}q\left\{\tilde{C}_1(k)\,[Q]\{\alpha\}+\tilde{C}_2(k)\,[Q]\left\{\frac{z}{\bar{c}/2}\right\}\right\} \quad (62a)$$

where the aerodynamic-influence-coefficient matrix $[Q]$ is defined by

$$[Q]=(1-K)\lfloor\gamma\rfloor\{1\}\lfloor I\rfloor\lfloor\gamma\rfloor+K\lfloor\gamma\rfloor$$

where, in turn, $\{1\}$ is a unit column matrix, and $\lfloor I\rfloor$ is a row of integrating coefficients suitable for integrating a continuous function for a range of its argument from 0 to 1. Thus, for instance, if n equidistant points on the semispan are considered, and n is odd, then according to Simpson's rule

$$\lfloor I\rfloor=\frac{1}{n-1}\left\lfloor\frac{1}{3},\frac{4}{3},\frac{2}{3},\frac{4}{3},\cdots\frac{4}{3},\frac{1}{3}\right\rfloor$$

Very little information is available concerning the spanwise distributions of the pitching moment on wings of finite span in unsteady flow. By means of the reciprocity theorems an appropriate Green's function could be estimated if the lift distribution for wings with parabolic camber were known; however, such lift distributions do not appear to have been calculated for wings of finite span in unsteady flow. In fact, relatively little is known about moment distributions even in steady flow. However, the available information indicates that the local center of pressure does not appear to be very sensitive to the lift distribution. (See ref. 9, for instance.) It will be assumed that this is also true in unsteady flow at a given frequency, and that, furthermore, these centers of pressure are given by two-dimensional theory. With this assumption the moment can be written as

$$\{m_T\}_a=C_{L_\alpha}\bar{c}q\left\{\tilde{C}_3(k)\lfloor c\rfloor[Q]\{\alpha\}+\tilde{C}_4(k)\lfloor c\rfloor[Q]\left\{\frac{z}{\bar{c}/2}\right\}\right\} \quad (62b)$$

The lift and moment distribution due to the gust can be calculated in a similar manner. In the following analysis, the magnitude of the gust intensity is considered to be unity, and the longitudinal reference point is the intersection of the elastic axis and the wing root, so that the instantaneous gust intensity at any station y is

$$w=e^{-ik\frac{|y|}{\bar{c}/2}\tan\Lambda} \quad (63)$$

With this function w,

$$\left.\begin{aligned}\{l\}_g&=\frac{C_{L_\alpha}\bar{c}q\phi(k)}{U}[Q]\{w\}\\ \{m_T\}_g&=\frac{C_{L_\alpha}\bar{c}q\phi(k)}{U}\lfloor e_1c\rfloor[Q]\{w\}\end{aligned}\right\} \quad (64)$$

where $\phi(k)$ is the Sears function, as before.

Finally, the inertia loads are

$$l_i=-\tilde{m}\ddot{z}+\tilde{m}e_2c\ddot{\alpha}$$

$$m_{T_i}=-(r^2+(e_2c)^2)\tilde{m}\ddot{\alpha}+\tilde{m}e_2c\ddot{z}$$

or

$$\left.\begin{aligned}\{l\}_i&=-\frac{q}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2\lfloor\tilde{m}e_2c\rfloor\{\alpha\}+\frac{q}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2\lfloor\tilde{m}\rfloor\{z\}\\ \{m_T\}_i&=\frac{q}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2\lfloor r^2+(e_2c)^2\rfloor\lfloor\tilde{m}\rfloor\{\alpha\}-\frac{q}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2\lfloor\tilde{m}e_2c\rfloor\{z\}\end{aligned}\right\} \quad (65)$$

The loads applied to the wing can thus be written, in summary, as

$$\begin{Bmatrix} l \\ m_T \end{Bmatrix} = q \left[\begin{array}{c|c} 2C_{L_\alpha}\tilde{C}_2(k)\,[Q] + \dfrac{k^2}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}[\tilde{m}] & C_{L_\alpha}\bar{c}\tilde{C}_1(k)\,[Q] - \dfrac{k^2}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}[me_2c] \\ \hline 2C_{L_\alpha}\tilde{C}_4(k)[c]\,[Q] - \dfrac{k^2}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}[\tilde{m}e_2c] & C_{L_\alpha}\bar{c}\tilde{C}_3(k)[c]\,[Q] + \dfrac{k^2}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}[r^2+(e_2c)^2][m] \end{array}\right] \begin{Bmatrix} z \\ \alpha \end{Bmatrix} + q \left[\begin{array}{c} \dfrac{C_{L_\alpha}\bar{c}\phi(k)}{U}[Q] \\ \hline \dfrac{C_{L_\alpha}\bar{c}\phi(k)}{U}[e_1c][Q] \end{array}\right] \begin{Bmatrix} w \end{Bmatrix} \tag{66}$$

LOADS APPLIED TO THE TAIL

The loads applied to the tail are similar in nature to those applied to the wing, but the tail experiences additional loads as a result of the downwash produced by the lift on the wing. Again, little is known about the downwash in unsteady flow, and even in steady flow the downwash cannot be predicted accurately because of boundary-layer effects on the fuselage and the wing root. Consequently, even in steady-flow analyses experimental results are usually relied upon.

In the following analysis, the assumption is therefore made that experimental results are available for steady flow, in the form of the downwash derivative $\partial\epsilon/\partial\alpha$. In order to determine the attenuation of this value with frequency, the results of the analysis of reference 16 will be used. These results indicate that the time variation of the tail lift due to the downwash caused by the wing lift which results from a unit jump in the wing angle of attack can be approximated by an immediate jump in the tail lift of —0.16 of the steady-state value and another jump to the steady-state value after the time required to travel the distance from the 45-percent-chord point of the wing to the quarter-chord point of the tail plus another eighth of the chord length. Hence, for sinusoidal angle-of-attack changes the tail lift due to downwash is

$$(L_{t_\epsilon})_{\alpha,z} = -C_{L_{\alpha_t}} q_t S_t \frac{\partial\epsilon}{\partial\alpha}\left[-0.16+1.16e^{-ik\left(\frac{x_t'}{\bar{c}/2}+\frac{1}{4}\frac{c_r}{\bar{c}}\right)}\right]\left[(1+2e_4ik)\alpha_r - ik\frac{z_r}{\bar{c}/2}\right] \tag{67}$$

where x_t' is the distance from the intersection of the elastic axis and the wing root (assumed for this purpose to be at the 45 percent point on the root chord) to the aerodynamic center of the tail. As pointed out in reference 16, this approximation is valid only for $k<0.35$; however, this range is adequate for the present purpose.

Similarly, the downwash associated with the wing lift due to sinusoidal gusts gives rise to a tail lift which, within this approximation, is

$$(L_{t_\epsilon})_g = -C_{L_{\alpha_t}} q_t \frac{S_t}{U}\frac{\partial\epsilon}{\partial\alpha}\left[-0.16+1.16e^{-ik\left(\frac{x_t'}{\bar{c}/2}+\frac{1}{4}\frac{c_r}{\bar{c}}\right)}\right] e^{-0.6ik\frac{c_r}{\bar{c}}} w_r \tag{68}$$

(The additional lag represents the time required to travel the 0.6 root semichords from the 45-percent-chord point of the root, which is the reference point for the gusts, to the 75-percent-chord point of the wing root, which is assumed to be the point governing the lift at the wing root, inasmuch as it is the centroid of the influence function for the chordwise pressure distribution.)

The other aerodynamic forces are those due to the motions of the airplane, those due to the tail deformations, and those directly due to the gusts. On the basis of the assumptions made in the preceding section, these forces are

$$L_{t_a} = C_{L_{\alpha_t}} q_t S_t\left[\tilde{C}_5(k)\alpha_r + \tilde{C}_6(k)\frac{z_r}{\bar{c}/2} + \tilde{C}_7(k)\Delta\alpha + \tilde{C}_6(k)\frac{\Delta z}{\bar{c}/2}\right] \tag{69}$$

$$L_{t_g} = \frac{C_{L_{\alpha_t}} q_t S_t}{U}\phi\left(\frac{c_t}{\bar{c}}k\right) e^{-ik\frac{x_t'-\frac{c_t}{4}}{\bar{c}/2}} \tag{70}$$

where

$$\tilde{C}_5(k) = \left(1+2ik\frac{x_t'+\frac{c_t}{2}}{\bar{c}}\right) C\left(\frac{c_t}{\bar{c}}k\right) + \frac{i}{2}\frac{c_t}{\bar{c}}k - \frac{c_t}{\bar{c}}\frac{x_t'+\frac{c_t}{4}}{\bar{c}}k^2$$

$$\tilde{C}_6(k) = -ikC\left(\frac{c_t}{\bar{c}}k\right) + \frac{1}{2}\frac{c_t}{\bar{c}}k^2$$

$$\tilde{C}_7(k) = \left(1+2ik\frac{e_{4_t}c_t}{\bar{c}}\right) C\left(\frac{c_t}{\bar{c}}k\right) + \frac{i}{2}\frac{c_t}{\bar{c}}k - e_{3_t}\left(\frac{c_t}{\bar{c}}\right)^2 k^2$$

and α_r and z_r are the angle of attack and vertical displacement of the airplane at the wing root.

The inertia load on the tail is

$$L_{t_i} = -m_t(\ddot{z}_r + \Delta\ddot{z} - x_t'\ddot{\alpha}_r)$$

or

$$L_{t_i} = \frac{m_t q k^2}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}(z_r + \Delta z - x_t'\alpha_r) \tag{71}$$

Here the center of gravity of the tail has been assumed to coincide with its aerodynamic center; in order to remove this assumption it is necessary only to add (or subtract) the distance between the two to x_t' in equation (71).

The normal forces on the tail can then be summarized as follows:

$$L_t=q[F_1(k)z_r+F_2(k)\alpha_r+F_3(k)\Delta\alpha+F_4(k)\Delta z+F_5(k)w_t] \quad (72)$$

where

$$F_1(k)=2C_{L_{\alpha_t}}\frac{q_t}{q}\frac{S_t}{\bar{c}}\left\{\tilde{C}_6(k)+ik\frac{\partial\epsilon}{\partial\alpha}\left[-0.16+1.16e^{-ik\left(\frac{x_t'}{\bar{c}/2}+\frac{1}{4}\frac{c_t}{\bar{c}}\right)}\right]\right\}+\frac{m_t}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2$$

$$F_2(k)=C_{L_{\alpha_t}}\frac{q_t}{q}S_t\left\{\tilde{C}_5(k)-(1+2e_4ik)\frac{\partial\epsilon}{\partial\alpha}\left[-0.16+1.16e^{-ik\left(\frac{x_t'}{\bar{c}/2}+\frac{1}{4}\frac{c_t}{\bar{c}}\right)}\right]\right\}-\frac{m_t x_t'}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2$$

$$F_3(k)=C_{L_{\alpha_t}}\frac{q_t}{q}S_t\tilde{C}_7(k)$$

$$F_4(k)=2C_{L_{\alpha_t}}\frac{q_t}{q}\frac{S_t}{\bar{c}}\tilde{C}_6(k)+\frac{m_t}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2$$

$$F_5(k)=\frac{C_{L_{\alpha_t}}q_tS_t}{U}\left\{\phi\left(\frac{c_t}{\bar{c}}k\right)e^{ik\frac{c_t}{2\bar{c}}}-\frac{\partial\epsilon}{\partial\alpha}\left[-0.16+1.16e^{-ik\left(\frac{x_t'}{\bar{c}/2}+\frac{1}{4}\frac{c_r}{\bar{c}}\right)}\right]e^{ik\left(\frac{x_t'}{\bar{c}/2}-0.6\frac{c_r}{\bar{c}}\right)}\right\}$$

and

$$w_t=e^{-ik\frac{x_t}{\bar{c}/2}}$$

The pitching moments corresponding to these normal forces can be obtained in the manner employed for the wing. However, inasmuch as the tail chord is usually small compared with the fuselage length, the travel of the center of pressure of the tail is small compared with the length x_t'. Hence, the center of pressure will be assumed to remain at the aerodynamic center of the tail, and the pitching moments are then $-x_t'$ times the corresponding forces, so that

$$M_t=-qx_t'[F_1(k)z_r+F_2(k)\alpha_r+F_3(k)\Delta\alpha+F_4(k)\Delta z+F_5(k)w_t] \quad (73)$$

WING AND TAIL DEFORMATIONS

The wing deformations may be calculated either from structural influence coefficients or from the bending and torsion stiffnesses of the wing used in conjunction with simple beam theory. The latter approach will be followed here, based on the method of reference 12.

The bending and torsion moments on the wing structure may be obtained by integrating the applied loads. If numerical methods are employed to perform these integrations the results may be written as follows:

$$\begin{Bmatrix}M_B\\M_T\end{Bmatrix}=\left[\begin{array}{c|c}\frac{(b/2)^2}{\cos\Lambda}[\mathrm{II}] & -\sin\Lambda\frac{b}{2}[\mathrm{I}]\\ \hline [0] & \cos\Lambda\frac{b}{2}[\mathrm{I}]\end{array}\right]\begin{Bmatrix}l\\m_T\end{Bmatrix} \quad (74)$$

Similarly, the deformations are

$$\begin{Bmatrix}z-z_r\\ \alpha-\alpha_r\end{Bmatrix}=\left[\begin{array}{c|c}\left(\frac{b}{2\cos\Lambda}\right)^2[\mathrm{II}'']\left[\frac{1}{EI}\right] & [0]\\ \hline \frac{b}{2}[\mathrm{I}'']\left[\frac{1}{GJ}\right] & -\frac{b}{2}\tan\Lambda[\mathrm{I}'']\left[\frac{1}{EI}\right]\end{array}\right]\begin{Bmatrix}M_B\\M_T\end{Bmatrix}$$

$$=\left[\begin{array}{c|c}\left(\frac{b}{2}\right)^4\frac{1}{\cos^2\Lambda}[\mathrm{II}'']\left[\frac{1}{EI}\right][\mathrm{II}] & -\left(\frac{b}{2}\right)^3\frac{\sin\Lambda}{\cos^2\Lambda}[\mathrm{II}'']\left[\frac{1}{EI}\right][\mathrm{I}]\\ \hline \left(\frac{b}{2}\right)^3\frac{1}{\cos\Lambda}[\mathrm{I}'']\left[\frac{1}{GJ}\right][\mathrm{II}] & -\sin\Lambda\left(\frac{b}{2}\right)^2[\mathrm{I}'']\left[\frac{1}{EI}+\frac{1}{GJ}\right][\mathrm{I}]\end{array}\right]\begin{Bmatrix}l\\m_T\end{Bmatrix} \quad (75)$$

where the integrating matrices (see ref. 12) perform the following operations:

$$[\mathrm{I}]\{f\}\backsim\int_\xi^1 f(\xi')d\xi'$$

$$[\mathrm{II}]\{f\}\backsim\int_\xi^1\int_{\xi'}^1 f(\xi'')d\xi''d\xi'$$

$$[\mathrm{I}'']\{f\}\backsim\int_0^\xi f(\xi')d\xi'$$

$$[\mathrm{II}'']\{f\}\backsim\int_0^\xi\int_0^{\xi'} f(\xi'')d\xi''d\xi'$$

These integrating matrices may be based on the trapezoidal rule, Simpson's rule, or any other numerical method; the intervals chosen for ξ ($0 \leqq \xi \leqq 1$) need not be of constant width unless a specific rule demands a uniform spacing.

The structural deformations of the wing may then be written in terms of the applied loads as

$$\begin{Bmatrix} z-z_r \\ \alpha-\alpha_r \end{Bmatrix} = q \left[\begin{array}{c|c} ① & ② \\ \hline ③ & ④ \end{array}\right] \begin{Bmatrix} z \\ \alpha \end{Bmatrix} + q \left[\begin{array}{c} ⑤ \\ \hline ⑥ \end{array}\right] \{w\} \tag{76}$$

where the submatrices [①], [②], [③], [④], [⑤], and [⑥] designate, respectively, the four quadrants and two halves of the matrices, obtained by postmultiplying the square matrix of equation (75) by the square and the rectangular matrix of equation (66), respectively.

For the purpose of the present analysis, which is concerned primarily with the wing stresses, the tail deformations are treated by including only the vertical displacement and angle-of-attack change of the tail as a whole due to the tail load. These quantities may be obtained from a static test which consists in applying a concentrated normal load at the aerodynamic center of the tail and measuring these deformations. They may also be obtained from a vibration test in which the deflection curve of the rear part of the fuselage in the lowest vertical-bending mode is measured; in this case the desired spring constants can be deduced from the frequency relation of a simple mass oscillator in terms of the measured frequency and of the mass of the empennage (including the part of the fuselage which may be considered to move with the empennage). In the absence of such tests these constants may be calculated in an analogous manner.

The tail deformations may then be written as

$$\left.\begin{aligned} \Delta\alpha &= -K_1 L_t \\ \Delta z &= K_2 L_t \end{aligned}\right\} \tag{77}$$

so that, also,

$$\Delta z = -\frac{K_2}{K_1} \Delta\alpha \tag{78}$$

Inasmuch as these deformations are not independent of each other, only one need be retained in the analysis. Therefore, if Δz is eliminated by means of equation (78), $\Delta\alpha$ can then be obtained in a form similar to that used for the wing deformations in equation (76):

$$\Delta\alpha = -qK_1 \left\{ F_1(k) z_r + F_2(k)\alpha_r + \left[F_3(k) - \frac{K_2}{K_1} F_4(k) \right] \Delta\alpha \right\} - qK_1 F_5(k) w_t \tag{79}$$

EQUATIONS OF MOTION

Equations (76) and (79) are equations of motion inasmuch as they describe balances of aerodynamic, structural, and inertia forces. In fact, if the airplane fuselage were immobile ($\alpha_r = z_r = 0$), they would be sufficient to calculate all unknown quantities. However, if the fuselage is free to move, two additional equations are required to obtain the two additional unknown quantities α_r and z_r. These additional equations are those expressing the dynamic equilibrium of the forces on the fuselage, namely,

$$\left.\begin{aligned} &L_w + L_t - m_f (\ddot{z}_r - \Delta x\, \ddot{\alpha}_r) = 0 \\ &M_w - x_t L_t - (r_f^2 + (\Delta x)^2)\, m_f \ddot{\alpha}_r + \Delta x\, m_f \ddot{z}_r = 0 \end{aligned}\right\} \tag{80}$$

where the wing lift and pitching moment can be expressed in terms of the lift and moment distributions l and m as

$$\left.\begin{aligned} L_w &= \left\lfloor 2\frac{b}{2}[\mathrm{I}], [0] \right\rfloor \begin{Bmatrix} l \\ m_T \end{Bmatrix} \\ M_w &= \left\lfloor -2\left(\frac{b}{2}\right)^2 \tan\Lambda\,[\mathrm{II}],\ 2\frac{b}{2}[\mathrm{I}] \right\rfloor \begin{Bmatrix} l \\ m_T \end{Bmatrix} \end{aligned}\right\} \tag{81}$$

or

$$\left.\begin{aligned} L_w &= q\lfloor ⑪ \rfloor \begin{Bmatrix} z \\ \alpha \end{Bmatrix} + q\lfloor ⑬ \rfloor \{w\} \\ M_w &= q\lfloor ⑫ \rfloor \begin{Bmatrix} z \\ \alpha \end{Bmatrix} + q\lfloor ⑭ \rfloor \{w\} \end{aligned}\right\} \tag{82}$$

where [⑪], [⑫], [⑬], and [⑭] are the rows obtained by postmultiplying the rows of equation (81) by the square and rectangular matrices of equation (66). In equation (80) the fuselage lift and moment have been neglected; they can easily be expressed in terms of α_r and z_r and included, if desired.

The equations for the tail deformation $\Delta\alpha$ and those for the overall normal force and pitching moment can be combined with equation (76) as follows: For the sake of definiteness it will be assumed that n stations on the wing are considered, including the one at the root, so that there are $2n+1$ unknown quantities, and that in the column matrices defining applied loads, deformations, and so on, the values at the root of the wing are written at the top:

$$\begin{Bmatrix} z \\ \alpha \\ \Delta\alpha \end{Bmatrix} \equiv \begin{Bmatrix} z_{root} \\ \cdot \\ \cdot \\ \cdot \\ z_{tip} \\ \alpha_{root} \\ \cdot \\ \cdot \\ \cdot \\ \alpha_{tip} \\ \Delta\alpha \end{Bmatrix}$$

The first and $(n+1)$th equations of the system defined by equation (76) express only the trivial fact that the structural deformation at the wing root is zero. They are replaced by

equations (82) and (79), which are adjoined to the system, to yield the combined equation of motion

$$\begin{bmatrix} 0 & & & \\ -1 & 1 & & \\ -1 & 0 & 1 & \\ -1 & 0 & 0 & 1 \\ \cdots & \cdots & \cdots & \cdots \\ & & 0 & \\ & 0 & & \\ & & & \\ 0 & & 0 & 1 \end{bmatrix} \begin{Bmatrix} z \\ \\ \alpha \\ \\ \Delta\alpha \end{Bmatrix} = q \begin{bmatrix} \textcircled{1'} & \textcircled{2'} & \\ & & \\ \textcircled{3'} & \textcircled{4'} & \\ & & \\ & & 0 \end{bmatrix} \begin{Bmatrix} z \\ \\ \alpha \\ \\ \Delta\alpha \end{Bmatrix} + q \begin{bmatrix} \textcircled{5'} & \\ & \\ \textcircled{6'} & \\ & \\ 0 & \end{bmatrix} \begin{Bmatrix} w \\ \\ w_t \end{Bmatrix} \tag{83a}$$

If the square matrix on the right side of this equation is designated by $[A]$, the rectangular matrix by $[B]$, and the quasi-unit matrix on the left side of the equation by $[1']$, the equation can also be written as

$$\Big[[1']-q[A]\Big]\begin{Bmatrix} z \\ \alpha \\ \Delta\alpha \end{Bmatrix} = q[B]\begin{Bmatrix} w \\ w_t \end{Bmatrix} \tag{83b}$$

The matrices $[\textcircled{1'}]$ to $[\textcircled{6'}]$ are the same as the matrices $[\textcircled{1}]$ to $[\textcircled{6}]$ of equation (76), except that the first rows of the latter, which are all zero, are replaced as follows:

First row of—	Replacement	Quantity added to the leading element
①	First half of [⑪]	$F_1(k)+\dfrac{m_f}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2$
②	Second half of [⑪]	$F_2(k)-\dfrac{m_f\Delta x}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2$
③	First half of [⑫]	$-x_tF_1(k)-\dfrac{m_fx_t}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2$
④	Second half of [⑫]	$-x_tF_2(k)+\dfrac{m_f[r_f^2+(\Delta x)^2]}{\frac{\rho}{2}\left(\frac{\bar{c}}{2}\right)^2}k^2$
⑤	[⑬]	0
⑥	[⑭]	0

Also, the elements of the last rows and columns of the matrices $[A]$ and $[B]$ are zero, except for the following:

$$A_{1,2n+1}=F_3(k)-\frac{K_2}{K_1}F_4(k)$$

$$A_{n+1,2n+1}=-x_t\left[F_3(k)-\frac{K_2}{K_1}F_4(k)\right]$$

$$A_{2n+1,1}=-K_1F_1(k)$$

$$A_{2n+1,n+1}=-K_1F_2(k)$$

$$A_{2n+1,2n+1}=-K_1\left[F_3(k)-\frac{K_2}{K_1}F_4(k)\right]$$

$$B_{1,n+1}=F_5(k)$$

$$B_{n+1,n+1}=-x_tF_5(k)$$

$$B_{2n+1,n+1}=-K_1F_5(k)$$

SOLUTION OF THE EQUATIONS OF MOTION

For the purpose of calculating the desired transfer functions, equation (83b) may be solved directly for a given value of q as a set of linear algebraic equations with coefficients given by the matrix $[1']-q[A]$ and with "knowns" given by the column matrix $q[B]\begin{Bmatrix} w \\ w_t \end{Bmatrix}$ (where $[A]$, $[B]$, and $\begin{Bmatrix} w \\ w_t \end{Bmatrix}$ are functions of k). The result is a column matrix of the unknown amplitudes of the motions of the airplane. If this column is calculated for several values of k in the range of interest, these amplitudes, considered as functions of k, are transfer functions from the gust to the motions.

This column matrix can be substituted into equation (66) and the resulting column matrix $\begin{Bmatrix} l \\ m_T \end{Bmatrix}$ substituted into equation (74), to yield a column matrix of bending and twisting moments which again, considered as a function of k, represents transfer functions from the gust to these moments. A set of transfer functions for the vertical shear could be calculated similarly from the relation

$$\{V\}=\left[\frac{b}{2}[\mathrm{I}] \;\vdots\; [0]\right]\begin{Bmatrix} l \\ m_t \end{Bmatrix}$$

The stress at any point of the structure can be assumed to be given by a linear superposition of the bending moment, twisting moment, and vertical shear at the given station, if elementary beam theory is used. If elementary beam theory cannot be used because of the interaction of bending and torsion stresses or because of shear lag, the stress at a given point can be expressed as a linear superposition of moments and shears at other stations as well as the given station. In either case, the transfer function for the given stress is then

produced by the same linear superposition of the transfer functions for the corresponding moments and shears.

It may be noted that, at zero frequency, solution of equation (83b) yields the static aeroelastic deformations and thus permits the calculation of the changes in the lift distribution and the shift of the aerodynamic center that result from static aeroelastic action. Also, inasmuch as this equation completely describes the dynamic behavior of the airplane, the speeds at which aeroelastic instability phenomena occur can be calculated from it, although such calculations are beyond the scope of this report. Suffice it to point out that for such a calculation the degrees of freedom of the body must be eliminated first, as a result of the way in which the problem has been set up. This elimination can be effected readily by considering the first and $(n+1)$th rows of $[A]$, but with A_{11}, $A_{1,n+1}$, $A_{n+1,1}$, and $A_{n+1,n+1}$ replaced by 0. If these rows are premultiplied by

$$-\begin{bmatrix} A_{11} & A_{1,n+1} \\ A_{n+1,1} & A_{n+1,n+1} \end{bmatrix}^{-1}$$

and used as the first and $(n+1)$th rows of a matrix which is otherwise a unit matrix, and if this resulting matrix is referred to as $[1'']$, then equation (83b) can be written for this homogeneous case as

$$[[1'][1'']-q[A][1'']]\begin{Bmatrix} z \\ \alpha \\ \Delta\alpha \end{Bmatrix}=\{0\}$$

The products $[1'][1'']$ and $[A][1'']$ will now have two null rows and columns each, which correspond to z_r and α_r. If these rows and columns are deleted and z_r and α_r are deleted in $\begin{Bmatrix} z \\ \alpha \\ \Delta\alpha \end{Bmatrix}$, yielding a column $\begin{Bmatrix} z \\ \alpha \\ \Delta\alpha \end{Bmatrix}'$, the remaining matrices are nonsingular, so that they can be inverted and the preceding equation can be written as

$$[[E]-q[D(k)]]\begin{Bmatrix} z \\ \alpha \\ \Delta\alpha \end{Bmatrix}'=\{0\} \tag{84}$$

where $[E]$ is the identity matrix, and

$$[D(k)]\equiv\left[\widehat{[1'][1'']}\right]^{-1}\left[\widehat{[A][1'']}\right]$$

The horizontal braces designate the fact that the null rows and columns have been deleted.

Equation (84) is in the canonical form for the calculation of eigenvalues. If k is set equal to zero and the eigenvalues of $[D(0)]$ are calculated by iteration, expansion of the determinant, or any other suitable method, the lowest real and positive one represents the value of the dynamic pressure at divergence. For swept wings the value lowest in absolute magnitude is usually negative and is therefore of no practical significance, although it is often used as an index of the aeroelastic behavior of the airplane.

This calculation can be repeated for various positive values of k, the first few eigenvalues being obtained for each. The results, which will generally be complex, can be plotted against k. When any of the eigenvalues becomes purely real, it represents a dynamic pressure at flutter, and the corresponding value of k represents the reduced frequency at flutter. (This statement is true only if the structural damping is zero; such damping effects can easily be included, but the details of the process are beyond the scope of this report.)

DYNAMICS OF THE LARGE FLEXIBLE AIRPLANE

For the large flexible airplane the fundamental proposition of power spectral analysis, that the output power spectrum of a system is the product of the absolute square of the transfer function and the input power spectrum, is no longer valid if the input is considered to be the gust intensity at a point. Nor can the output power spectrum be expressed directly in terms of an effective input spectrum, as in the case of the rigid airplane, where this simplification resulted from the assumption that the indicial-response function was expressible as the product of a function of time alone and a function of distance along the span alone.

In the first section of this part of the report the statistical problems involved in an analysis of the response of a large flexible airplane are considered. The nature of the generalized transfer functions required for this purpose is described, and the means whereby they are combined with the input spectrum are indicated.

The second section is concerned with an extension of the method outlined in the preceding part to the case of the large airplane. Although fundamentally the dynamic aspects of the problem are unchanged, and although the longitudinal and lateral degrees of freedom can still be separated, a direct application of the approaches outlined in the preceding parts of the report to the large airplane requires consideration of the entire wing, rather than only one half of the wing. Little additional computing time is then required to treat the lateral and longitudinal degrees of freedom simultaneously, and the necessity of combining the results of two separate analyses is obviated. However, attention can still be confined to one half of the wing by using the technique outlined in the discussion following equation (55) and in the section headed "Combination of the Results Obtained From Analyses of the Longitudinal and Lateral Degrees of Freedom." Basically this technique consists in splitting the influence functions of concern into symmetric and antisymmetric parts and using one part for an analysis involving the longitudinal degrees, and the other in an analysis involving the lateral degrees. If this approach is adopted, separate analysis of longitudinal and lateral degrees of freedom is still preferable.

EXTENSION OF THE STATISTICAL APPROACH

The power spectrum and, hence, the mean-square values of the responses such as the stress at a given point on the wing of a large flexible airplane due to flight through turbulent air can be calculated in several ways. Perhaps the most direct of these consists in using the basic approach outlined in the first part of this paper and starting with an expression

for the instantaneous value of the stress in terms of a suitable indicial-response influence function, namely,

$$\sigma(t)=\int_{-\infty}^{\infty}\int_{-b/2}^{b/2} h_\sigma^w(t_1,y)\,w(U(t-t_1),y)\,dy\,dt_1 \qquad (85)$$

The function $h_\sigma^w(t,y)$ is, as before, an indicial-response influence function or Green's function for the partial differential equation. It relates the stress as a function of space and time coordinates to the applied loads, which are also functions of space and time coordinates. The essential difference between the problem considered in this section and those treated in the first two parts of the report is that this function can no longer be expressed as a product of a function of t alone and y alone. In some cases—in a modal approach, for instance—it may be expressible as a sum of several such functions, and then the approach used previously for the bending moment of a large rigid airplane free to move vertically may be adopted, as has been done in reference 13. However, in this section the case is considered in which even this simplification cannot be made.

The correlation function for σ can be calculated directly from equation (85), and for the case of axisymmetric turbulence it is

$$\psi_\sigma(\tau)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2} h_\sigma^w(t_1,y_1)h_\sigma^w(t_2,y_2)\,\psi_w\left(\sqrt{U^2(\tau+t_1-t_2)^2+(y_2-y_1)^2}\right)dy_1\,dy_2\,dt_1\,dt_2 \qquad (86)$$

Hence, the power spectrum of σ can be obtained by calculating the Fourier transform of this function and is

$$\varphi_\sigma(\omega)=\int_{-b/2}^{b/2}\int_{-b/2}^{b/2} H_\sigma^{w*}(\omega,y_1)H_\sigma^w(\omega,y_2)\,\tilde{\varphi}_w(\omega,|y_2-y_1|)\,dy_1\,dy_2 \qquad (87)$$

where $\tilde{\varphi}_w(\omega,\eta)$ is the two-dimensional spectrum considered previously, $H_\sigma^w(\omega,y)$ is the Fourier transform of $h_\sigma^w(t,y)$ with respect to time, and the asterisk designates a complex conjugate, as before. Thus, the function $H_\sigma^w(\omega,y)$ is a transfer function from sinusoidal vertical gusts (of width dy) impinging on the wing at a given station y on the wing to the stress σ, or a Green's function for the ordinary differential equation (with the quantity ω as a parameter) that relates the stress amplitude as a function of the space coordinate y to the amplitude of the applied sinusoidal gusts.

The term $H_\sigma^{w*}(\omega,y_1)\,H_\sigma^w(\omega,y_2)$ in equation (87) is complex; however, the imaginary part can be ignored because it contributes nothing to the integral as a result of the fact that $\tilde{\varphi}_w$ depends only on $|y_2-y_1|$.

In a manner analogous to the one employed in the first part of this report, the double integral in equation (87) can be evaluated by introducing the function $\tilde{H}_\sigma^w(\omega,\eta)$ which takes the place of the function $\Gamma(\eta)$ used previously and is defined by an autoconvolution of $H_\sigma^w(\omega,\eta)$:

$$\tilde{H}_\sigma^w(\omega,\eta)=2\int_{-b/2}^{b/2}\mathrm{R}\{H_\sigma^{w*}(\omega,y)\,H_\sigma^w(\omega,y+\eta)\}\,dy$$

where R{ } designates the real part. Hence,

$$\varphi_\sigma(\omega)=\int_0^b \tilde{H}_\sigma^w(\omega,\eta)\,\tilde{\varphi}_w(\omega,\eta)\,d\eta \qquad (88)$$

Another approach consists in using the double Fourier transform $\Phi_w(\lambda)$ of the axisymmetric input correlation defined in the first part of this report. In terms of this function the correlation function $\psi_\sigma(\tau)$ can be written as

$$\begin{aligned}\psi_\sigma(\tau)&=\frac{1}{4}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h_\sigma^w(t_1,y_1)h_\sigma^w(t_2,y_2)\,e^{i[\lambda_1U(\tau+t_1-t_2)+\lambda_2(y_2-y_1)]}\Phi_w\left(\sqrt{\lambda_1^2+\lambda_2^2}\right)d\lambda_1 d\lambda_2 dy_1 dy_2 dt_1 dt_2\\&=\frac{1}{4}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{i\lambda_1U\tau}\left|\hat{H}_\sigma^w(\lambda_1,\lambda_2)\right|^2\Phi_w\left(\sqrt{\lambda_1^2+\lambda_2^2}\right)d\lambda_1 d\lambda_2\end{aligned}$$

where the function

$$\hat{H}_\sigma^w(\lambda_1,\lambda_2)=\int_{-\infty}^{\infty}\int_{-b/2}^{b/2} h_\sigma^w(t,y)\,e^{-i(\lambda_1Ut+\lambda_2y)}\,dy\,dt$$

represents the Fourier transform (with respect to y) of the function $H_\sigma^w(\omega,y)$, that is,

$$\hat{H}_\sigma^w(\lambda_1,\lambda_2)=\int_{-b/2}^{b/2} e^{-i\lambda_2y}H_\sigma^w(\lambda_1U,y)\,dy \qquad (89)$$

Hence,

$$\varphi_\sigma(\omega)=\frac{1}{4\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}e^{i\lambda_1 U\tau}e^{-i\omega\tau}\left|\hat{H}_\sigma^w(\lambda_1,\lambda_2)\right|^2\Phi_w\left(\sqrt{\lambda_1^2+\lambda_2^2}\right)d\lambda_1 d\lambda_2\, d\tau$$

$$=\frac{1}{2U}\int_{-\infty}^{\infty}\left|\hat{H}_\sigma^w\left(\frac{\omega}{U},\lambda\right)\right|^2\Phi_w\left(\sqrt{\left(\frac{\omega}{U}\right)^2+\lambda^2}\right)d\lambda \tag{90}$$

With the approach outlined in the next section, the function $H_\sigma^w(\omega,y)$ can be calculated either directly or indirectly, by first calculating the transfer function from the gust to the lift distribution and then the transfer function from the lift distribution to the stress. For the indirect method,

$$H_\sigma^w(\omega,y)=\int_{-b/2}^{b/2}H_\sigma^l(\omega,y)H_l^w(\omega)\,G(\eta,y)d\eta$$

where the function $H_l^w(\omega)\ G(\eta,y)$ is the influence function for the local lift or the Green's function for the aerodynamic problem involving sinusoidal gusts considered in the first part of this report; the symbols η and y in $G(\eta,y)$ are interchanged, however, so that the function now defines the contribution of a gust at station y to the lift at station η. The transfer function $H_\sigma^l(\omega,\eta)$ relates the (sinusoidal) stress at the given point to a unit concentrated (sinusoidal) normal force acting at station η.

With this indirect method, the power spectrum for the stress at a given point can be calculated by starting with the power spectrum for the lift distribution calculated in the first part of the report. For this approach $\sigma(t)$ may be written as

$$\sigma(t)=\int_{-\infty}^{\infty}\int_{-b/2}^{b/2}h_\sigma^l(t_1,y)\,l(t-t_1,y)dy\,dt_1$$

so that

$$\psi_\sigma(\tau)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}h_\sigma^l(t_1,y_1)h_\sigma^l(t_2,y_2)\psi_l(\tau+t_1-t_2,y_1,y_2)dy_1dy_2dt_1dt_2$$

and

$$\varphi_\sigma(\omega)=\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}H_\sigma^{l*}(\omega,y_1)H_\sigma^l(\omega,y_2)\varphi_l(\omega,y_1,y_2)dy_1\,dy_2 \tag{91}$$

where

$$\psi_l(\tau,y_1,y_2)\equiv\overline{l(t,y_1)l(\tau+t,y_2)}$$

The Fourier transform of this correlation function is, then,

$$\varphi_l(\omega,y_1,y_2)=|H_l^w(\omega)|^2\varphi_{w_\epsilon}(\omega) \tag{92}$$

(See the section headed "Generalized Aerodynamic Influence Functions in Unsteady Flow.") Hence,

$$\varphi_\sigma(\omega)=|H_l(\omega)|^2\int_{-b/2}^{b/2}\int_{-b/2}^{b/2}H_\sigma^{l*}(\omega,y_1)H_\sigma^l(\omega,y_2)\varphi_{w_\epsilon}(\omega)dy_1dy_2 \tag{93}$$

If $\varphi_{w_\epsilon}(\omega)$ is given by equation (35), the double integral can be expressed in terms of single integrals as follows:

$$\varphi_\sigma(\omega)=|H_l^w(\omega)|^2\left[(1-K)^2|G(\omega)|^2\varphi_{w_\epsilon}(\omega)+2K(1-K)\mathrm{R}\{G(\omega)G'^*(\omega)\}+K^2\int_0^b G''(\omega,\eta)\varphi_w(\omega,\eta)\,d\eta\right] \tag{94}$$

where

$$G(\omega)\equiv\int_{-b/2}^{b/2}H_\sigma^l(\omega,y)\gamma(y)\,dy$$

$$G'(\omega)\equiv\int_{-b/2}^{b/2}H_\sigma^l(\omega,y)\varphi_{w_\epsilon}{}^*(\omega,y)\gamma(y)dy$$

$$G''(\omega,\eta)\equiv 2\int_{-b/2}^{(b/2)-\eta}[\mathrm{R}\{H_\sigma^l(\omega,y)\}\mathrm{R}\{H_\sigma^l(\omega,y+\eta)\}+\mathrm{I}\{H_\sigma^l(\omega,y)\}\mathrm{I}\{H_\sigma^l(\omega,y+\eta)\}]\gamma(y)\gamma(y+\eta)dy$$

as before, R{ } designates the real part, and I{ } designates the imaginary part.

Equations (88), (90), and (93) thus represent three methods of obtaining the power spectrum of the given stress. One requires a transfer function from the local gust intensities directly to the stress, an autoconvolution of this transfer function, and the spectrum of turbulence defined by equation (16); the second requires a two-dimensional spectrum of the turbulence defined by equations (17a) and (17b) and a Fourier transform of the aforementioned transfer function with respect to y; the third utilizes an autoconvolution of the transfer functions from local concentrated loads to the stress and the spectrum for local lifts due to vertical gusts calculated in the first part of the report. The choice of approach depends to some extent on the information available, but is largely a matter of individual preference.

The analysis in this section has been based on the premise that both halves of the wing would be treated simultaneously. Attention can be confined to one wing by using only the symmetric parts of the influence functions in an analysis involving the longitudinal degrees of freedom, and only the antisymmetric parts in an analysis involving the lateral degrees of freedom. The symmetric part of an influence function for a unit concentrated load or gust acting at station y is the response function for two loads or gusts of ½ unit intensity acting at stations y and $-y$, respectively. Similarly, the antisymmetric part is the response for a load or gust of ½ unit intensity acting at station y and an equal and opposite load or gust acting at station $-y$. If this approach is chosen, some of the integral expressions given in this section assume slightly simpler forms. For instance, equation (89) can then be written for the symmetric part as

$$\hat{H}_\sigma^w(\lambda_1,\lambda_2)=2\int_0^{b/2}\cos\lambda_2 y H_\sigma^w(\lambda_1 U,y)dy$$

and for the antisymmetric part as

$$\hat{H}_\sigma^w(\lambda_1,\lambda_2)=-2i\int_0^{b/2}\sin\lambda_2 y H_\sigma^w(\lambda_1 U,y)dy$$

CALCULATION OF THE REQUIRED TRANSFER FUNCTIONS

Depending on which of the methods outlined in the preceding section is used, one of two types of transfer functions is required—either the one from local gusts to the stress of interest, or the one from the local lift to that stress. Both of these functions differ in several respects from those considered in the preceding part of this report.

For either type of transfer function the structural deformations of the wing under concentrated loads as well as under distributed loads will be required, so that the numerical-integration schemes used in the preceding part have to be modified to some extent. Also, it may now be preferable to consider the entire wing (rather than the one semispan considered in the case of the small flexible airplane), so that the various transfer functions are asymmetric. With the degrees of freedom considered in the analysis thus doubled, it becomes preferable to include one additional degree of freedom, roll, rather than to perform two separate analyses for symmetric and antisymmetric motions with, respectively, one and two less degrees of freedom, and then to combine the results. However, if the alternative approach of splitting up the influence functions into symmetric and antisymmetric parts for use in two separate analyses is adopted, only one semispan need be considered, and the results presented in this section can then be simplified to a large extent.

Before discussing the modifications required to extend the dynamic analysis outlined in the preceding part of the report to the large airplane, it might be pointed out that chordwise deformations (deformations parallel to the chord) will again be ignored. Again, they can readily be included by a straightforward extension of the approach used here if it is felt that they may be significant in any given case. If they are included, however, yawing and possibly also sideslipping motions can probably no longer be ignored, because they may give rise to large forces in the chordwise direction. If the entire wing is treated, these two additional degrees of freedom can readily be included, and all longitudinal and lateral degrees of freedom are then treated simultaneously; if two separate analyses are performed for the longitudinal and lateral degrees of freedom, the symmetric and antisymmetric parts of the influence functions being used and only one semispan being treated, these additional degrees of freedom enter only into the lateral analysis.

The structural deformation due to local (concentrated) loads can be obtained in several ways. If measured influence coefficients are used, they pertain precisely to such loads and, in fact, must be modified before they can be used for distributed loads (see ref. 12) so that it is necessary only to use the unmodified coefficients.

If the deformations are to be calculated in a manner similar to that employed in the preceding part, the integrating matrices must be replaced as follows:

$$\frac{b}{2}[\mathrm{I}] \text{ by } \frac{b}{2}[\mathrm{I}']$$

where

$$\mathrm{I}_{pq}'=1 \qquad (q>p)$$

$$\mathrm{I}_{pq}'=\frac{1}{2} \qquad (q=p)$$

$$\mathrm{I}_{pq}'=0 \qquad (q<p)$$

and

$$\left(\frac{b}{2}\right)^2[\mathrm{II}] \text{ by } \frac{b}{2}[\mathrm{II}']$$

where

$$\mathrm{II}_{pq}'=y_q-y_p \qquad (q\geqq p)$$

$$\mathrm{II}_{pq}'=0 \qquad (q<p)$$

The factor of ½ for $I_{pp'}$ constitutes an approximation which implies fairing through a discontinuity. If this approximation is to be avoided, the deflections due to unit concentrated loads (the structural influence coefficients) can be calculated directly from simple beam theory, in which case the limits of integration take care of the discontinuities. Thus, for instance, for an unswept wing, the normal deflection and twist at y_p due to a unit concentrated load and torque, respectively, at y_q are

$$z_{pq}=\int_0^{y_p}\int_0^{y'}\frac{y_q-y}{EI(y)}\,dy\,dy' \qquad (y_p \leqq y_q)$$

$$z_{pq}=\int_0^{y_q}\int_0^{y'}\frac{y_q-y}{EI(y)}\,dy\,dy'+(y_p-y_q)\int_0^{y_q}\frac{y_q-y}{EI(y)}\,dy \qquad (y_p > y_q)$$

$$\alpha_{pq}=\int_0^{y_p}\frac{1}{GJ(y)}\,dy \qquad (y_p \leqq y_q)$$

$$\alpha_{pq}=\int_0^{y_q}\frac{1}{GJ(y)}\,dy \qquad (y_q < y_p)$$

The concentrated loads under consideration arise as follows: For the transfer functions relating local lifts to the desired stress, the local lifts may be considered to be concentrated loads of unit magnitude, associated with concentrated torques of magnitude e_1c. Equation (83b) can then be written as (see also eq. (76))

$$\left[[1']-q[A]\right]\begin{bmatrix}z\\ \alpha\\ \Delta\alpha\end{bmatrix}=[R']\begin{bmatrix}[w]\\ \hline [e_1c]\,[w]\end{bmatrix} \qquad (95)$$

where $[w]$ is a diagonal matrix of the values of w defined by equation (63), and where the matrix $[R']$ represents either the four influence-coefficient matrices for z and α due to concentrated loads and torques, or the square matrix of equation (75) with modified integrating matrices, as discussed in the preceding paragraphs.

It may be noted that equation (95) now represents not one set of simultaneous equations but several, all having the same coefficients but different sets of knowns (as defined by the columns of the matrix on the right side) and, hence, different sets of unknowns (the columns of the matrix $\begin{bmatrix}z\\ \alpha\\ \Delta\alpha\end{bmatrix}$). This situation is due to the fact that the functions under consideration are, in effect, the responses of the airplane as a whole to sinusoidally varying concentrated loads and are different for each location of the applied load.

Once this equation has been modified to take into account the overall body motions and tail deflections (as explained in the preceding part) as well as the rolling motions (as explained in the following paragraphs), it can be solved to yield the unknown values of $\begin{bmatrix}z\\ \alpha\\ \Delta\alpha\end{bmatrix}$. From these values the bending and twisting moments, as well as the vertical shears, can be calculated and added to those due to the concentrated loads. When combined linearly as required for the desired stress, these moments and shears yield the desired transfer functions $H_\sigma^l(\omega, y)$.

If the transfer function directly from the local gusts to the desired stress is to be determined, the response of the airplane to the lift distribution induced by a sinusoidal gust of width dy acting at station y must be calculated. This lift distribution is the Green's function considered previously. If it is represented by the relation $H_l^w(\omega)\ G(y,\eta)$, with $G(y,\eta)$ defined by the approximation given in equation (34), the concentrated loads arise from the delta function in that expression. The right side of equation (95) becomes, in that case,

$$q(1-K)\,H_l^w(\omega)\,[R]\begin{bmatrix}[\gamma(y)\,\gamma(\eta)]\\ \hline [e_1c]\,[\gamma(y)\,\gamma(\eta)]\end{bmatrix}[w]+ qbK\,H_l^w(\omega)\,[R']\begin{bmatrix}[\gamma(y)]\,[w]\\ \hline [e_1c]\,[\gamma(y)]\,[w]\end{bmatrix}$$

where $[R]$ represents the square matrix of equation (75), and $[R']$ the one discussed in connection with equation (95). Again, several sets of simultaneous equations are implied. Their solution (after modification for overall motions and tail deflections) yields values of z and α from which the transfer functions $H_\sigma^w(\omega,y)$ can be calculated.

The extension of the method of the preceding part to the calculation of the deformations on both wings is straightforward. Essentially, distributed lifts and torques now have to be calculated for both wings and integrated with matrices which can be assembled from those used for one wing alone. No new problems arise in this process, so that it need not be discussed further.

The inclusion of rolling motion, however, is not so straightforward. One method consists in replacing all values of z in equation (83a) or its equivalent by $z+\Theta y$ and then reducing the columns involving this quantity by the following relation (which assumes that the new unknown quantity, the roll angle Θ, is listed at the end of the column):

$$\begin{Bmatrix}z+\Theta y\\ \hline \alpha\\ \hline \Delta\alpha\\ \Theta\end{Bmatrix}=\left[\begin{array}{ccc:c:c}1 & & & & \\ & 1 & & & \\ & & 1 & & \\ & & & 1 & \\ & & & & \ddots \\ & & & & \ddots \\ \hdashline & & & 1 & \\ & & & & 1 \\ & & & & & \ddots \\ \hdashline & & & & \\ & & & & \end{array}\right.\begin{array}{c}0\\ \hline 0\\ \hline 0\\ 0\end{array}\left.\begin{array}{c}\left\{\begin{matrix}y\\ \\ \\ \\ \\ \end{matrix}\right\}\\ \hline \\ \hline \\ \end{array}\right]\begin{Bmatrix}z\\ \hline \alpha\\ \hline \Delta\alpha\\ \Theta\end{Bmatrix}$$

An additional equation must then be joined to the set, namely, the equation of equilibrium in roll

$$\int_{-b/2}^{b/2} l(y)\, y\, dy - I_x\ddot{\Theta} - M_{D_t}\dot{\Theta} = 0 \qquad (96)$$

where I_x is the inertia in roll of the fuselage and empennage alone inasmuch as the inertia effects of the wing are included in $l(y)$, and M_{D_t} is the coefficient of damping in roll for the empennage. For most cases both of these contributions are negligible. If they are ignored, equation (96) can be written in matrix notation as

$$[\mathrm{II}]\{l\} = 0$$

where [II] is now a matrix which serves to perform the integration required in equation (96). This condition can then be adjoined to the other equations of the set in the same manner as equations (82) were adjoined to the set in the preceding part.

The result, again, is a set of simultaneous equations for z, α, $\Delta\alpha$, and Θ from the solution of which the desired transfer functions can be obtained as outlined in the preceding paragraphs. Also, as before, once the unknowns z_r, α_r, and Θ are eliminated from the set, the divergence and flutter speeds can be calculated by conventional matrix operations; these speeds will then pertain to an airplane free to move vertically as well as in pitch and roll and, hence, will include divergence and flutter speeds in antisymmetric as well as symmetric modes.

DISCUSSION

SOME IMPLICATIONS OF THE ASSUMPTIONS CONCERNING THE NATURE OF ATMOSPHERIC TURBULENCE

The turbulence was assumed to be homogeneous in order to make the problem stationary in the statistical sense and thus permit the use of the mathematical techniques developed for such problems. In a practical sense, turbulence can be homogeneous only in a limited body of air. The assumption thus implies that the dimension of this body of air along the flight path is large compared with the distance traversed in the reaction time of the airplane, which in the case of load studies is of the order of the time to damp to one-half amplitude, but in the case of motion studies may be much larger. Obviously, the greater the body of air, the greater the reliability with which the loads and motions can be predicted (in a statistical sense) for one run through it. In general, turbulence at very low altitudes, which may be influenced significantly by the configuration of the ground, and turbulence in thunderstorms may not be sufficiently homogeneous for the purpose of this type of analysis, but other types of turbulence are likely to be substantially homogeneous over sufficiently large distances.

Isotropy was assumed in order to permit the required two-dimensional correlation functions to be expressed simply in terms of the one-dimensional correlation functions. For sufficiently short wave lengths all turbulence is isotropic, but for long wave lengths it can be isotropic only if it is homogeneous (both in the plane of the flight path and perpendicular to it). The condition of axisymmetry, which is sufficient for most of the results presented herein, is less restrictive than isotropy inasmuch as it does not specify the variation of the characteristics of the turbulence in the vertical direction. In practical problems, if the turbulence may be assumed to be homogeneous, the conditions of axisymmetry and isotropy are likely to be satisfied to a sufficient extent to permit the use of the approach presented herein for all but very long wave lengths. The wave length at which it ceases to be valid depends on the size of the body of air under consideration, being larger for a large body.

Taylor's hypothesis (to the effect that a space displacement Δx along the flight path may be identified with a time displacement $\tau = \Delta x/U$ in the gust correlation functions) implies that the variation in gust intensity that prevails along the flight path at any instant will remain substantially the same until the airplane has traversed the given body of air. The required correlation functions for atmospheric turbulence are thus in the nature of space correlation functions (rather than time correlation functions) and have been considered as such. The statistical characteristics of the turbulence are then independent of the speed at which it is traversed. Clearly, whether or not this hypothesis is valid depends on the flying speed of the airplane. On the basis of present knowledge no definite lower limiting speed can be quoted. However, indications are that the hypothesis is valid for flying speeds greater than about 100 or 200 feet per second. The effect of finite flying speed on the gust correlation function can be expected to be most pronounced for large distances, where the correlation is weak, so that the effect on the various spectra is likely to be small and to occur at the longest wave lengths, where, as previously mentioned, the spectrum is somewhat uncertain for other reasons as well; this effect is thus more likely to be significant for large than for small airplanes.

The particular correlation function used herein for the calculations of the "averaged" correlation functions and spectra has certain theoretical shortcomings—primarily that the associated spectrum does not decrease rapidly enough for very short wave lengths. However, it does appear to be adequate to represent the available information concerning the spectra of atmospheric turbulence (see ref. 17, for instance) because the behavior at very short wave lengths is relatively unimportant, inasmuch as airplanes cannot respond to them, and the behavior at very long wave lengths is usually in doubt by reason of the nonhomogeneity of actual turbulence. In the intermediate range of wave lengths, this correlation function appears to be quite satisfactory.

The parameter L^* (the integral scale of turbulence) used herein is, for practical purposes, a largely fictitious quantity, inasmuch as it is proportional to the values of the gust spectrum for infinite wave lengths, which, in view of the uncertainties in the values of the spectra at large wave lengths, have little physical significance. Therefore, at present, insufficient information is available to give a value for L^* to be used in connection with the numerical results calculated herein, although a value of 1,000 to 2,000 feet appears to be appropriate. As more information concerning the spectrum of atmospheric turbulence becomes avail-

able, more definite values can be deduced by fitting an analytical expression of the type used here to measured results in the range of frequencies of primary interest, and then using this expression as a means of obtaining a value of L^* by extrapolation of the measured results to infinite wave lengths (zero frequency).

CONSIDERATIONS PERTINENT TO THE APPLICATION OF STATIONARY-RANDOM-PROCESS TECHNIQUES TO GUST-LOAD PROBLEMS

The purpose of this section is to point out how, in principle, the results of analyses of the type outlined herein may be used in overall load analysis and, hence, in the design of an airplane.

Consideration is confined in this paper primarily to the power spectra of the motions and stresses of interest. As pointed out in references 1, 2, 3, and 11, for instance, a great deal of statistical information of direct interest can be obtained from the power spectrum. For instance, if the random process of concern (say, the given stress as a function of time) has a Gaussian probability distribution, the expected number of peaks at or beyond a given level in a given period of time can be calculated very simply from the integral of the spectrum and its second and fourth moments.

The results obtained in this manner pertain to continued flight in a given body of turbulent air. They have to be generalized by determining the likelihood of flying through turbulence of the given characteristics. (See ref. 18.) The probability of exceeding a given stress level during the expected life of the airplane while flying through atmospheric turbulence can thus be calculated in straightforward fashion. To this probability must then be added the probability of exceeding this level in maneuvers, landings, and, possibly, also in turbulence due to thunderstorms, because in view of the possibly nonhomogeneous character of turbulence in thunderstorms and the possibly nonlinear nature of the aerodynamic forces incurred while flying through them, the techniques used herein may not be applicable to flight through thunderstorms, and a separate analysis may have to be performed.

Although the available information concerning atmospheric turbulence is inadequate to permit of any definite conclusion, the results obtainable with the approach outlined herein may turn out to be most significant for the prediction of the low- and medium-amplitude stress cycles which are important to fatigue studies; their validity for or contribution to the prediction of very severe loads remains to be seen.

CONCLUDING REMARKS

The statistical approach to the problem of calculating the dynamic responses and the stresses of an airplane subjected to continuous random atmospheric turbulence has been extended in several respects; basically, only the assumptions of linearity, that is, of small motions and deformations, as well as homogeneity and axisymmetry of the turbulence are retained.

The first problem considered was the effect of spanwise variations of the instantaneous turbulent velocities on the lift and moments due to turbulence. The mean-square lift has been shown to be reduced considerably if the span of the airplane is relatively large compared with the integral scale of turbulence. The shape of the spectrum of this lift is affected relatively little by spanwise variations of gust intensity, except at very high frequencies, if the decrease in the effective mean-square intensity is taken into account. The effect of sweep on the mean-square lift and its spectrum has been shown to be small for wings with a given distance from root to tip.

If the variation of the instantaneous velocities is taken into account, the rolling moment to which the airplane is subjected can be calculated. The mean-square rolling moment has been shown to be proportional to the ratio of the wing span to the integral scale of turbulence for small values of that ratio. Similarly, expressions for the mean-square values and the power spectra of the local lift, the bending moments, and the pitching moment have been given. For some of these forces the required aerodynamic information cannot be calculated by existing methods. Therefore, certain approximations, based on experience with steady aerodynamic forces and available knowledge concerning unsteady forces, had to be made for the aerodynamic influence functions in unsteady flow.

The next problem considered was the dynamic response of a rigid airplane to random turbulence. This problem had previously been treated for the case of an airplane free to move only in the vertical direction and small enough so that variation of the turbulent velocities along the span could be neglected. In the present report the response of an airplane in three longitudinal degrees of freedom was considered; calculations were made which suggest that the inclusion of deviations from the mean horizontal motion is superfluous in gust-load calculations. For the remaining two longitudinal degrees of freedom, the mean-square normal and angular acceleration have been shown to be functions of only two parameters other than the mass ratio and scale parameter of the single-degree-of-freedom case, namely, dimensionless forms of the short-period frequency and of the time to damp to one-half amplitude. An indication is given of the manner in which the results obtained in connection with the first problem can be used to extend this dynamic analysis to the case in which variations of the turbulent velocity along the span have to be taken into account.

The last problem treated was the dynamic response of a flexible airplane, including vertical motion, pitch, and, when necessary (as when spanwise variations in gust intensity are taken into account), roll. Horizontal and lateral (yawing and sideslipping) motions were disregarded because they do not generally affect the wing stresses due to vertical gusts. A method which represents an extension to the dynamic case of a numerical-integration approach to the static aeroelastic problem has been outlined for the analysis of the problem at hand. The modifications required in the basic statistical approach and in this method of dynamic analysis in order to treat the case in which spanwise variations of the gust intensity are important have been discussed.

Although most of this analysis has been confined to the vertical component of turbulence, it has been shown that the simultaneous action of longitudinal, vertical, and lateral

gusts on the wing stresses (with due allowance for the fact that vertical gusts affect both the longitudinal and the lateral motions of the airplane) can be taken into account by simply adding the power spectra of the various contributions, provided the turbulence is isotropic; the cross correlations or spectra have been shown to vanish either by the symmetry or antisymmetry of the influence functions involved or as a result of the statistical independence of mutually perpendicular velocity components.

The approach presented herein thus furnishes a foundation for the prediction of the statistical properties of the stress experience of a given airplane once the appropriate statistical characteristics of the atmosphere have been determined.

REPORT 1346

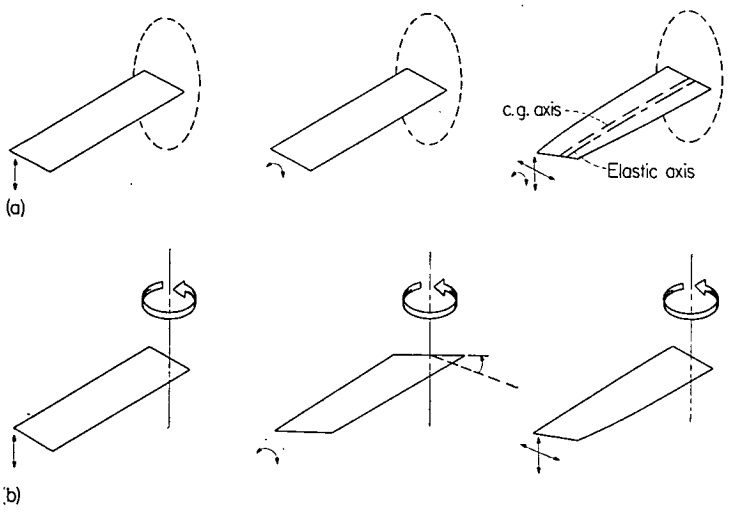
DIFFERENTIAL EQUATIONS OF MOTION FOR COMBINED FLAPWISE BENDING, CHORDWISE BENDING, AND TORSION OF TWISTED NONUNIFORM ROTOR BLADES [1]

By JOHN C. HOUBOLT and GEORGE W. BROOKS

SUMMARY

The differential equations of motion for the lateral and torsional deformations of twisted rotating beams are developed for application to helicopter rotor and propeller blades. No assumption is made regarding the coincidence of the neutral, elastic, and mass axes, and the generality is such that previous theories involving various simplifications are contained as subcases to the theory presented in this paper.

Special attention is given the terms which are not included in previous theories. These terms are largely coupling-type terms associated with the centrifugal forces. Methods of solution of the equations of motion are indicated by selected examples.



INTRODUCTION

This paper deals with the deformation theory of rotating blades. The structural problems of these blades have become more acute in almost every phase of aeronautical-engineering application: For example, propellers have become larger and thinner, particularly in connection with aircraft designed for vertical take-off and landing and short take-off and landing, and as a consequence are more susceptible to vibration and flutter troubles; helicopter blades are subject to numerous vibration, divergence, and flutter problems; and turbine and compressor blades fail frequently because of some vibration phenomena. There is therefore much interest in the development of a more general deformation theory which is fundamental in the structural and dynamic analysis of these problems.

Although many theories on blade deformation exist, these theories either neglect some of the factors of concern or treat them only approximately. The factors are many and include variable stiffness and mass distributions, noncoincidence of the elastic and mass axes, built-in twist, coupling brought about by inertia and centrifugal forces, and so forth. In order to give a rough perspective of the scope of available theory, figure 1 has been prepared. The nonrotating-beam cases have also been included in figure 1 (a). The first two cases refer to uncoupled bending and uncoupled torsion of beams without twist, and much work on these cases has been done; their treatment is in fact classical. The third case is that of coupled bending in two directions and torsion of a twisted beam, wherein the elastic and mass axes are noncoincident (see ref. 1); the subcase where no twist is present has also been given extensive treatment. Additional treatments on general theory of pretwisted beams are also given in references 2 to 4.

The rotating-beam cases which have been treated with the inclusion of centrifugal forces are shown in figure 1 (b). The first case, that of pure flapwise bending of an untwisted beam, has been considered by several investigators; reference 5 is a notable example in which beams of variable cross section and different root-end suspensions are analyzed from a design-application standpoint in considerable detail. References 6 to 8 also give substantial treatments to this case. Pure torsion of untwisted rotating beams is treated in references 9 and 10, and combined bending in two directions is treated by various means which include both vector and matrix methods in references 11 to 16.

The case treated in the present paper is shown in figure 2; this case represents the coupled bending in two directions and torsion of a twisted rotating beam where the elastic axis, mass axis, and tension axis are not necessarily coincident. The tension axis is defined as the spanwise locus of the centroids of the cross-sectional area effective in carrying tension. The specific purpose of the paper is to develop the differential equation of deformation of the blade under

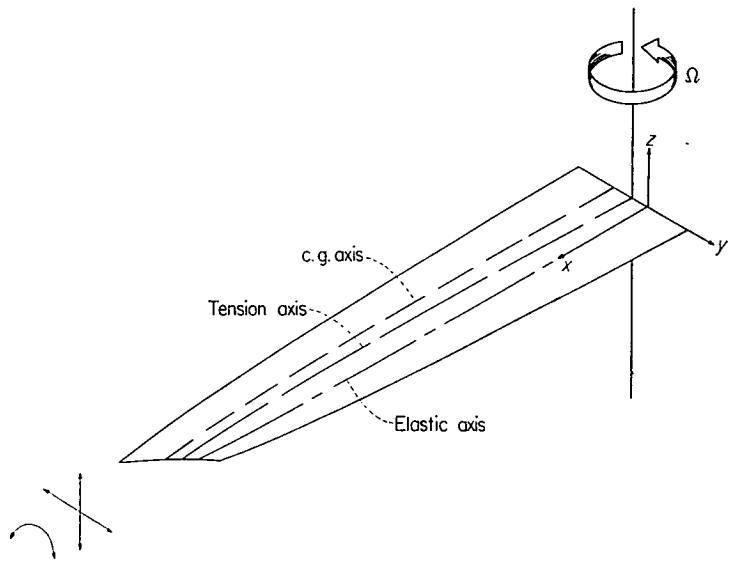

FIGURE 2.—Present theory. Case of coupled bending-torsion of twisted rotating beam.

the action of various applied loads. The development is made along the principles of "engineering" beam theory, and secondary effects, such as deformation due to shear, are not included. The theory is therefore intended primarily for blades of moderate to high aspect ratios, for which plate bending effects are probably not significant. Special subcases which involve simplifications that appear justified in the treatment of certain problems (for example, helicopter blade deformation) are then deduced. Finally, methods of solving the equations are discussed, and examples are given.

SYMBOLS

A cross-sectional area of blade effective in carrying axial tension

B_1, B_2 section constants, see equations (9)

ds incremental distance measured along beam fiber in undeformed state

ds_1 incremental distance measured along beam fiber in deformed state

E Young's modulus of elasticity

e distance between mass and elastic axis, positive when mass axis lies ahead of elastic center

e_A distance between area centroid of tensile member and elastic axis, positive for centroid forward

e_o distance at root between elastic axis and axis about which blade is rotating, positive when elastic axis lies ahead

G shear modulus of elasticity

I_1, I_2 bending moments of inertia about major and minor neutral axes, respectively (both pass through centroid of cross-sectional area effective in carrying tensions)

J torsional stiffness constant

k_A polar radius of gyration of cross-sectional area effective in carrying tensile stresses about elastic axis

k_m polar radius of gyration of cross-sectional mass about elastic axis ($k_m^2=k_{m1}^2+k_{m2}^2$)

k_{m1}, k_{m2} mass radii of gyration about major neutral axis and about an axis perpendicular to chord through the elastic axis, respectively

L_y intensity per unit length of laterally applied aerodynamic load in plane of rotation

L_z intensity per unit length of applied aerodynamic loading perpendicular to plane of rotation

M intensity per unit length of applied aerodynamic torque loading

M_1 resultant cross-sectional moment about major principal axis

M_2 resultant cross-sectional moment about axis perpendicular to major principal axis and passing through elastic axis

M_x, M_y, M_z resultant moments in x-, y-, and z-directions, respectively, of M_1, M_2, and Q moments

m mass of beam per unit length

$\bar{p}_x$, $\bar{p}_y$, $\bar{p}_z$ resultant or total loadings per unit length in x-, y-, and z-directions

Q resultant cross-sectional torque about elastic axis

q torque loading per unit length

$\bar{q}_x$, $\bar{q}_y$, $\bar{q}_z$ resultant torque loadings per unit length in x-, y-, and z-directions

R blade radius

T tension in beam, $T\cong\int_x^R \Omega^2 mx\,dx$

t thickness of cross section at any chordwise position

V_y, V_z cross-sectional shears in y- and z-directions

v, w lateral displacements of beam, in plane of rotation and normal to plane, respectively

x, y, z coordinate system which rotates with blade such that x-axis falls along initial or undeformed position of elastic axis (see figs. 2 and 3)

β blade angle of station x prior to any deformation, positive when leading edge is upward

ϵ strain

ϵ_T strain due to tension, $\frac{T}{EA}$

ζ,η cross-sectional coordinates; η-axis lies along major axis, ζ-axis is perpendicular to major axis and passes through elastic axis (see fig. 3)

η_{te}, η_{le} values of η for trailing edge and leading edge of cross section

ρ mass density

σ stress

ϕ angle of twisting deformation, positive when leading edge is upward

Ω angular velocity of rotation

ω frequency of vibration, radians/sec

Primes denote derivatives with respect to x; dots denote derivatives with respect to time.

ANALYSIS

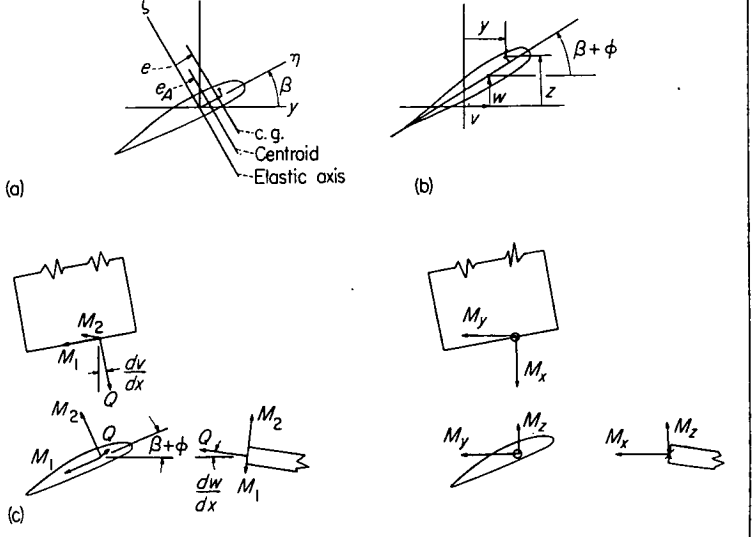
GENERAL PROCEDURE

As noted from figure 2, the beam is considered as though it were a rotating helicopter blade with rotation counterclockwise when viewed from above. The x-axis of the x, y, z coordinate axes system shown lies outward along the blade and is coincident with the undeformed position of the elastic axis. This set of axes moves with the blade around the axis of rotation at the given rotational velocity Ω, and all deformations of the blade are referred to this coordinate system. The blade is considered under the action of distributed aerodynamic loadings in the y- and z-directions and under a distributed torque loading about the elastic axis, where the intensities per unit length are denoted by L_y, L_z, and M, respectively. The tension in the beam is denoted by T.

Figures 3 (a) and (b) show the coordinate system used for the blade cross section and the chosen displacements of this analysis. The η- and ζ-axes, with the origin at the elastic axis and the η-axis along the major axis of the cross section, move with the cross section. The blade deformations are denoted by a displacement v of the elastic axis in the plane of rotation, positive when in the direction of rotation, a displacement w out of the plane of rotation, positive upward, and a rotation ϕ about the elastic axis. The built-in twist β and also ϕ are positive when the blade leading edge is up.

The aim of this analysis is to derive the differential equation of motion in terms of v, w, and ϕ. The derivation proceeds along the following steps:

(1) The equation for longitudinal strain at any point on the cross section is derived in terms of the displacements.



(2) With the aid of this strain equation the internal elastic moments are derived; these are the resultant moments taken about the η- and ζ-axes and are shown in figure 3 (c).

(3) The transformation is then made of these elastic moments to the more easily handled moments which have vectors parallel to the x, y, z axes system. (See fig. 3 (c).)

(4) The equilibrium expressions for these latter moments are derived, and this consideration involves the introduction of the total loading on the beam.

(5) The total loadings, composed of the body forces and applied loadings, are derived.

(6) Steps 3, 4, and 5 are combined to give the final differential equations.

(a) Coordinates. (b) Displacements. (c) Moments.

FIGURE 3.—Nomenclature.

DERIVATION OF STRAIN EQUATION

Both longitudinal and shearing strains are, of course, produced during bending and torsion of the beam. In general, both types of strains must be considered in determining the resultant forces and moments that act on a given cross section. In the treatment given in the present paper, however, an approach is used which requires that only the longitudinal strains have to be considered explicitly. In appendix A a derivation akin to an engineering beam theory is given for the strain that develops in any longitudinal fiber of a twisted beam which undergoes translational displacements v and w and a torsional displacement ϕ. The derivation is mainly formal, but a physical insight of how strain is developed may be gained by considering the possible motions of the imaginary cutting planes shown in figure 4 and which are assumed to remain plane during deformation. In general, strain may arise from four types of motion: pure displacement of the planes toward or away from each other, rotation of the planes associated with chordwise bending, rotation of the planes associated with flapwise bending, and rotation of the planes relative to one another about the elastic axis to cause beam twisting. With the assumption that the cross section is symmetrical about the major principal axis, the resulting longitudinal strain is found to be

$$\epsilon=\epsilon_T+(e_A-\eta)\ (v''\cos\beta+w''\sin\beta)+\zeta\ (v''\sin\beta-w''\cos\beta)+(\zeta^2+\eta^2-k_A^2)\beta'\phi' \tag{1}$$

The longitudinal stresses follow directly from this equation and are

$$\sigma=E[\epsilon_T+(e_A-\eta)\ (v''\cos\beta+w''\sin\beta)+\zeta(v''\sin\beta-w''\cos\beta)+(\zeta^2+\eta^2-k_A^2)\beta'\phi'] \tag{2}$$

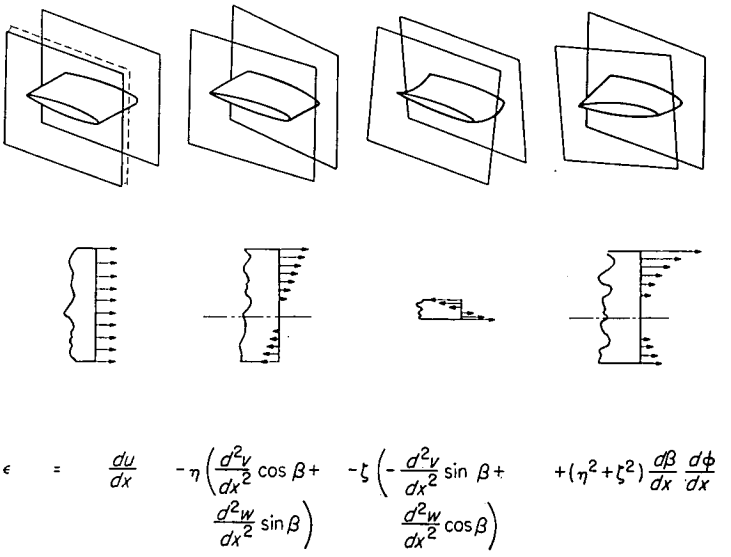


FIGURE 4.—Strains.

No further development of cross-sectional stresses or strains is necessary. The consideration of shearing stresses which are associated with longitudinal stresses, that is, the shearing stresses which are necessary to satisfy equilibrium of an elemental tube, is avoided by choosing the elastic axis (defined here as the locus of shear centers) as a reference axis; the consideration of shearing stresses due to twisting deformation is obviated through use of the assumption that the resisting torque includes a St. Venant type torsional term which is the same as would develop if the beam were initially untwisted. Both of these items will be introduced in the next section.

DERIVATION OF INTERNAL ELASTIC MOMENTS

The stress distributions over the cross section may now be resolved into effective internal resisting moments at the elastic-axis position, as shown in figures 3 and 5. In order to determine these moments, the inclination relative to the elastic axis of the general beam fiber due to initial twist and twisting deformation must be considered. The stress along this fiber is resolved into two components, one parallel to the elastic axis and one in a plane perpendicular to the elastic axis. (See fig. 5.) From the longitudinal component, the flapwise bending moment M_1 and the chordwise bending moment M_2 are given as follows:

$$M_1=-\int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2}\sigma\zeta\,d\zeta\,d\eta \tag{3}$$

$$M_2=-\int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2}\sigma\eta\,d\zeta\,d\eta \tag{4}$$

where the minus signs have been introduced to make the moments positive when they produce compression in the upper and nose fibers, respectively.

The component in the plane normal to the elastic axis leads to an effective torsional resisting moment. The consideration of this component and the addition of the torque associated with St. Venant twisting mentioned previously leads to the following equation for total resisting torque:

$$Q=GJ\phi'+\int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2}\sigma(\beta+\phi)'\,(\eta^2+\zeta^2)d\zeta\,d\eta \tag{5}$$

where a positive torque is associated with a positive ϕ'. In equation (5), the choice of the elastic axis as a reference axis is significant. The elastic axis does not necessarily coincide with the centroidal axis, and if the centroidal axis, or for that matter any other axis, were used as a reference, then the shearing stresses associated with longitudinal stresses would contribute to the total resisting torque.

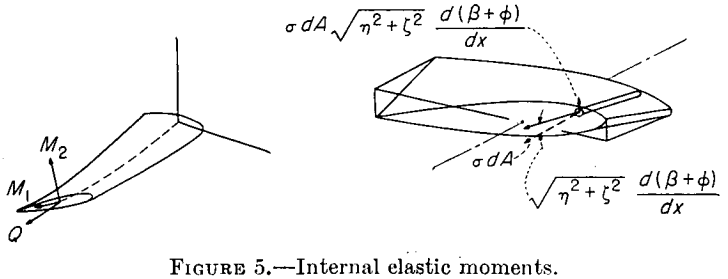

FIGURE 5.—Internal elastic moments.

Such a term would have to be included in equation (5) and would thus lead to considerable complication in the analysis. With the choice of the elastic axis, however, no such term appears, because the elastic axis is defined herein as the axis about which the resultant torque of the shearing stresses due to longitudinal stresses is zero.

Since the elastic axis is important, the establishment of this axis position will be discussed now. Consider differential longitudinal stresses to arise which have a cross-sectional distribution the same as that given by equation (2). The differential longitudinal stresses associated with the expression $E[\epsilon_T+e_A(v''\cos\beta+w''\sin\beta)-k_A^2\beta'\phi']$ are uniform across the cross section and hence do not produce any shearing stresses. For the expression

$$E[-\eta(v''\cos\beta+w''\sin\beta)+(\zeta^2+\eta^2)\beta'\phi']$$

the differential stresses would be symmetrical about the major axis (η-axis) and, since the cross section is assumed symmetrical, would lead to a resultant shear directed along the major axis. Only the remaining term $E\zeta(v''\sin\beta-w''\cos\beta)$ can lead to shearing stresses which produce torque. Thus in order to locate the position of the elastic axis, it is sufficient to consider the beam in bending about the major axis only, with a linear stress distribution in the ζ-direction, and then to determine the shearing stresses over the cross section (in the η- and ζ-directions) and the position along the major axis for which these shearing stresses produce no resultant torque. (See treatments on elastic axis and shear center in ref. 17.)

The substitution of equation (2) into equations (3), (4), and (5) gives the following equations for total elastic moments in terms of the displacements:

$$M_1=EI_1(-v''\sin\beta+w''\cos\beta) \tag{6}$$

$$M_2=EI_2(v''\cos\beta+w''\sin\beta)-Te_A-EB_2\beta'\phi' \tag{7}$$

$$Q=[GJ+Tk_A^2+EB_1(\beta')^2]\phi'+Tk_A^2\beta'-EB_2\beta'(v''\cos\beta+w''\sin\beta) \tag{8}$$

where I_1 and I_2 are the principal moments of inertia of the tensile carrying area (I_2 is the moment of inertia about the mean principal axis, not about the ζ-axis) and where B_1 and B_2 are section constants defined by

$$\left.\begin{aligned}B_1&=\int_{\eta_{te}}^{\eta_{le}}t\eta^2\left(\eta^2+\frac{t^2}{6}-k_A^2\right)d\eta\\ B_2&=\int_{\eta_{te}}^{\eta_{le}}t\eta\left(\eta^2+\frac{t^2}{12}-k_A^2\right)d\eta\end{aligned}\right\} \tag{9}$$

In equations (9) it is interesting to note that if displacements parallel and perpendicular to the blade chord had been used instead of v and w the results obtained would differ from those used by other investigations. (See appendix A for the results obtained.) Also of interest is the form that equation (8) would take if large deflections in ϕ were considered, but with $v=w=0$. This point, which is connected with the possibility of a torsional instability, is discussed also in appendix A.

MOMENT TRANSFORMATION

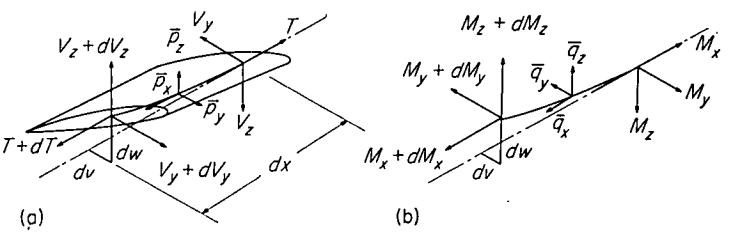
In the consideration of the equilibrium between moments, shears, and tension, it is more convenient to deal with moments that are orientated parallel to the x-, y-, and z-axes, that is, the moments M_x, M_y, and M_z shown in figure 3. A simple transformation of the moments M_1, M_2, and Q to these newer moments is thus desired. When the M_1, M_2, and Q moments are resolved into components in the x-, y-, and z-directions, respectively, and use is made of the relations that when ϕ is small

$$\left.\begin{aligned}\sin(\beta+\phi)&=\sin\ \beta+\phi\ \cos\ \beta\\ \cos(\beta+\phi)&=\cos\ \beta-\phi\ \sin\ \beta\end{aligned}\right\} \tag{10}$$

the following relations are obtained:

$$\left.\begin{aligned}M_x=&Q+M_1(\cos\ \beta-\phi\ \sin\ \beta)v'+\\ &M_1(\sin\ \beta+\phi\ \cos\ \beta)w'+M_2(\sin\ \beta+\\ &\phi\ \cos\ \beta)v'-M_2(\cos\ \beta-\phi\ \sin\ \beta)w'\\ M_y=&M_1(\cos\ \beta-\phi\ \sin\ \beta)+M_2(\sin\ \beta+\phi\ \cos\ \beta)-Qv'\\ M_z=&-M_1(\sin\ \beta+\phi\ \cos\ \beta)+M_2(\cos\ \beta-\phi\ \sin\ \beta)+Qw'\end{aligned}\right\} \tag{11}$$

Now when equations (6), (7), and (8) are substituted into equations (11), and all the second-order terms are dropped, the following desired equations for M_x, M_y, and M_z in terms of the displacements are found:



$$M_x=[GJ+Tk_A^2+EB_1(\beta')^2]\phi'+Tk_A^2\beta'-EB_2\beta'(v''\cos\ \beta+w''\sin\ \beta)-Te_Av'\sin\ \beta+Te_Aw'\cos\ \beta \tag{12}$$

$$M_y=(EI_1\cos^2\beta+EI_2\sin^2\beta)w''+(EI_2-EI_1)\sin\ \beta\cos\ \beta v''-(Te_A+EB_2\beta'\phi')\sin\ \beta-Te_A\phi\cos\ \beta \tag{13}$$

$$M_z=(EI_2-EI_1)\sin\ \beta\cos\ \beta\ w''+(EI_1\sin^2\beta+EI_2\cos^2\beta)v''-(Te_A+EB_2\beta'\phi')\cos\ \beta+Te_A\phi\sin\ \beta \tag{14}$$

EQUILIBRIUM CONDITIONS

The equilibrium of the forces and moments that act on a differential beam element is now considered. In this consideration the element is formed by slices parallel to the yz-plane, because this choice leads to rather simple results. The forces that act on such an element are shown in figure 6(a); the moments, in figure 6(b). The quantities $\bar{p}_x$, $\bar{p}_y$, $\bar{p}_z$, $\bar{q}_x$, $\bar{q}_y$, and $\bar{q}_z$ are resultant force and moment loadings, which involve both the acceleration body forces and the applied aerodynamic loading. The acceleration body forces,

(a) Forces. (b) Moments.

FIGURE 6.—Equilibrium of forces and moments.

due to both centrifugal and transverse accelerations, are derived in appendix B.

Summation of the forces in the x-, y-, and z-directions and summation of the moments about the x-, y-, and z-axes lead to the following equilibrium conditions for shear and moment:

$$\left.\begin{aligned}T'+\bar{p}_x&=0\\ V_y'+\bar{p}_y&=0\\ V_z'+\bar{p}_z&=0\end{aligned}\right\} \tag{15}$$

$$M_x'-V_yw'+V_zv'+\bar{q}_x=0 \tag{16a}$$

$$M_y'-Tw'+V_z+\bar{q}_y=0 \tag{16b}$$

$$M_z'-Tv'+V_y+\bar{q}_z=0 \tag{16c}$$

By substitution the shears in these equations may be eliminated to give the following basic equilibrium conditions:

$$\left.\begin{aligned}&M_x'-M_y'v'+M_z'w'-\bar{q}_yv'+\bar{q}_zw'+\bar{q}_x=0\\ &M_y''-(Tw')'+\bar{q}_y'-\bar{p}_z=0\\ &M_z''-(Tv')'+\bar{q}_z'-\bar{p}_y=0\end{aligned}\right\} \tag{17}$$

Substitution of equations (12), (13), and (14) into equations (17) gives

$$-\{[GJ+Tk_A^2+EB_1(\beta')^2]\phi'+Tk_A^2\beta'-EB_2\beta'(v''\cos\ \beta+w''\sin\ \beta)\}'+Te_Av''\sin\ \beta-Te_Aw''\cos\ \beta+\bar{q}_yv'-\bar{q}_zw'-\bar{q}_x=0 \tag{18}$$

$$[(EI_1\cos^2\beta+EI_2\sin^2\beta)w''+(EI_2-EI_1)\sin\ \beta\cos\ \beta\ v''-(Te_A+EB_2\beta'\phi')\sin\ \beta-Te_A\phi\cos\ \beta]''-(Tw')'+\bar{q}_y'-\bar{p}_z=0 \tag{19}$$

$$[(EI_2-EI_1)\sin\ \beta\cos\ \beta\ w''+(EI_1\sin^2\beta+EI_2\cos^2\beta)v''-(Te_A+EB_2\beta'\phi')\cos\ \beta+Te_A\phi\sin\ \beta]''-(Tv')'+\bar{q}_z'-\bar{p}_y=0 \tag{20}$$

where second-order terms have been dropped. Only the loadings now remain to be considered.

RESULTANT LOADINGS

As mentioned previously, the resultant or total loadings are composed of both the inertia loading due to centrifugal and vibratory accelerations and the applied aerodynamic loading. The inertia loadings, which consist of the forces and moments which oppose accelerations of the blade elements, are derived in appendix B whereas the aerodynamic loadings L_y, L_z, and M are left in this symbolic form, since they are in the nature of externally applied loadings.

The procedure that follows is employed in the derivation of the total loadings which is given in appendix B. The acceleration of any mass particle on the vibrating, rotating blade is derived and the components in the x-, y-, and z-directions are obtained. These component accelerations include terms for the Coriolis force and transverse and centrifugal accelerations along with higher order terms. The inertia force and moment loadings are then obtained by integrating over the cross section; these are simplified by

dropping second-order terms and are then added with the aerodynamic or applied loadings to yield the following desired resultant loadings $\bar{p}_x$, $\bar{p}_y$, $\bar{p}_z$, $\bar{q}_x$, $\bar{q}_y$, and $\bar{q}_z$:

$$\left.\begin{aligned}
&\bar{p}_x = -T' = \Omega^2 m x \\
&\bar{p}_y = L_y - m[\ddot{v} - \Omega^2(v+e_o)] + me[\ddot{\phi}\sin\beta + \Omega^2(\cos\beta - \phi\sin\beta)] \\
&\bar{p}_z = L_z - m(\ddot{w} + e\ddot{\phi}\cos\beta) \\
&\bar{q}_x = M - \Omega^2 me[(v+e_o)\sin\beta + e_o\phi\cos\beta] + me(\ddot{v}\sin\beta - \ddot{w}\cos\beta) - \Omega^2 m(k_{m2}^2 - k_{m1}^2)(\sin\beta\cos\beta + \phi\cos 2\beta) - mk_A^2\ddot{\phi} \\
&\bar{q}_y = -\Omega^2 mex(\sin\beta + \phi\cos\beta) \\
&\bar{q}_z = -\Omega^2 mex(\cos\beta - \phi\sin\beta)
\end{aligned}\right\} \quad (21)$$

FINAL DIFFERENTIAL EQUATIONS

The substitution of equations (21) into equations (18), (19), and (20) gives now the desired final differential equations of equilibrium

$$-\{[GJ + Tk_A^2 + EB_1(\beta')^2]\phi' - EB_2\beta'(v''\cos\beta + w''\sin\beta)\}' + \underline{Te_A(v''\sin\beta - w''\cos\beta)} + \underline{\Omega^2 mxe(-v'\sin\beta + w'\cos\beta)} + \underline{\Omega^2 me\sin\beta}v + \Omega^2 m[(k_{m2}^2 - k_{m1}^2)\cos 2\beta + \underline{ee_o\cos\beta}]\phi + mk_m^2\ddot{\phi} - me(\ddot{v}\sin\beta - \ddot{w}\cos\beta) = M + (Tk_A^2\beta')' - \Omega^2 m[(k_{m2}^2 - k_{m1}^2)\sin\beta\cos\beta + \underline{ee_o\sin\beta}] \quad (22)$$

$$[(EI_1\cos^2\beta + EI_2\sin^2\beta)w'' + (EI_2 - EI_1)\sin\beta\cos\beta v'' - \underline{Te_A\phi\cos\beta - EB_2\beta'\phi'\sin\beta}]'' - (Tw')' - \underline{(\Omega^2 mxe\phi\cos\beta)'} + m(\ddot{w} + e\ddot{\phi}\cos\beta) = L_z + \underline{(Te_A\sin\beta)''} + \underline{(\Omega^2 mxe\sin\beta)'} \quad (23)$$

$$[(EI_2 - EI_1)\sin\beta\cos\beta w'' + (EI_1\sin^2\beta + EI_2\cos^2\beta)v'' + \underline{Te_A\phi\sin\beta - EB_2\beta'\phi'\cos\beta}]'' - (Tv')' + \underline{(\Omega^2 mxe\phi\sin\beta)'} + \underline{\Omega^2 me\phi\sin\beta} + m(\ddot{v} - e\ddot{\phi}\sin\beta) - \Omega^2 mv = L_y + \underline{(Te_A\cos\beta)''} + \underline{(\Omega^2 mxe\cos\beta)'} + \underline{\Omega^2 m(e_o + e\cos\beta)} \quad (24)$$

In these equations, the terms that are not included in previous theories have been underlined. (It should be noted that ref. 18 suggests the existence of the centrifugal coupling terms $\Omega^2 mxew'$ and $(\Omega^2 mxe\phi)'$ for the case of a blade with $\beta=0$.) Many of these new terms are coupling-type terms which are associated with the centrifugal forces. A number of the new terms take the forms of lateral and twisting loadings which tend to deflect the blade even in the absence of externally applied loads; because of this fact they have been written on the right-hand sides along with the applied loads L_y, L_z, and M.

Importance of coupling forms.—It is beyond the scope of this paper to make a complete evaluation of the magnitude of each of the coupling terms and their influence on such phenomena as, say, blade vibration. A rough idea of their importance can be gathered by analyzing each term in detail and comparing them to other terms of known importance. As an example, consider $(Te_A\phi\cos\beta)''$ in equation (23). If, for simplicity in the consideration, e_A and m are considered independent of x, and if $\beta=0$, then this term would become on expansion

$$-\Omega^2 me_A\phi + 2T'(e_A\phi)' + T(e_A\phi)''$$

These terms may now be compared with other terms of known importance. Thus, if $e_A\phi$ is interpreted as a deflection, then the last two terms of this expansion are seen to be exactly comparable to the expansion of the well-known and important term $(Tw')' = T'w' + Tw''$. Also the first term $-\Omega^2 me_A\phi$ is directly comparable with the coupling term of established importance in the consideration of coupled bending-torsion of vibrating beams, namely, $\omega^2 me\phi$. A similar consideration may be given each of the other new terms in the final equations. The examples to be presented later will also give an indication of the importance of some of the terms.

Boundary conditions.—Since the problem is, of course, a boundary-value problem, some mention of the associated boundary conditions should be made. The most general case involves ten boundary conditions—two conditions associated with equation (22), and four each for equations (23) and (24). These conditions all evolve from the type of constraint that is imposed on the ends of the beam on the displacements v, w, and ϕ, the moments M_y and M_z (eqs. (13) and (14)), the torque Q (eq. (8)), and the shears V_y and V_z which are defined by equations (16b) and (16c). For a completely fixed end, the boundary conditions would be

$$v = w = \phi = v' = w' = 0$$

For a free end, the conditions would be

$$Q = M_y = M_z = V_y = V_z = 0$$

In this case, the alternate choice of $M_1 = M_2 = 0$ (see eqs. (6) and (7)) may be used instead of $M_y = M_z = 0$.

For the present system, an end cannot be referred to simply as pin-ended; care must be taken to specify the number and directions of pins present. For example, an end may have a pin which runs parallel to the y-axis but may be fixed as regards displacements v and ϕ. In this example, the moment M_y has been relaxed and the boundary conditions become

$$v = w = v' = \phi = M_y = 0$$

Other pin-ended conditions follow in a similar fashion.

Elastically restrained ends may be handled in a manner similar to that used in the usual treatment of beams, except that the direction of the restraint must be properly taken into account.

Subcases of the general theory.—In actual applications, several special subcases of the present theory are frequently

encountered. Three of these subcases are described as follows:

Case I: The built-in twist is zero, $\beta=0$.

Case II: Bending in two directions without torsion, $\phi=0$.

Case III: Torsion only, $v=w=0$.

The equations of motion which result when the theory is reduced to these special cases are as follows:

For case I, $\beta=0$,

$$-[(GJ+Tk_A^2)\phi']'-\underline{Te_Aw''}+\Omega^2mxew'+\Omega^2m(k_{m2}^2-k_{m1}^2+\underline{ee_o})\phi+mk_m^2\ddot{\phi}+me\ddot{w}=M \quad (25)$$

$$(EI_1w''-Te_A\phi)''-(Tw')'-(\Omega^2mxe\phi)'+m(\ddot{w}+e\ddot{\phi})=L_z \quad (26)$$

$$(EI_2v'')''-(Tv')'-\Omega^2mv+m\ddot{v}=L_y-\underline{(Te_A)''}+(\Omega^2mxe)'+\Omega^2\underline{m(e_o}+e) \quad (27)$$

For case II, $\phi=0$,

$$[(EI_1\cos^2\beta+EI_2\sin^2\beta)w''+(EI_2-EI_1)\sin\beta\cos\beta\,v'']''-(Tw')'+m\ddot{w}=L_z+(Te_A\sin\beta)''+(\Omega^2mxe\sin\beta)' \quad (28)$$

$$[(EI_2-EI_1)\sin\beta\cos\beta\,w''+(EI_1\sin^2\beta+EI_2\cos^2\beta)v'']''-(Tv')'-\Omega^2mv+m\ddot{v}=L_y+(Te_A\cos\beta)''+(\Omega^2mxe\cos\beta)'+\Omega^2m(e_o+e\cos\beta) \quad (29)$$

For case III, $v=w=0$,

$$-\{[GJ+Tk_A^2+EB_1(\beta')^2]\phi'\}'+\Omega^2m[(k_{m2}^2-k_{m1}^2)\cos2\beta+ee_o\cos\beta]\phi+mk_m^2\ddot{\phi}=M+(Tk_A^2\beta')'-\Omega^2m[(k_{m2}^2-k_{m1}^2)\sin\beta\cos\beta+ee_o\sin\beta] \quad (30)$$

ASSOCIATED ENERGY EQUATION

As a check on the derivation presented herein, the differential equations of equilibrium were derived by a completely different approach that involves energy principles. In this energy approach the strain energy of deformation, in which the longitudinal strains were arrived at in a different manner than that presented herein, and the work performed by all the forces present were considered. The equation for total potential energy of the system is, of course, closely allied to the differential equations and is of intrinsic value in the treatment of the problem of the present paper from an energy standpoint. For completeness, the equation is presented here without derivation. If U denotes the total strain energy and V represents the work performed by the centrifugal body forces and the applied loading, then

$$U-V=\frac{1}{2}\int_0^R\{EI_1(v''\sin\beta-w''\cos\beta)^2+EI_2(v''\cos\beta+w''\sin\beta)^2+[GJ+EB_1(\beta')^2](\phi')^2-2EB_2(v''\cos\beta+w''\sin\beta)\beta'\phi'\}dx-\int_0^R\Bigg(T\Big\{-\frac{1}{2}[(v')^2+(w')^2]+e_A(v''\cos\beta+w''\sin\beta)-e_A\phi(v''\sin\beta-w''\cos\beta)-k_A^2\Big[\frac{1}{2}(\phi')^2+\beta'\phi'\Big]\Big\}+\Omega^2m\Big\{xe[-(v'\cos\beta+w'\sin\beta)+\phi(v'\sin\beta-w'\cos\beta)]+\frac{1}{2}v^2+(e\cos\beta+e_o-e\phi\sin\beta)v+[-(k_{m2}^2-k_{m1}^2)\sin\beta\cos\beta-ee_o\sin\beta]\phi-\frac{1}{2}[(k_{m2}^2-k_{m1}^2)\cos2\beta+ee_o\cos\beta]\phi^2\Big\}+p_yv+p_zw+q\phi\Bigg)dx \quad (31)$$

where p_y, p_z, and q are the applied loadings considered in a static sense. Application of the minimum variational principles to this expression yields differential equations which are the same as those given by equations (22), (23), and (24) when ϕ, v, and w are not time dependent. The variation also gives the boundary conditions on moments, shears, and torques that are for stipulated geometrical conditions at the ends of the beam and are given in the section entitled "Boundary Conditions". The differential equations applicable when time dependent motion is considered may now be obtained by writing the loadings p_y, p_z, and q as the sum of the applied loadings and vibratory inertia loads (as obtained by D'Alembert's principle); specifically,

$$\left.\begin{aligned}p_y&=L_y-m(\ddot{v}-e\ddot{\phi}\sin\beta)\\p_z&=L_z-m(\ddot{w}+e\ddot{\phi}\cos\beta)\\q&=M+me(\ddot{v}\sin\beta-\ddot{w}\cos\beta)-mk_m^2\ddot{\phi}\end{aligned}\right\} \quad (32)$$

The substitution of these loadings into the differential equations obtained by the variational process then gives equations identical to equations (22), (23), and (24).

METHOD OF SOLUTION AND EXAMPLES

The general differential equations of this paper cannot be solved exactly, and it is therefore necessary to resort to some approximate means. Two means, which differ in manipulations but which yield equivalent results, will be considered here—one is a modified Galerkin type procedure, the other a Rayleigh-Ritz procedure.

In the modified Galerkin procedure, the displacements are assumed to be expressed in finite series of known functions as follows:

$$\left.\begin{aligned}\phi&=a_1\phi_1+a_2\phi_2+\ \ldots\ a_p\phi_p\\w&=b_1w_1+b_2w_2+\ \ldots\ b_qw_q\\v&=c_1v_1+c_2v_2+\ \ldots\ c_rv_r\end{aligned}\right\} \quad (33)$$

where a_n, b_n, and c_n are unknown coefficients, which may be time dependent, and ϕ_n, w_n, and v_n are chosen modal functions which satisfy the geometrical boundary conditions of the problem. A set of linear simultaneous equations which allow the evaluation of the unknown coefficients is now

formed through application of the following equations:

$$\int_0^R \phi_n D_1(\phi,w,v)\,dx+Q\phi_n\Big]_0^R=0 \qquad (n=1,2,3,\ldots p) \tag{34a}$$

$$\int_0^R w_n D_2(\phi,w,v)\,dx+M_y w_n'\Big]_0^R+V_z w_n\Big]_0^R=0 \qquad (n=1,2,3,\ldots q) \tag{34b}$$

$$\int_0^R v_n D_3(\phi,w,v)\,dx+M_z v_n'\Big]_0^R+V_y v_n\Big]_0^R=0 \qquad (n=1,2,3,\ldots r) \tag{34c}$$

where $D_1(\phi,w,v)$, $D_2(\phi,w,v)$, and $D_3(\phi,w,v)$ denote, respectively, equations (22), (23), and (24) with all the right-hand terms transferred to the left-hand side; Q, M_y, and M_z are given by equations (8), (13), and (14); and V_z and V_y are found from equations (16b) and (16c). For static or other externally imposed loading conditions, the set of equations formed by equations (34) will be nonhomogeneous; the solution for the unknown coefficients and, hence, the displacements then proceeds by ordinary means. For a characteristic-value problem, such as free vibrations, the set of equations will be homogeneous, and the vanishing determinant will yield the characteristic frequencies.

This procedure is called a modified Galerkin procedure because of the presence of the boundary terms in equations (34). In general, it would be very difficult to choose modal functions in equations (33) so that both the geometric and "force" (shear, moment, torque) boundary conditions are satisfied, which is necessary in the usual Galerkin approach. Therefore, the force boundary terms are added in equations (34), and, thus, the stipulations on the chosen modal functions are relaxed so that only the geometric conditions need be satisfied. It should be mentioned that in actual applications these force boundary conditions do not have to be evaluated, since they can always be cancelled by integrating certain of the terms of the integrals by parts. A justification of this procedure can be obtained from the Rayleigh-Ritz procedure.

In this Rayleigh-Ritz approach the displacements are expanded in series as before (see eqs. (33)), with the same requirement on the geometric boundary conditions. These expansions are substituted into the energy equation (31), and a minimization is then made with respect to the unknown coefficients; that is,

$$\left.\begin{aligned} \frac{\partial(U-V)}{\partial a_n}&=0 \qquad (n=1,2,\ldots p)\\ \frac{\partial(U-V)}{\partial b_n}&=0 \qquad (n=1,2,\ldots q)\\ \frac{\partial(U-V)}{\partial c_n}&=0 \qquad (n=1,2,\ldots r) \end{aligned}\right\} \tag{35}$$

The resulting equations will be identical with those of equations (34). As a matter of fact, equations (35) may be used to prove the validity of equations (34) (through appropriate integration by parts) and thus to show that the two procedures outlined here are really equivalent. Because of the confusion that often arises about boundary conditions when the Galerkin process is applied, the safest procedure is to use the Rayleigh-Ritz approach.

Two examples are now given to show the application of the two procedures discussed and to show further the importance of some of the coupling terms.

EXAMPLE 1

In example 1, it is desired to determine the natural frequencies of a rotating cantilever blade having zero initial twist or blade angle of attack ($\beta=0$) and with $v=0$. The Rayleigh-Ritz procedure will be used. Assume that the displacements ϕ and w are given as follows:

$$\left.\begin{aligned} \phi&=a_1\phi_1+a_2\phi_2+a_3\phi_3\\ w&=b_1w_1+b_2w_2+b_3w_3 \end{aligned}\right\} \tag{36}$$

where ϕ_n and w_n are the natural uncoupled modes of the nonrotating beam in torsion and bending, respectively, and are expressed in terms of a unit tip displacement. Equations (36) are substituted into equation (31) with $v=\beta=0$, and a minimization is made with respect to a_n and b_n, and then use is made of equations (32), with the applied loadings $L_y=L_z=M=0$. The resulting equations are then reduced as follows. First, the relations which apply to uncoupled vibrations are used, namely

$$\left.\begin{aligned} \int_0^R mw_m w_n\,dx&=0 && (m\neq n)\\ &=M_n && (m=n)\\ \int_0^R EI_1 w_m''w_n''\,dx&=0 && (m\neq n)\\ &=\omega_n^2\int_0^R mw_n^2\,dx && (m=n)\\ &=\omega_n^2M_n\\ \int_0^R mk_A^2\phi_m\phi_n\,dx&=0 && (m\neq n)\\ &=N_n && (m=n)\\ \int_0^R GJ\phi_m'\phi_n'\,dx&=0 && (m\neq n)\\ &=\mu_n^2\int_0^R mk_m^2\phi_n^2 && (m=n)\\ &=\mu_n^2N_n \end{aligned}\right\} \tag{37}$$

where ω_n and μ_n are the natural circular frequencies of the uncoupled bending and torsion modes, respectively. Second, the constant terms are dropped, since they apply to static deformation of the blade. And third, motion representative of simple harmonic motion is considered by setting

$$a_n=\bar{a}_n \sin \omega t$$

$$b_n=\bar{b}_n \sin \omega t$$

The final equations will be homogeneous, and the vanishing of the determinant of the $\bar{a}_n$ and $\bar{b}_n$ coefficients will define the natural coupled rotating frequencies. This determinant is

$$\begin{bmatrix}
(\omega_1^2-\omega^2)M_1+A_{11} & A_{12} & A_{13} & -B_{11}-\omega^2C_{11}+\Omega^2D_{11} & -B_{21}-\omega^2C_{21}+\Omega^2D_{21} & -B_{31}-\omega^2C_{31}+\Omega^2D_{31} \\
A_{12} & (\omega_2^2-\omega^2)M_2+A_{22} & A_{23} & -B_{12}-\omega^2C_{12}+\Omega^2D_{12} & -B_{22}-\omega^2C_{22}+\Omega^2D_{22} & -B_{32}-\omega^2C_{32}+\Omega^2D_{32} \\
A_{13} & A_{23} & (\omega_3^2-\omega^2)M_3+A_{33} & -B_{13}-\omega^2C_{13}+\Omega^2D_{13} & -B_{23}-\omega^2C_{23}+\Omega^2D_{23} & -B_{33}-\omega^2C_{33}+\Omega^2D_{33} \\
-B_{11}-\omega^2C_{11}+\Omega^2D_{11} & -B_{12}-\omega^2C_{12}+\Omega^2D_{12} & -B_{13}-\omega^2C_{13}+\Omega^2D_{13} & (\mu_1^2-\omega^2)N_1+E_{11}+\Omega^2F_{11} & E_{12}+\Omega^2F_{12} & E_{13}+\Omega^2F_{13} \\
-B_{21}-\omega^2C_{21}+\Omega^2D_{21} & -B_{22}-\omega^2C_{22}+\Omega^2D_{22} & -B_{23}-\omega^2C_{23}+\Omega^2D_{23} & E_{12}+\Omega^2F_{12} & (\mu_2^2-\omega^2)N_2+E_{22}+\Omega^2F_{22} & E_{23}+\Omega^2F_{23} \\
-B_{31}-\omega^2C_{31}+\Omega^2D_{31} & -B_{32}-\omega^2C_{32}+\Omega^2D_{32} & -B_{33}-\omega^2C_{33}+\Omega^2D_{33} & E_{13}+\Omega^2F_{13} & E_{23}+\Omega^2F_{23} & (\mu_3^2-\omega^2)N_3+E_{33}+\Omega^2F_{33}
\end{bmatrix}=0$$

where the coefficients are

$$\left.\begin{aligned}
M_n &= \int_0^R m w_n^2 dx \\
N_n &= \int_0^R m k_m^2 \phi_n^2 dx \\
A_{mn} &= \int_0^R T w_m' w_n' dx \\
B_{mn} &= \int_0^R T e_A \phi_m w_n'' dx \\
C_{mn} &= \int_0^R m e \phi_m w_n dx \\
D_{mn} &= \int_0^R m x e \phi_m w_n' dx \\
E_{mn} &= \int_0^R T k_A^2 \phi_m \phi_n dx \\
F_{mn} &= \int_0^R m (k_{m2}^2 - k_{m1}^2 + e e_o) \phi_m \phi_n dx
\end{aligned}\right\} \qquad (38)$$

No numerical evaluation of this example is made, but the importance of some of the new coupling terms of the present theory is realized by comparing the associated coupling terms which appear in the determinant. For example, $\Omega^2 D_{11}$, which is new, may be compared with $\omega^2 C_{11}$, a conventional term of established importance. The frequencies Ω^2 and ω^2 may be of the same order of magnitude; the factors under the integral are the same except for w_1 and xw_1'. These may be shown to be of the same order of magnitude, however, and so both coupling terms are comparable in magnitude. This is another indication, therefore, that the new coupling terms are of significance in the treatment of rotating blades.

EXAMPLE 2

The case treated for example 2 is a uniform blade with an offset mass at the tip and with β, v, e_A, and e_o equal 0. (See top sketch in fig. 7.) This system may be regarded as having a behavior similar to an actual helicopter blade which is heavily loaded along the leading edges, as depicted in the lower sketch of figure 7. An approximation to the first two natural frequencies will be found by the modified Galerkin procedure. The differential

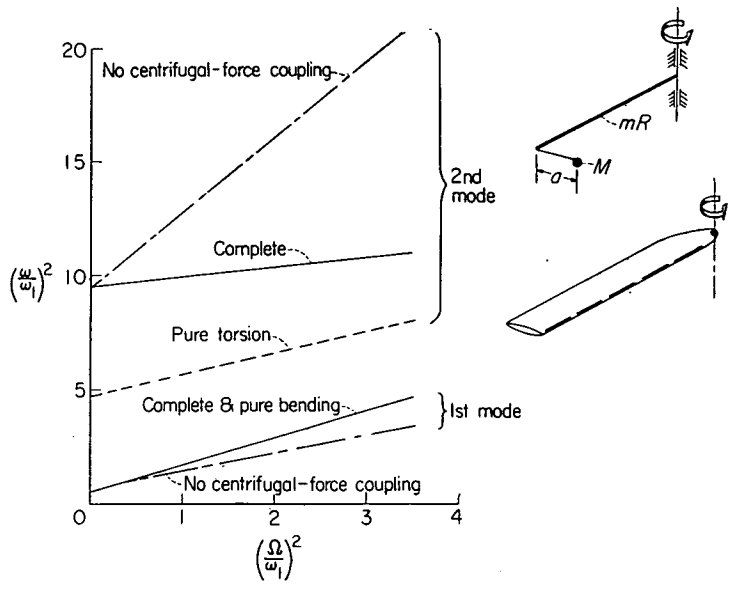


FIGURE 7.—Natural frequencies of example 2 showing the importance of centrifugal-force coupling.

equations for shear, moment, torque, and tension (eqs. (25), 26), (16), (13), and (8) with $\beta=v=e_A=e_o=0$) applicable here are

$$\left.\begin{aligned}-[(GJ+Tk_A^2)\phi']'+\Omega^2 mxew'+\Omega^2 m(k_{m2}^2-k_{m1}^2)\phi-\omega^2(mew+mk_m^2\phi)=0\\ (EI_1w'')''-(Tw')'-(\Omega^2 mxe\phi)'-\omega^2(mw+me\phi)=0\end{aligned}\right\} \quad (39)$$

$$\left.\begin{aligned}M_y&=EI_1w''\\ V_z&=-(EI_1w'')'+Tw'+\Omega^2 mex\phi\\ Q&=(GJ+Tk_A^2)\phi'\\ T&=\int_x^R \Omega^2 mx\,dx+\Omega^2 MR\end{aligned}\right\} \quad (40)$$

In these equations the mass per unit length m should be interpreted to apply to both the distributed mass of the beam and to the concentrated offset mass. This concentrated mass can be handled, for example, by imagining the mass to be distributed over an infinitesimal length, say λ, with intensity M/λ, then to perform the integrations of the Galerkin process as though all quantities involved in the integrations are uniform in this interval, and finally to squeeze the interval down to zero length. An equivalent procedure is to take the concentrated mass into account through means of the Dirac delta function.

With this in mind, equations (39) and (40) are substituted into equations (34a) and (34b); the terms $\phi_n(GJ+Tk_A^2)\phi'$ and $w_n[-(Tw')'-(\Omega^2 mxe\phi)']$ are integrated once by parts, the term $w_n(EI_1w'')''$ is integrated twice by parts, the boundary terms cancel, and the results are the following two equations:

$$\int_0^R (GJ+Tk_A^2)\phi'\phi_n'dx+\int_0^R [\underline{\Omega^2 mxew'}+\Omega^2 m(k_{m2}^2-k_{m1}^2)\phi-\omega^2(mew+mk_m^2\phi)]\phi_n dx=0 \quad (41)$$

$$\int_0^R EI_1w''w_n''dx+\int_0^R (Tw'+\underline{\Omega^2 mxe\phi})w_n'dx-\omega^2\int_0^R (mw+me\phi)w_n dx=0 \quad (42)$$

Approximations to the displacements are now chosen as

$$\left.\begin{aligned}\phi&=\bar{a}_1\phi_1\\ w&=\bar{b}_1w_1\end{aligned}\right\} \quad (43)$$

where ϕ_1 and w_1 are the fundamental uncoupled vibration modes of the beam without the tip mass, in torsion and bending, respectively, and each is given in terms of a unit tip displacement; these functions satisfy the equations

$$\left.\begin{aligned}\int_0^R GJ(\phi_1')^2dx&=\mu_1^2\int_0^R mk_m^2\phi_1^2dx\\ &=\mu_1^2 mk_m^2\frac{R}{2}\qquad\left(\mu_1=\frac{\pi}{2}\sqrt{\frac{GJ}{mk_m^2R^2}}\right)\\ \int_0^R EI_1(w_1'')^2dx&=\omega_1^2\int_0^R mw_1^2dx\\ &=\omega_1^2\frac{mR}{4}\qquad\left(\omega_1=3.46\sqrt{\frac{EI_1}{mR^4}}\right)\end{aligned}\right\} \quad (44)$$

where m refers only to the mass per unit length of the beam. Equations (43) are now substituted into equations (41) and (42), use is made of equations (44) and the equation for tension (applicable here) $T=\frac{1}{2}\Omega^2 m(R^2-x^2)+\Omega^2 MR$, and the integrations are performed with due cognizance being given the offset tip mass; the values found for the integrals are as follows:

$$\left.\begin{aligned}&\int_0^R GJ\phi_1^2dx=\mu_1^2 mk_m^2\frac{R}{2}\\ &\int_0^R \Omega^2 mxew_1'\phi_1dx=1.38\Omega^2 Ma\\ &\int_0^R \Omega^2 m(k_{m2}^2-k_{m1}^2)\phi_1^2dx=\Omega^2 Ma^2\\ &\int_0^R mew_1\phi_1dx=Ma\\ &\int_0^R mk_m^2\phi_1^2dx=mk_m^2\frac{R}{2}+Ma^2\\ &\int_0^R EI_1(w_1'')^2dx=\omega_1^2\frac{mR}{4}\\ &\int_0^R T(w_1')^2dx\approx\Omega^2\frac{4}{15}\left(mR+\frac{4}{3}M\right)\\ &\int_0^R mw_1^2dx=\frac{mR}{4}+M\end{aligned}\right\} \quad (45)$$

(The contribution of Tk_A^2 is found negligible in the first integral.) The final equations are given now in nondimensional form

$$\left[\frac{\mu_1^2}{\omega_1^2}\frac{mRk_m^2}{2Ma^2}+\frac{\Omega^2}{\omega_1^2}-\frac{\omega^2}{\omega_1^2}\left(\frac{mRk_m^2}{2Ma^2}+1\right)\right]\bar{a}_1+\left(\underline{1.38\frac{\Omega^2}{\omega_1^2}}-\frac{\omega^2}{\omega_1^2}\right)\frac{\bar{b}_1}{a}=0$$

$$\left(\underline{1.38\frac{\Omega^2}{\omega_1^2}}-\frac{\omega^2}{\omega_1^2}\right)\bar{a}_1+\left[\frac{mR}{4M}+\frac{\Omega^2}{\omega_1^2}\left(\frac{4}{3}+\frac{4mR}{15M}\right)-\frac{\omega^2}{\omega_1^2}\left(1+\frac{mR}{4M}\right)\right]\frac{\bar{b}_1}{a}=0$$

The vanishing of the determinant of these equations will yield the natural frequencies. Specific evaluation has been made for the following values:

$$M=\frac{mR}{4}$$

$$\frac{R}{a}=4$$

$$\frac{k_m}{a}=\sqrt{0.02}$$

$$\frac{\mu_1^2}{\omega_1^2}=0.152\frac{R^2}{k_m^2}$$

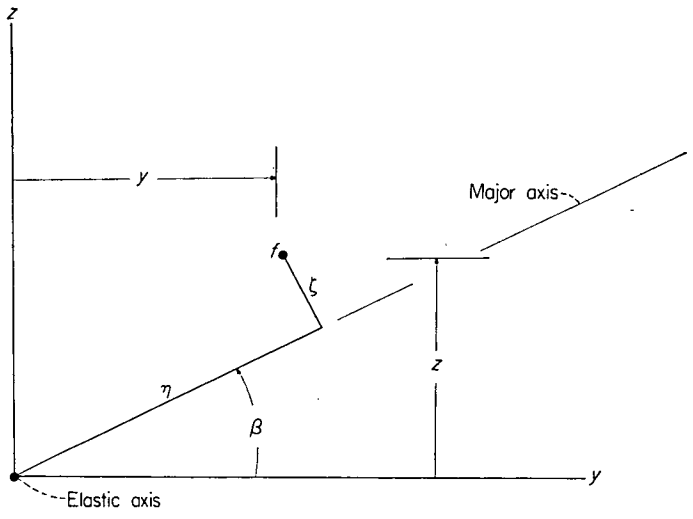
and the results are shown in figure 7. Results are shown for three conditions: (a) for vibration of the beam with offset mass in pure bending or pure torsion, (b) for vibration in the conventional coupled sense but with no centrifugal-force coupling (that is, the underlined terms of the equations of this example are omitted), and (c) for vibration with all coupling terms considered (the curves labeled complete in fig. 7). It may be seen that the inclusion of centrifugal-force coupling, which is new in this paper, has a very pronounced influence on the vibration characteristics. In fact, this centrifugal-force coupling seems to be of the same general strength as the conventional offset mass coupling normally considered.

CONCLUDING REMARKS

The differential equations of deformation of a twisted rotating blade under arbitrary loading have been derived. A special feature of the analysis is the consideration of the noncoincidence of the tension, mass, and elastic axes, whereby coupling is allowed to occur in a more general form than heretofore considered. This theory can therefore be used to solve problems in which these effects are significant and to evaluate the less complete theories which perhaps are more easily applied.

The aerodynamic loading considered was left in general form. It can be replaced, however, by whatever terms are appropriate for the case being treated. If these aerodynamic forces are taken as zero, then the loadings for free vibration result.

Because of its usefulness, the energy equation for blade deformation is also presented. Two methods of solution are discussed: one is a modified Galerkin process which makes use of the differential equations; the other is a Rayleigh-Ritz procedure which makes use of the energy expression. Two examples are presented which illustrate the application of both of these procedures.



A discussion of the importance of the new coupling terms that arise is made and their significance is further brought out by the examples. The indications are that the centrifugal-force coupling may be as important as the mass coupling that is normally considered in beam analysis and therefore should be included as a regular part in the treatment of rotating blades.

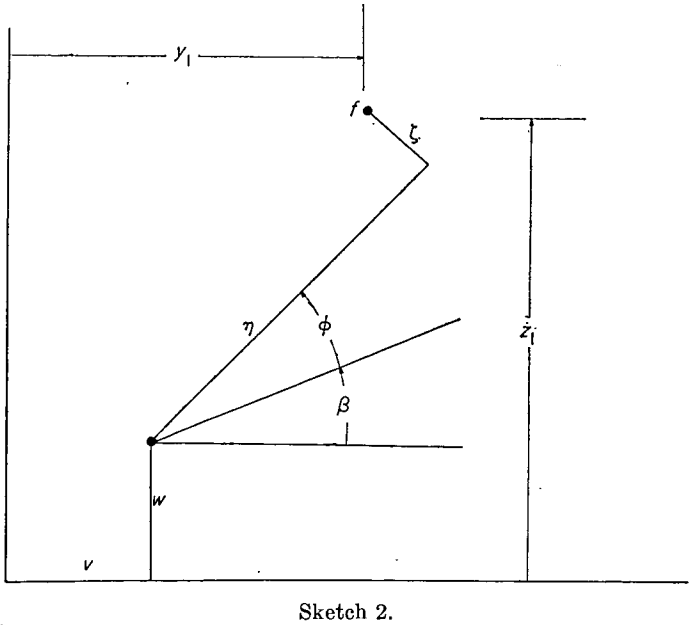
LANGLEY FIELD, VA., *October 5, 1956.*



APPENDIX A

DERIVATION OF LONGITUDINAL STRAINS

In this appendix the equation is derived for the longitudinal strain that is developed when a twisted beam undergoes both lateral and twisting deformations. Consider an imaginary plane to cut through the beam perpendicular to the elastic axis; the location of a fiber f of the cross section, both before and after the deformation, may then be given according to sketches 1 and 2. The x-axis is normal to the paper and is made coincident with the undeformed position of the elastic axis. In terms of the distance η along the major axis, the distance ζ perpendicular to this axis, and the built-in twist β, the initial y- and z-positions of the fiber

Sketch 1.

Sketch 2.

and the rate of change of these positions with respect to the x are

$$\left.\begin{aligned} y &= \eta \cos\beta - \zeta \sin\beta \\ z &= \eta \sin\beta + \zeta \cos\beta \end{aligned}\right\} \tag{A1}$$

$$\left.\begin{aligned} y' &= -\eta\beta' \sin\beta - \zeta\beta' \cos\beta = -\beta' z \\ z' &= \eta\beta' \cos\beta - \zeta\beta' \sin\beta = \beta' y \end{aligned}\right\} \tag{A2}$$

Now consider beam displacements to occur so that the point of intersection of the elastic axis and the cutting plane moves the distances u, v, and w in the directions of x, y, and z, respectively, and so that the cutting plane remains perpendicular to the elastic axis and rotates around it by an angle ϕ. Then if the usual small-angle assumptions that $\cos(\beta+\phi) = \cos\beta - \phi\sin\beta$ and $\sin(\beta+\phi) = \sin\beta + \phi\cos\beta$ are made, the new position of the fiber is defined by the following equations:

$$\left.\begin{aligned} x_1 &= x + u - v'(y_1 - v) - w'(z_1 - w) \\ &= x + \mu - v'y - w'z \\ y_1 &= v + \eta(\cos\beta - \phi\sin\beta) - \zeta(\sin\beta + \phi\cos\beta) = v + y - z\phi \\ z_1 &= w + \eta(\sin\beta + \phi\cos\beta) + \zeta(\cos\beta - \phi\sin\beta) = w + z + y\phi \end{aligned}\right\} \tag{A3}$$

and the derivatives of x_1, y_1, and z_1 with respect to x are given as follows:

$$\left.\begin{aligned} x_1' &= 1 + u' - v''y + v'\beta' z - w''z - w'\beta' y \\ &= 1 + u' - y(v'' + \beta' w') - z(w'' - \beta' v') \\ y_1' &= v' - \beta' z - \beta' y\phi - z\phi' = v' - y\beta'\phi - z(\beta' + \phi') \\ z_1' &= w' + \beta' y - \beta' z\phi + y\phi' = w' + y(\beta' + \phi') - z\beta'\phi \end{aligned}\right\} \tag{A4}$$

The longitudinal strain that is developed in a fiber may be found from these equations by considering the amount an elemental fiber of length ds changes in length as a result of deformation. In terms of the differential components of length in the x-, y-, and z-directions, the final length ds_1 of a fiber is given by the following equation:

$$ds_1^2 = dx_1^2 + dy_1^2 + dz_1^2 \tag{A5}$$

Thus

$$\left(\frac{ds_1}{dx}\right)^2 = (x_1')^2 + (y_1')^2 + (z_1')^2 \tag{A6}$$

which becomes with the use of equations (A4)

$$\left(\frac{ds_1}{dx}\right)^2=1+2\,[u'-y(v''+\beta'w')-z(w''-\beta'v')]+z^2\beta'^2-2z\beta'(v'-y\beta'\phi-z\phi')+y^2\beta'^2+2y\beta'(w'+y\phi'-z\beta'\phi) \quad (A7)$$

or

$$\frac{ds_1}{dx}=\{1+(y^2+z^2)(\beta')^2+2\,[u'-yv''-zw''+(y^2+z^2)\beta'\phi']\}^{1/2} \quad (A8)$$

Now the analogous equation for the original length ds may be determined directly from equation (A8) by letting $u=v=w=\phi=0$. Thus

$$\frac{ds}{dx}=[1+(y^2+z^2)(\beta')^2]^{1/2} \quad (A9)$$

The tensile strain in the fiber can now be written

$$\epsilon=\frac{ds_1-ds}{ds}$$

$$=\frac{ds_1}{ds}-1$$

$$=\left\{1+\left[\frac{2}{1+(y^2+z^2)(\beta')^2}\right][u'-yv''-zw''+(y^2+z^2)\beta'\phi']\right\}^{1/2}-1$$

$$=\left[\frac{1}{1+(y^2+z^2)\beta'^2}\right][u'-yv''-zw''+(y^2+z^2)\beta'\phi'] \quad (A10)$$

Now with $(y^2+z^2)(\beta')^2\ll 1$ (say less than 0.03 to 0.04, which is generally the case), then

$$\epsilon=u'-yv''-zw''+(y^2+z^2)\beta'\phi' \quad (A11)$$

Use is now made of equations (A1) in order to express the strain in terms of the cross-sectional coordinates η and ζ as follows:

$$\epsilon=u'-\eta(v''\cos\beta+w''\sin\beta)-\zeta(-v''\sin\beta+w''\cos\beta)+(\eta^2+\zeta^2)\beta'\phi' \quad (A12)$$

It is convenient now to eliminate the strain component u'; this is done by making use of the equilibrium condition that the integral of the longitudinal stress over the cross section must be equal to the total tension. Thus, with the assumption that the cross section is symmetrical about the major principle axis, the following equation applies:

$$T=E\int_{\eta_{le}}^{\eta_{te}}\int_{-t/2}^{t/2}\epsilon\,d\zeta\,d\eta$$

$$=E\int_{\eta_{le}}^{\eta_{te}}\int_{-t/2}^{t/2}[u'-\eta(v''\cos\beta+w''\sin\beta)-\zeta(-v''\sin\beta+w''\cos\beta)+(\eta^2+\zeta^2)\beta'\phi']d\zeta\,d\eta \quad (A13)$$

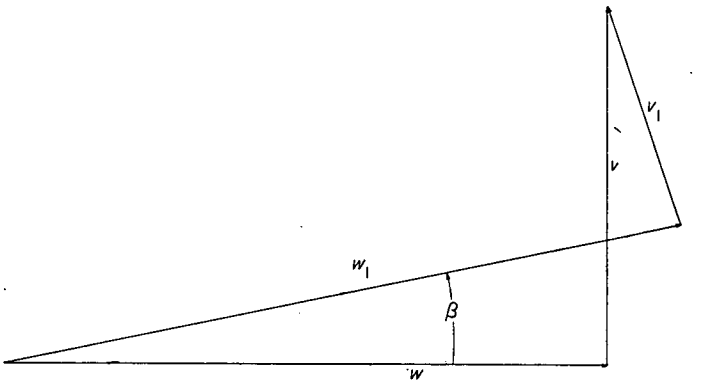
526597—60——14

or

$$T=E[Au'-Ae_A(v''\cos\beta+w''\sin\beta)+Ak_A^2\beta'\phi'] \quad (A14)$$

This equation yields

$$u'=\frac{T}{EA}+e_A(v''\cos\beta+w''\sin\beta)+k_A^2\beta'\phi' \quad (A15)$$



If T/EA is denoted by the tensile strain ϵ_T, then equation (A15) combined with equation (A12) yields

$$\epsilon=\epsilon_T+(e_A-\eta)(v''\cos\beta+w''\sin\beta)+\zeta(v''\sin\beta-w''\cos\beta)+(\eta^2+\zeta^2-k_A^2)\beta'\phi' \quad (A16)$$

which is the complete expression for the strain of any fiber in the cross section.

EXPRESSION FOR STRAIN IN TERMS OF DISPLACEMENTS IN AND NORMAL TO THE BLADE CHORD

Because of apparent anomalies that have arisen in the past, it is of interest to show the development of the strain in terms of displacements in and normal to the blade chord. These displacements have been used by some investigators and are shown in relation to the displacements of this paper in sketch 3.

Sketch 3.

These displacements are related according to the equations

$$\left.\begin{aligned}v&=v_1\cos\beta-w_1\sin\beta\\ w&=v_1\sin\beta+w_1\cos\beta\end{aligned}\right\} \quad (A17)$$

If two derivatives of these equations are taken, and due care is given the fact that β may vary with x, then the following combination of these derivatives may be found:

$$\left.\begin{aligned}v''\cos\beta+w''\sin\beta&=v_1''-2\beta'w_1'-\beta''w_1-(\beta')^2v_1\\ -v''\sin\beta+w''\cos\beta&=w_1''+2\beta'v_1'+\beta''v_1-(\beta')^2w_1\end{aligned}\right\} \quad (A18)$$

If these expressions are now substituted in equation (A16),

then the equation for strain becomes

$$\epsilon=\epsilon_T+(e_A-\eta)[v_1''-2\beta' w_1'-\beta'' w_1-(\beta')^2 v_1]-$$
$$\zeta[w_1''+2\beta' v_1'+\beta'' v_1-(\beta')^2 w_1]+(\eta^2+\zeta^2-k_A^2)\beta'\phi' \tag{A19}$$

The interesting fact to be noted here with respect to v_1 and w_1 is that the strain is not proportional only to the derivatives v_1'' and w_1'', as might first be supposed, but rather to additional terms which involve the rate of change of initial twist.

This observation has some significance. If the analysis of this paper had been carried through in terms of displacements v_1 and w_1, then the moments and all the results would be in terms of the group of terms appearing on the right-hand side of equations (A18), and the final result would be in agreement with the results presented in reference 11. This consideration indicates that the treatment in reference 1 may be subject to correction, since the assumption is made in this reference that the moments are proportional to v_1'' and w_1''. Evidently this assumption is not valid when the beam has a finite rate of change of initial twist.

STRAIN WHEN ϕ IS NOT SMALL

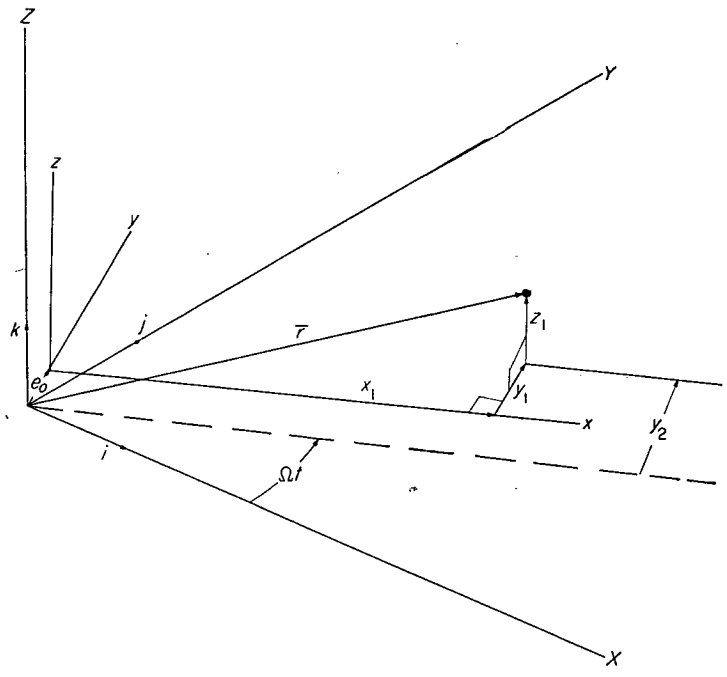
The preceding derivation was made on the assumption that the displacements u, v, w, and ϕ were small, and a linear equation for strain results. An interesting observation may be made, however, for the case of $v=w=0$, but with large displacements in ϕ, such that nonlinear effects are present. Thus, if the derivation is repeated with ϕ considered large, and with $v=w=0$, then equation (A11) would take the form

$$\epsilon=u'+(y^2+z^2)\left[\beta'\phi'+\frac{1}{2}(\phi')^2\right]$$
$$=u'+(\eta^2+\zeta^2)\left[\beta'\phi'+\frac{1}{2}(\phi')^2\right] \tag{A20}$$

The strain component u' is now handled as before, and the equation for strain becomes

$$\epsilon=\epsilon_T+(\eta^2+\zeta^2-k_A^2)\left[\beta'\phi'+\frac{1}{2}(\phi')^2\right] \tag{A21}$$

This equation may be used to demonstrate the fact pointed out in reference 19 that pretwisted blades may possess a torsional instability. Thus if use is made of equation (5), and the stress is based on equation (A21), then the following equation for internal elastic resisting torque results:



$$Q=GJ\phi'+Tk_A^2(\beta'+\phi')+EB_1\left[\beta'\phi'+\frac{1}{2}(\phi')^2\right](\beta'+\phi')$$
$$=GJ\phi'+Tk_A^2(\beta'+\phi')+\frac{EB_1}{2}[(\beta'+\phi')^3-(\beta')^2(\beta'+\phi')] \tag{A22}$$

Observations similar to those made in reference 19 may be made about equation (A22) with respect to the possibility of torsional instability; as a matter of fact, if the net tension over the cross section is zero, the equation becomes similar to equation (2) presented and discussed in reference 19.

APPENDIX B

DERIVATION OF ACCELERATIONS AND INERTIA LOADINGS

The purpose of this appendix is to derive the acceleration of a mass particle of the twisted rotating blade and to derive the inertia loadings from this acceleration. In order to do this it is convenient to introduce the fixed X, Y, Z coordinate axes system shown in sketch 4. This sketch

Sketch 4.

also shows the rotating x, y, z axes system (used in the body of the report and in appendix A) and the deformed positions x_1, y_1, and z_1 of the mass particle (see eqs. (A3)). The azimuth position of the rotating system relative to the fixed-axes system is denoted by Ωt.

In terms of the unit vectors i, j, and k, the vector $\bar{r}$ may be written

$$\bar{r}=(x_1\cos\Omega t-y_2\sin\Omega t)i+(x_1\sin\Omega t+y_2\cos\Omega t)j+z_1k \quad \text{(B1)}$$

Differentiating with respect to time gives the velocity vector of the mass particle

$$\dot{\bar{r}}=(\dot{x}_1\cos\Omega t-\Omega x_1\sin\Omega t-\dot{y}_2\sin\Omega t-\Omega y_2\cos\Omega t)i+$$
$$(\dot{x}_1\sin\Omega t+\Omega x_1\cos\Omega t+\dot{y}_2\cos\Omega t-\Omega y_2\sin\Omega t)j+\dot{z}_1k \quad \text{(B2)}$$

and differentiating once again gives the acceleration

$$\ddot{\bar{r}}=[(\ddot{x}_1-\Omega\dot{y}_2)\cos\Omega t-\Omega(\dot{x}_1-\Omega y_2)\sin\Omega t-(\ddot{y}_2+\Omega\dot{x}_1)\sin\Omega t-$$
$$\Omega(\dot{y}_2+\Omega x_1)\cos\Omega t]i+[(\ddot{x}_1-\Omega\dot{y}_2)\sin\Omega t+\Omega(\dot{x}_1-\Omega y_2)\cos\Omega t+$$
$$(\ddot{y}_2+\Omega\dot{x}_1)\cos\Omega t-\Omega(\dot{y}_2+\Omega x_1)\sin\Omega t]j+\ddot{z}_1k \quad \text{(B3)}$$

The components a_x, a_y, and a_z of the acceleration vector in the x–, y–, and z–directions may be found from this equation by letting $t=0$, thus

$$\ddot{\bar{r}}=(\ddot{x}_1-\Omega^2x_1-2\Omega\dot{y}_2)i+(\ddot{y}_2-\Omega^2y_2+2\Omega\dot{x}_1)j+\ddot{z}_1k$$
$$=a_xi+a_yj+a_zk \quad \text{(B4)}$$

Use is now made of equations (A3) and the fact that $y_2=y_1+e_o$. Thus,

$$x_1=x+u-v'y-w'z$$
$$y_2=v+y-z\phi+e_o$$
$$z_1=w+z+y\phi$$

The first two derivatives with respect to time are given as follows:

$$\left.\begin{aligned}\dot{x}_1&=\dot{u}-\dot{v}'y-\dot{w}'z\\ \dot{y}_2&=\dot{v}-z\dot{\phi}\\ \dot{z}_1&=\dot{w}+y\dot{\phi}\end{aligned}\right\} \quad \text{(B5)}$$

$$\left.\begin{aligned}\ddot{x}_1&=\ddot{u}-\ddot{v}'y-\ddot{w}'z\\ \ddot{y}_2&=\ddot{v}-z\ddot{\phi}\\ \ddot{z}_1&=\ddot{w}+y\ddot{\phi}\end{aligned}\right\} \quad \text{(B6)}$$

Substitution of these equations into equation (B4) yields the desired acceleration vector, with the following components in the x–, y–, and z–directions:

$$\left.\begin{aligned}a_x&=\ddot{u}-\ddot{v}'y-\ddot{w}'z-\Omega^2(x+u-v'y-w'z)-2\Omega(\dot{v}-z\dot{\phi})\\ a_y&=\ddot{v}-z\ddot{\phi}-\Omega^2(v+y-z\phi+e_o)+2\Omega(\dot{u}-\dot{v}'y-\dot{w}'z)\\ a_z&=\ddot{w}+y\ddot{\phi}\end{aligned}\right\} \quad \text{(B7)}$$

By substitution of the expressions (A1) for y and z, the accelerations of the particle are obtained as follows in terms of the coordinates of the cross-section ζ and η:

$$\left.\begin{aligned}a_x&=\ddot{u}-\Omega^2(x+u)-2\Omega v+\eta[-\ddot{v}'\cos\beta-\ddot{w}'\sin\beta+\\ &\quad\Omega^2(v'\cos\beta+w'\sin\beta)+2\Omega\dot{\phi}\sin\beta]+\zeta[\ddot{v}'\sin\beta-\\ &\quad\ddot{w}'\cos\beta+\Omega^2(-v'\sin\beta+w'\cos\beta)+2\Omega\dot{\phi}\cos\beta]\\ a_y&=\ddot{v}-\Omega^2(v+e_o)+2\Omega\dot{u}+\eta[-\ddot{\phi}\sin\beta-\Omega^2(\cos\beta-\\ &\quad\phi\sin\beta)+\\ &\quad2\Omega(-\dot{v}'\cos\beta-\dot{w}'\sin\beta)]+\zeta[-\ddot{\phi}\cos\beta-\\ &\quad\Omega^2(-\sin\beta-\phi\cos\beta)+2\Omega(\dot{v}'\sin\beta-\dot{w}'\cos\beta)]\\ a_z&=\ddot{w}+\eta\ddot{\phi}\cos\beta-\zeta\ddot{\phi}\sin\beta\end{aligned}\right\} \quad \text{(B8)}$$

The inertia loadings on the beam may now be derived from these acceleration equations by appropriate integrations over the cross section. The total or resultant loadings desired in the analysis given in the body of this paper are the sum of the inertia loadings and the applied loadings, and are given by the following equations, when the assumption is made that the cross section is symmetrical about the major principal axis:

$$\left.\begin{aligned}
\bar{p}_x &= -\int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2} a_x\rho\, d\zeta\, d\eta \\
\bar{p}_y &= L_y - \int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2} a_y\rho\, d\zeta\, d\eta \\
\bar{p}_z &= L_z - \int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2} a_z\rho\, d\zeta\, d\eta \\
\bar{q}_x &= M - \int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2} [-a_y(z_1-w)+a_z(y_1-v)]\rho\, d\zeta\, d\eta \\
\bar{q}_y &= -\int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2} [-a_x(z_1-w)]\rho\, d\zeta\, d\eta \\
\bar{q}_z &= -\int_{\eta_{te}}^{\eta_{le}}\int_{-t/2}^{t/2} [-a_x(y_1-v)]\rho\, d\zeta\, d\eta
\end{aligned}\right\} \quad \text{(B9)}$$

where ρ is the density of the structural material and may be a function of ζ and η. If the integrations are performed with the use of equations (B8), the following loadings are found:

$$\bar{p}_x = -m[\ddot{u}-\Omega^2(x+u)-2\Omega\dot{v}] - me[-\ddot{v}'\cos\beta - \ddot{w}'\sin\beta + \Omega^2(v'\cos\beta + w'\sin\beta) + 2\Omega\dot{\phi}\sin\beta] \quad \text{(B10)}$$

$$\bar{p}_y = L_y - m[\ddot{v}-\Omega^2(v+e_o)+2\Omega\dot{u}] - me[-\ddot{\phi}\sin\beta - \Omega^2(\cos\beta-\phi\sin\beta) + 2\Omega(-\dot{v}'\cos\beta - \dot{w}'\sin\beta)] \quad \text{(B11)}$$

$$\bar{p}_z = L_z - m(\ddot{w}) - me\ddot{\phi}\cos\beta \quad \text{(B12)}$$

$$\bar{q}_x = M - \Omega^2 me[(v+e_o)\sin\beta + e_o\phi\cos\beta] + me(\ddot{v}\sin\beta - \ddot{w}\cos\beta + 2\Omega\dot{u}\sin\beta) - \Omega^2 m[(k_{m2}^2-k_{m1}^2)\sin\beta\cos\beta + (k_{m2}^2-k_{m1}^2)\phi\cos 2\beta] - \ddot{\phi}mk_m^2 - 2\Omega m(k_{m2}^2-k_{m1}^2)\dot{v}'\cos\beta\sin\beta - 2\Omega m(k_{m2}^2\sin^2\beta + k_{m1}^2\cos^2\beta)\dot{w}' \quad \text{(B13)}$$

$$\bar{q}_y = -\Omega^2 me[(x+u)\sin\beta + x\phi\cos\beta] + me(\ddot{u}\sin\beta - 2\Omega\dot{v}\sin\beta) + \Omega^2 m[(k_{m2}^2-k_{m1}^2)v'\sin\beta\cos\beta + (k_{m2}^2\sin^2\beta + k_{m1}^2\cos^2\beta)w'] - m(k_{m2}^2-k_{m1}^2)\ddot{v}'\sin\beta\cos\beta + m(k_{m2}^2\sin^2\beta + k_{m1}^2\cos^2\beta)(2\Omega\dot{\phi}-\ddot{w}') \quad \text{(B14)}$$

$$\bar{q}_z = -\Omega^2 me[(x+u)\cos\beta - x\phi\sin\beta] + me(\ddot{u}\cos\beta - 2\Omega\dot{v}\cos\beta) + \Omega^2 m[(k_{m2}^2-k_{m1}^2)w'\sin\beta\cos\beta + (k_{m2}^2\cos^2\beta + k_{m1}^2\sin^2\beta)v'] - m(k_{m2}^2-k_{m1}^2)\ddot{w}'\sin\beta\cos\beta - m(k_{m2}^2\cos^2\beta + k_{m1}^2\sin^2\beta)\ddot{v}' + 2\Omega m(k_{m2}^2-k_{m1}^2)\dot{\phi}\sin\beta\cos\beta \quad \text{(B15)}$$

Equations (B10) to (B15) give the general expressions for the loadings and contain many terms of second order which for most engineering purposes can be neglected. In equation (B10), for example, all other terms are small in comparison to $m\Omega^2x$, which is the conventional expression for $\bar{p}_x$ (note that $\bar{p}_x=-T'$); for most practical purposes these small terms may therefore be neglected. For any specific application, however, particularly in the case of unusual configurations, the relative magnitude and importance of the terms should be determined. In the case of conventional helicopter or propeller blades, it is believed that the following first-order reductions of equations (B10) to (B15) are suitable for most engineering applications:

$$\left.\begin{aligned}
\bar{p}_x &= -T' = m\Omega^2 x \\
\bar{p}_y &= L_y - m[\ddot{v}-\Omega^2(v+e_o)] + me[\ddot{\phi}\sin\beta + \Omega^2(\cos\beta-\phi\sin\beta)] \\
\bar{p}_z &= L_z - m(\ddot{w}+e\ddot{\phi}\cos\beta) \\
\bar{q}_x &= M - \Omega^2 me[(v+e_o)\sin\beta + e_o\phi\cos\beta] + me(\ddot{v}\sin\beta - \ddot{w}\cos\beta) - \Omega^2 m(k_{m2}^2-k_{m1}^2)(\sin\beta\cos\beta+\phi\cos 2\beta) - mk_m^2\ddot{\phi} \\
\bar{q}_y &= -\Omega^2 mex(\sin\beta+\phi\cos\beta) \\
\bar{q}_z &= -\Omega^2 mex(\cos\beta-\phi\sin\beta)
\end{aligned}\right\} \quad \text{(B16)}$$

where

$$k_m^2 = k_{m2}^2 + k_{m1}^2$$

REPORT 1347

DITCHING INVESTIGATIONS OF DYNAMIC MODELS AND EFFECTS OF DESIGN PARAMETERS ON DITCHING CHARACTERISTICS [1]

By Lloyd J. Fisher and Edward L. Hoffman

SUMMARY

Data from ditching investigations conducted at the Langley Aeronautical Laboratory with dynamic scale models of various airplanes are presented in the form of tables. The effects of design parameters on the ditching characteristics of airplanes, based on scale-model investigations and on reports of full-scale ditchings, are discussed. Various ditching aids are also discussed as a means of improving ditching behavior.

INTRODUCTION

The designers of an airplane have control over many factors that will affect the chances of survival of the occupants of the airplane in a ditching. Since a considerable variation in ditching behavior is found in airplane designs that have similar performance in the air, it is evidently possible to choose values of design parameters that will give some measure of ditching safety without appreciable sacrifice of aerodynamic properties. Therefore, available ditching data are presented and evaluated herein in order to assist the designer and the operator in making preliminary ditching evaluations of airplanes by comparison with similar configurations or by the study of various design parameters. This information is based on data from scale-model investigations conducted at the Langley Aeronautical Laboratory and from actual full-scale ditchings. The data from ditching investigations with scale models are presented in the form of tables.

Scale-model investigations can give information regarding the motions of an airplane when ditched but data regarding the ability of personnel to withstand the motions, and subsequently to escape from the sinking airplane, must be obtained from other sources.

APPARATUS AND PROCEDURE

The investigations of the ditching characteristics of airplanes were conducted in Langley tank no. 2 with dynamic scale models. Damage which was likely to occur in a full-scale ditching was simulated in the models either by the removal of parts, by the installation of simulated crumpled sections, by the installation of scale-strength sections or aluminum-foil coverings which failed during the test, or by a combination of these methods. The models were launched either from the towing carriage or from the monorail so that they were free to glide onto the water at the desired landing attitude and speed. The control surfaces were set in such a manner that the model did not yaw or change attitude appreciably in flight. Landing attitude was measured between the longitudinal axis of the airplane and the smooth-water surface.

The behavior of the models was recorded from visual observations and from motion pictures of the tests. Average decelerations were derived from the landing speeds and lengths of run. Maximum longitudinal decelerations were measured with an accelerometer installed near the cockpit. Various accelerometers were used that had natural frequencies of about 20 to 70 cycles per second and all were damped to about 65 percent of the critical damping value. The reading accuracy of the least accurate instrument was about $\pm \frac{1}{2}g$.

RESULTS AND DISCUSSION

The results of the model-ditching investigations are shown in tables 1 to 37. The information in these tables is based on calm-water landing tests. In rough-water landings made parallel to waves or swells, the same general type of performance should be obtained. In landings made perpendicular to waves, however, more damage and more violent motions may occur, depending on the choice of ditching site and the size and portion of the wave contacted.

EFFECTS OF DESIGN PARAMETERS

Wing.—From a ditching standpoint, the vertical location of the wing with respect to the fuselage is a compromise between having the wing low enough to provide buoyancy to help keep the airplane afloat after ditching and having the wing high enough so that the landing flaps and engine installations (discussed further under "Flaps" and under "Engine installation") do not seriously impair ditching behavior. It is generally considered that the most favorable position of the wing is slightly above the bottom of the fuselage or in a low midwing position.

The thickness and size of the wings had little effect on ditching behavior other than the obvious effect on buoyancy. Sweptback and delta wings had little hydrodynamic influence on ditching but they did have aerodynamic influence

[1] Supersedes NACA Technical Note 3946 by Lloyd J. Fisher and Edward L. Hoffman, 1957.

Preceding Page Blank

on handling and landing characteristics. The flying wing appeared to have reasonably good ditching characteristics but it was very susceptible to damage although no violent motions occurred.

Flaps.—The landing flaps had a noticeable hydrodynamic effect on about 25 percent of the models investigated. For most of the models there was only a slight nose-down moment observed, and in no test was a flaps-up condition preferable. For certain models (as example, table 16), a flaps-down condition caused diving, but with the flaps retracted and with the corresponding increase in speed the damage and deceleration were even more severe than in the dives. It is therefore preferable to have flaps down in a ditching in order to obtain a low forward speed and thus to decrease fuselage damage; however, the flaps should be weak enough to fail before producing an undesirable diving moment. For airplanes having very low wings, the manner in which the flaps failed, that is, whether they were completely torn from the wing or whether the linkage failed and left the flaps free to rotate toward a neutral position, had an effect on the results. In table 28 it is noted that a flap which merely rotated toward a neutral position was occasionally detrimental.

Engine installation.—Reciprocating engines have caused differences in airplane ditching behavior because of the location of the nacelle. When placed low on an airplane, the engine nacelle acts as a "water brake" and increases decelerations; therefore, it is generally desirable to place the engine well above the level of the bottom of the fuselage.

Jet engines mounted on the wing (table 11) or turbopropeller engines mounted similarly will have about the same effect as a reciprocating-engine nacelle except that they may be smaller and have less water resistance. Pusher-propeller engines installed on the wing (table 10) also may have low water resistance.

Jet engines have brought about a design freedom in engine location because propeller clearance is no longer a factor. Jet engines installed at the wing root, on struts, under the fuselage, and on the side of the fuselage have been investigated in model-ditching tests. In general, the wing-root nacelles have very little effect on dynamic behavior and will have little influence on structural damage. The strut-mounted nacelles (tables 12 and 26) will probably be torn off in a ditching but will have little effect on dynamic behavior. With engine nacelles mounted under the fuselage, various effects can be expected, depending on the rigidity and the fore and aft location of the installation. If the engines are too far aft, a dive may be produced. A forward location may cause porpoising, but generally an intermediate position can be found that will produce a smooth run. Side-mounted engine nacelles will probably require the horizontal tail to be mounted high on the vertical tail. Generally, with a high tail the rear part of the fuselage runs deeply in the water and the nacelles cause considerable spray and drag as they enter the water. If the nacelles tear away during a ditching, extensive structural damage may result and possibly the aft portion of the fuselage will be torn away. Fighter airplanes usually have jet engines located within the fuselage; therefore, the location of the air intake is the most important feature of such installations. The inlets may cause detrimental behavior when a ditching is made at a low enough attitude to get them into the water at high speeds (see table 23). Usually, however, an airplane can be landed so that the inlets are held clear of the water until a fairly slow speed is reached. Tests were made of one fighter airplane model that had jet engines mounted on the underside of the fuselage (table 20); diving did not occur with this particular installation, but some very high decelerations resulted.

Tail surfaces.—The location of the tail surfaces has not previously been considered to have hydrodynamic influence on ditching behavior. However, data obtained in scale-model investigations indicate that the horizontal-tail location can affect the attitude at which the airplane will run on the water. When the horizontal tail is located very high on the vertical tail the model will, when there is a tendency to trim up, trim higher than when the horizontal tail is in a low position. Occasionally a horizontal tail was partially torn away in the scale-model tests but no appreciable change in behavior due to this damage was noted.

Landing gear.—It is considered advisable that ditchings be made with the landing gear retracted because an extended gear usually causes diving. (For example, see table 32.) There have been some full-scale ditchings with wheels down in which diving did not occur, but apparently these were exceptional.

The arrangement of the landing gear when retracted has not shown an appreciable effect on ditching behavior, but it can affect the amount of damage and the safety of personnel during a ditching. Tricycle-gear arrangements have nose-wheel doors that are likely to fail in a ditching. In no case have scale-model investigations shown that such a failure will cause diving, but secondary failures that ensue as a result of the water pouring into this opening may be extensive enough to endanger nearby personnel. In general, the landing-gear installation that has a tail wheel tends to give a better arrangement for ditching than the tricycle gear, provided that all wheels are retracted. However, if a ditching aid attached under the nose of the airplane were considered, the tricycle landing gear would provide structural members advantageously located to carry the concentrated load of the ditching aid. The bicycle-landing-gear installation requires doors in the fuselage bottom which are undesirable in ditching unless they are much stronger than doors generally are. In investigations of one airplane model employing the bicycle landing gear, the simulated main-wheel doors failed (table 12). In this test no detrimental behavior occurred but the fuselage was flooded. The outrigger wheels required with a bicycle main gear offer no difficulties in ditching. A contribution of the bicycle-landing-gear design favorable to ditching is a very strong fuselage structure. The fuselage of some airplanes has broken apart near the wing in ditching but it is unlikely that a fuselage strong enough to support a bicycle landing gear would separate in this manner. In an investigation of a model with the main landing gear located in nacelles on the sides of the fuselage (table 33), the nacelles crumpled considerably but the damage did not affect the ditching behavior. Damage is likely to occur when the

nacelle type of wheel fairing is used, and the damage could have undesirable effects on flotation unless precautions are taken to prevent entry of water into the main part of the fuselage.

Fuselage strength.—Most airplanes could be ditched with relative safety if extensive damage to the fuselage could be avoided; therefore, the strength of the fuselage bottom is probably the most important parameter influencing ditching behavior. It is impractical to consider designing fuselages which will not fail in ditching, but damage may be reduced by using ditching aids (discussed further under "Ditching Aids"), and the danger to personnel may be minimized by providing safe ditching stations (discussed under "Safe Location of Personnel"). The middle third of the fuselage bottom is considered the critical region because of its susceptibility to damage and the consequent effects on ditching behavior. The investigations with models by the use of scale-strength bottoms to determine the location and amount of probable damage have substantiated this conclusion.

Bombers are particularly susceptible to damage and undesirable ditching behavior because the bomb-bay doors are usually located in the critical region. Manufacturers estimate that the bomb-bay doors have an ultimate strength in resistance to water loads of approximately ½ to 2 pounds per square inch and that the remainder of the lower fuselage is also comparatively weak. Bomb-bay-door failure generally occurs and sometimes causes violent behavior; however, whether or not violent behavior occurred, safe ditching stations in the rear part of the fuselage are generally unobtainable because of the rush of water through the airplane when damage occurs.

There is a wide variation in the bottom strength of fighter airplanes; some have strength as low as 2 pounds per square inch, but others can withstand a pressure of 40 pounds per square inch on some parts of the fuselage bottom. Fighters frequently sustain extensive damage to the bottom skin, but the structure usually remains more or less intact. If damage does not occur, fighters will make smooth runs or at worst they might skip. If damage occurs, almost any behavior from a smooth run to a violent dive or flipover might result according to the amount of damage and the particular airplane configuration.

Transport airplanes have marginal-strength fuselages—the lower part of the fuselages sustains some damage when ditching but usually is not demolished. The average resistance to water loads is estimated by manufacturers to be from 8 to 12 pounds per square inch. The fuselage strength of a transport is greater than that of a bomber because the requirements for cargo floors and pressurized cabins in the transport contribute to a stronger fuselage and because the bomber fuselage is considerably weakened by the presence of the bomb-bay doors. Damage usually does not cause the behavior in transports to be violent, but water flooding into the fuselage through damaged sections is a hazard.

Fuselage shape.—Some current airplanes have large amounts of curvature at the rear of the fuselage. A high degree of longitudinal curvature results in a suction which causes the models to trim up in the water (tables 30, 31, and 37). A high degree of lateral curvature at the rear of the fuselage results in suctions and motions similar to those produced by high longitudinal curvature (ref. 1). Trimming up is not necessarily detrimental but could contribute to undesirable results such as skipping and subsequent diving. A fuselage bottom with little longitudinal and lateral curvature tends to decrease trimming up but is undesirable because of the accompanying high water loads. There are indications that flattened cross sections in combination with high longitudinal curvature tend to cause skipping (tables 19 and 30). Moderately curved sections rearward of the center of gravity are desirable with respect to stability and water loads.

From early scale-model tests, it was concluded that the small differences in the ratio of fuselage length forward of the center of gravity to the total fuselage length indicated no consistent differences in the hydrodynamic performance. Recent trends in fighter design have led to increases in this ratio from approximately ¼ to ½. There is evidence that the increase in nose length has been advantageous to fighter airplanes because it has resulted in a decrease in diving or nosing-in tendency. For bombers, the increase in this ratio has been small and there has been little noticeable effect on ditching behavior.

Curvature at the nose also has an influence on ditching behavior. A fuselage that is more or less straight on the bottom but curves up abruptly at the nose offers less nose-up moment and thus is more likely to dive than one that curves up gradually. The desirability of gradual curvature of the forward part of the fuselage has been substantiated by limited tests.

The effect of cross-sectional curvature of the forward part of the fuselage has not been investigated but it appears that a moderately curved cross section would probably be most desirable.

Size.—The physical magnitude of airplanes appears to affect the degree of violence of ditching behavior. Small differences are not noticeable but in the overall range from fighters to large bombers and transports the effect of size and pitching moment of inertia is apparent. As the size of airplanes increases, the ditching behavior becomes less violent.

Interior arrangement.—Probably the item of interior arrangement that has the greatest effect on ditching behavior is the bulkhead just aft of the bomb bay. Bomb-bay doors usually fail; therefore, this bulkhead is immediately subjected to water loads. For the configurations shown in tables 11 and 13, diving was prevented by removing the bulkhead and the part of the fuselage bottom that might be torn away if the bulkhead failed. In table 4, removing the bulkhead or part of the bulkhead reduced the severity of diving. There have been cases in which bomb-bay doors failed but diving was not produced; in such cases the bulkhead caused no detrimental behavior and offered some protection to the interior of the rearward part of the fuselage.

Protuberances.—Protuberances under the wing or the fuselage of an airplane may cause undesirable ditching behavior and high longitudinal decelerations. Protuberances located rearward of the center of gravity are the most undesirable and may cause diving. Radiators projecting below the fuselage rearward of the center of gravity have

caused dives. Radiators under the nose have caused violent ditching behavior and high decelerations. Belly-gun turrets and radar housings placed forward of the center of gravity generally have caused no diving or other violent motions when tested on models (tables 8 and 14). However, such protuberances located rearward of the center of gravity have caused diving (table 3).

Scale-model investigations with cargo containers located under the fuselage (table 27 (b)) indicated that no detrimental effect was due to the presence of the cargo container; in fact, it was beneficial because it afforded protection to the bottom of the airplane. The construction of the container was such that it caved in on contact with the water and thus acted as a shock absorber.

The need for greater fuel storage in jet-propelled airplanes has resulted in the use of external fuel tanks, usually located under the wing or at the wing tip. Streamlined auxiliary fuel tanks under the wing (table 23) should be jettisoned before ditching because they increase hydrodynamic resistance and because their shape is such that they produce a suction force detrimental to successful ditching. Tanks that were modified in shape by the addition of either chine strips or dead rise with chines (ref. 2) would improve the ditching behavior if they were strong enough to withstand the water loads. Wing-tip tanks probably will not be detrimental since they do not enter the water until a low speed is reached and, if empty, they offer additional buoyancy (tables 21 and 24).

SAFE LOCATION OF PERSONNEL

The availability of good ditching stations for personnel will in some measure compensate for unavoidable deficiencies in hydrodynamic characteristics. Scale-model investigations indicate that decelerations in severe ditchings may exceed $10g$, but apparently personnel can withstand such decelerations if they are braced against or strapped to a unit of the airplane that will not fail. The danger that parts of the airplane will be broken off and thrown against occupants cannot be completely eliminated, but adequate strength can be provided to prevent obvious hazards, such as overhead turrets, from being torn off.

Available records of ditchings indicate that the survival rate for fighter pilots is higher now than in the past. Although the behavior of current fighter airplanes is sometimes violent, a more important factor may be the increase in use of the safety harness. The fuselage of a fighter is strong and the pilot can usually be braced well enough to withstand the decelerations. The bottom skin of the fuselage may be damaged but there is little water flow through the pilot's compartment.

In bomber and transport airplanes, the pilot's compartment is usually high enough to avoid quick flooding except in a dive, damage is not severe, and escape hatches are available. The most dangerous ditching stations in a bomber airplane are rearward of the bomb bay because of the likelihood of an inrush of water through the low-strength bomb-bay doors and the probable failure of the bulkhead just rearward of the bomb bay. The survival rate for bombers as a whole is very low, and as a class the bomber is considered to have unacceptable ditching characteristics.

In a transport airplane, the fuselage generally has no predominantly weak part, such as bomb-bay doors, and the floor of the passenger compartment is more substantial than the floor of a bomber. Consequently, the rearward part of the fuselage is possibly less hazardous in a transport than in a bomber; however, because of the chance that the rear fuselage might sustain extensive damage, ditching stations should be as far forward as possible. In transports that have double decks (tables 36 and 37), the upper deck offers relatively safe ditching stations. The most hazardous type of transport, as far as ditching stations are concerned, is the "flying boxcar" (tables 29, 30, 32, and 33). This type of airplane has large doors and a wide flat bottom that are subject to high water pressures; therefore, some damage is very probable. The high wing of the flying boxcar affords no buoyancy until the airplane sinks deeply; consequently, the cargo or passenger compartment is likely to be flooded to a hazardous extent.

It would seem that the ditching requirements for transports should be more severe than for other types of airplanes because of the large number of passengers involved and the general lack of training in ditching procedures.

DITCHING AIDS

When the use of an airplane is such that a high degree of ditching safety is required, a ditching aid may be the best method of insuring such safety. If a ditching aid were included as an integral part of the airplane in the early stages of design, it possibly could be incorporated with little or no penalty in performance.

Hydroflap.—One method which can be used to prevent diving or "nosing in" during the high-speed part of a ditching run is to provide a device under the fuselage forward of the center of gravity that will have sufficient hydrodynamic lift to furnish the necessary positive pitching moment. Scale-model investigations have been made with planing surfaces, called hydroflaps, installed on models for this purpose. The hydroflaps, which usually have an incidence angle of about 30°, have been tested in various forms. In some investigations, existing rectangular doors in the fuselage were braced open to form hydroflaps (tables 2 (b) and 15 (b)). In other investigations where the hydroflap had a trapezoidal or triangular plan form (tables 4 (b), 11 (b), and 33 (b)), smoother runs were obtained than with rectangular plan forms. In addition to eliminating the diving, hydroflaps reduced the amount of damage sustained by scale-strength sections.

Certain types of airplanes require speed brakes or dive brakes. These devices have various forms, one of which is an approximately flat plate hinged at its leading edge to the bottom of the fuselage and opening outward. A few airplanes have had this type of brake located forward of the center of gravity. Such a device possibly could be located so that it could serve as a hydroflap as well as a speed brake. Speed brakes have not yet been located far enough forward of the center of gravity to serve advantageously as hydroflaps and have not been made strong enough for such use. Scale-model investigations (table 24 (b)) indicate that such

a brake could be used as a ditching aid if these requirements were met.

Hydrofoil.—Two general methods for using hydrofoils to improve hydrodynamic ditching characteristics of airplanes have been investigated with scale models: in one method, the hydrofoil was placed below the nose of the model with a positive incidence, and in the other it was placed aft of the center of gravity with a negative incidence in order to hold the tail down. Both schemes were effective in improving the performance of the models, but the hydrofoil below the nose of the model was a more positive and practical installation. In addition to improving ditching behavior, the hydrofoil forward of the center of gravity offered the possibility of reducing fuselage damage.

Hydro-ski.—Another possible ditching aid is a planing surface that can be extended on struts so that in a landing the airplane rides on the planing surface and the main body of the airplane is not subjected to large water loads at high water speeds. Such a device has been called a hydro-ski (tables 14 (c), 27 (c), and 34 (b)). With a hydro-ski ditching aid, the hazardous motions and structural damage associated with ditching can be eliminated. For a bomber airplane, twin skis retracting into the side of the fuselage or into the wings could be used. For a transport airplane, either a single ski or twin skis retracting into the bottom of the fuselage would be practical.

CONCLUDING REMARKS

Performance requirements and the relatively low frequency of emergency landings even in wartime make it unlikely that airplanes will ever be designed specifically for "safe" ditchings. It appears possible, however, to reduce the hazards by some attention to the effects of the design parameters. It may also in certain cases be possible to incorporate ditching aids to protect the structure from peak water loads without significant performance penalties. These possibilities together with the establishment of proper approach procedures, provision of adequate means of escape, and early rescue remain the most effective means of increasing survival rates in future ditchings.

TABLE 1

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER A

Model scale, $\frac{1}{10}$; gross weight, 21,500 lb; center-of-gravity location, 28 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
2	0	104	200	------	2½	u h
2	40	104	200	------	2½	u h
6	0	104	400	------	1	u h
6	40	87	200	------	1½	u h
10	0	87	350	------	1	u h
10	40	69	200	1½	1	u h
Damaged model						
2	40	104	150	5½	3	b
†10	40	69	100	3	2	b

*In this column, the letters indicate the following motions:

b ran deeply—the model settled deeply in the water with little change in attitude
h ran smoothly—the model made a very stable run
u trimmed up—the attitude of the model increased while running in the water

† Recommended ditching attitude and flap setting.

Remarks: Simulation of damage on this model stopped the trimming-up tendency and caused the model to run deeper in the water. The large nacelles caused violent turns when the model was ditched with one wing low.

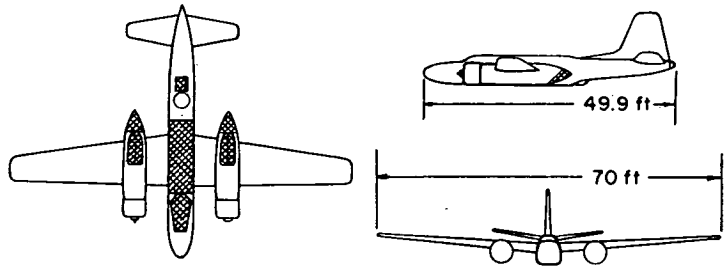

TABLE 2

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER B

[Model scale, $\frac{1}{12}$; gross weight, 25,730 lb; center-of-gravity location, 28 percent M.A.C.; all values full scale]

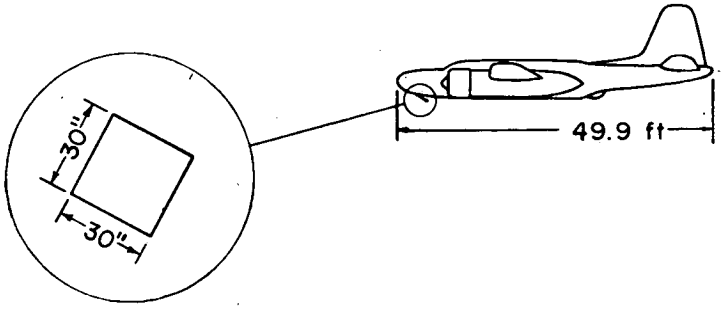
(a) Without hydroflap.

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
3	55	102	400	2	1	s d_1
3	55	102	400	3	1	s t
8	0	115	600	4½	1	s t
8	55	96	500	------	1	h
13	0	102	250	8	2	d_1
13	55	90	150	5	2½	d_1
Damaged model						
3	55	101	100	------	4½	d_1
8	0	115	250	6½	2½	d_1
†8	55	86	100	------	3½	d_1
13	0	102	250	------	2	d_1
13	55	86	150	------	2	d_1

*In this column, the letters indicate the following motions:

d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
h ran smoothly—the model made a very stable run
s skipped—the model rebounded from the water
t turned sharply—the model pivoted quickly about a vertical axis
†Recommended ditching attitude and flap setting.



Remarks: The behavior of the model was exceptionally violent. Violent dives occurred with the undamaged model. In general, the dives at the attitude of 8° were less violent than those at the attitude of 13°. When the model was ditched with one wing slightly low, the large nacelles dug into the water and caused sharp turns.

TABLE 2—Concluded

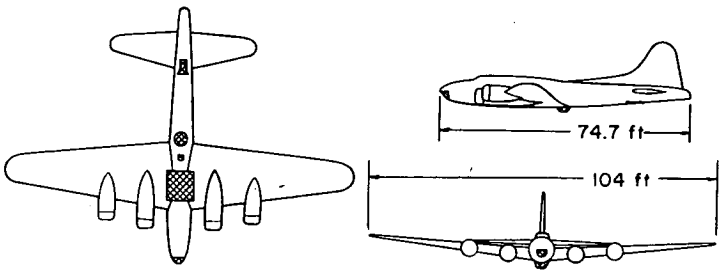
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER B

(b) With hydroflap.

Damage as shown in three-view sketch. All-purpose nose door (open at an angle of 30° to thrust line) used as hydroflap.

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
3	55	101	300	------	2	p
†8	55	86	250	3½	1½	p
13	55	86	200	------	1½	p

*In this column, the letters indicate the following motions:
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
†Recommended ditching attitude and flap setting



Remarks: Rather violent porpoising runs occurred with the hydroflap, but these runs were considerably better than the violent dives that occurred without the hydroflap.

TABLE 3

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER C

[Model scale, $\frac{1}{16}$; gross weight, 57,000 lb; center-of-gravity location, 30 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
0	45	122	---	7	------	d_1

10	45	87	---	------	------	d_1
Damaged model						
0	45	122	---	7½	------	t
3½	45	104	---	------	------	t s
†7	45	87	---	------	------	s
10	45	87	---	------	------	p

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
t turned sharply—the model pivoted quickly about a vertical axis
†Recommended ditching attitude and flap setting.

Remarks: The tests indicated that the lower turret was the principal cause of diving. It was recommended that this turret be made easily jettisonable.

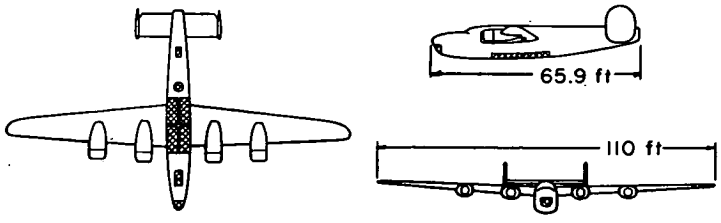

TABLE 4

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER D

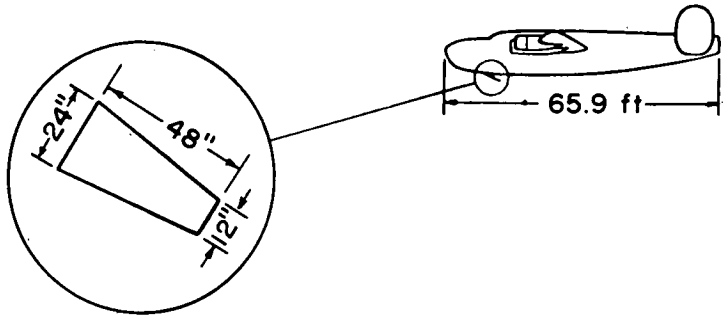
[Model scale, $\frac{1}{16}$; gross weight, 48,500 lb; center-of-gravity location, 30 percent M.A.C.; all values full scale]

(a) Without hydroflap.

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
1	40	104	550	1½	1	h
			900	2½	½	s
5	0	104	950	1	½	s
			800	1	½	p
5	40	87	600	1½	½	h
			550	1½	½	p
9	0	87	300	3	1	h
9	40	87	250	3½	1½	h
			550	--	½	p
Damaged model						
1	40	104	200	------	2½	d_1
			300	------	1½	s
†5	40	87	250	------	1½	p d_1
9	40	87	150	------	2	d_1

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with water
s skipped—the model rebounded from the water
†Recommended ditching attitude and flap setting.



Remarks: The bomb-bay doors on this airplane are exceptionally weak and will probably fail in a ditching. The tests of models indicated that failure of the bomb-bay doors caused a diving moment. The amount of damage to the bulkhead aft of the bomb bay determined the severity of the behavior of the airplane.

TABLE 4—Concluded

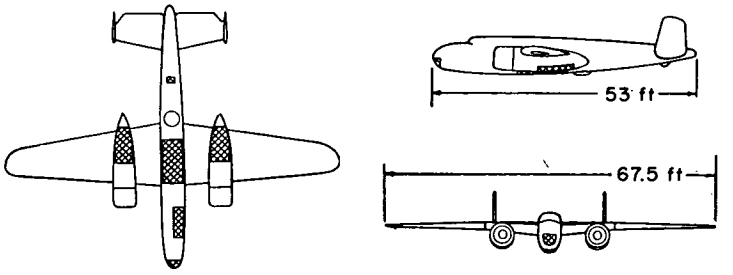
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER D

(b) With hydroflap.

Damage same as shown in three-view sketch. Hydroflap as indicated.

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
1	40	104	450	------	1	p
†6	40	87	300	------	1	p
9	40	87	350	------	1	p

*In this column, the letters indicate the following motions:
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with water
†Recommended ditching attitude and flap setting.



Remarks: The hydroflap was considered the most practical of several ditching aids which were tested on this model.

TABLE 5

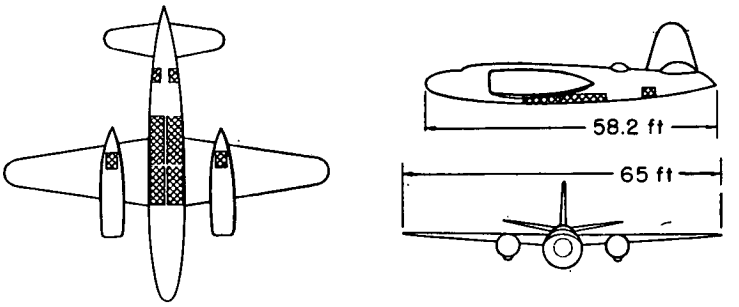
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER E

[Model scale, $\frac{1}{11}$; gross weight, 26,000 lb; center-of-gravity location, 25 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
0	0	104	200	3½	2½	h
0	45	104	250	4	2	t
6	0	104	250	3	2	h
6	45	87	150	3	2	h
12	0	104	300	3	1½	h
12	45	87	200	3½	1½	h
Damaged model						
0	45	104	350	2½	1½	s
6	45	87	250	3	1½	b
†12	45	87	150	3½	2	b

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
s skipped—the model rebounded from the water
t turned sharply—the model pivoted quickly about a vertical axis
†Recommended ditching attitude and flap setting.



Remarks: The performance of the model was not appreciably changed by simulation of damage. The model ran deeper in the water with the parts removed, but the behavior in general was similar. The large nacelles tended to cause violent turns when one wing was low.

TABLE 6

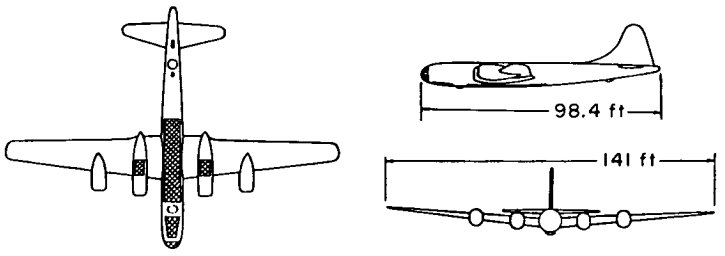
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER F

[Model scale, $\frac{1}{12}$; gross weight, 31,000 lb; center-of-gravity location, 14 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
−1	0	122	400	------	1½	u h
−1	55	104	400	2	1	u h
6	0	104	350	------	1½	u h
6	55	104	350	------	1½	u s
13	0	104	300	------	1½	h
13	55	104	350	2	1½	h
Damaged model						
−1	55	104	400	3	1	s
†6	55	104	350	4	1½	s
13	55	104	300	6	1½	s

*In this column, the letters indicate the following motions:
h ran smoothly—the model made a very stable run
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The model had a trimming-up tendency in the undamaged condition. The large nacelles caused sharp turns when the model was ditched with one wing low.

TABLE 7

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER G

[Model scale, $\frac{1}{20}$; gross weight, 105,000 lb; center-of-gravity location, 25 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
1	45	122	250	8	2½	d_1
5	45	104	650	1	½	h
9	0	122	850	2	1	h
9	45	87	450	1	½	h
13	0	104	700	2	½	h

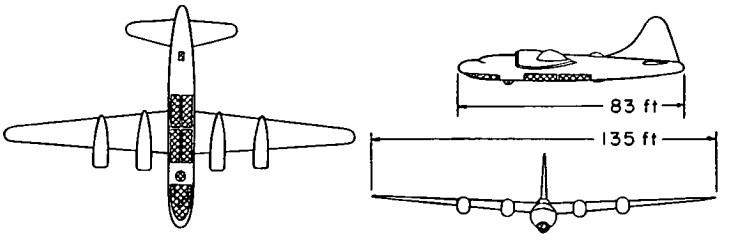
Damaged model						
1	45	122	600	------	1	p
			200	------	3½	d_1
5	45	104	350	------	1½	p
†9	45	87	300	------	1	h
13	45	87	250	------	1½	h

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
d_2 dived slightly—the model stopped abruptly in a nose-down attitude with nose of the model submerged
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
†Recommended ditching attitude and flap setting.



Remarks: The scale-strength landing flaps on the model did not fail consistently. When the flaps did not fail, the model usually dived.

TABLE 8

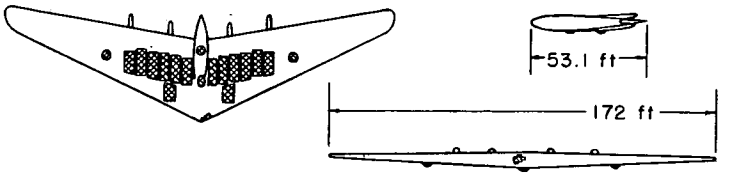
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER H

[Model scale, $\frac{1}{20}$; gross weight, 100,000 lb; center-of-gravity location, 30 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
0	40	122	550	1½	1	u h b
6	40	102	500	2	1	u h b
13	0	115	600	2	1	h b
13	40	88	450	1½	1	h b
Damaged model						
0	40	122	450	4	1½	p b
†6	40	102	350	4½	1½	h b
13	40	88	400	3½	1	h b

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: Decelerations were increased when damage was simulated, but the behavior of the model was not appreciably changed.

TABLE 9

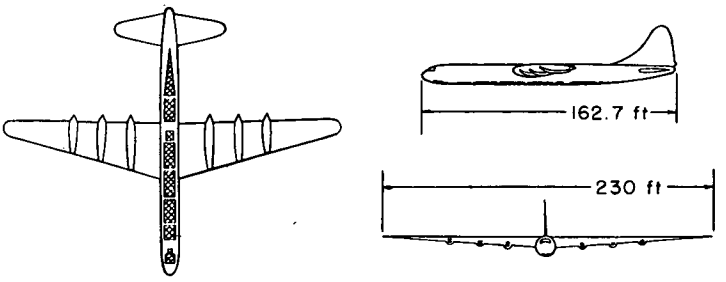
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER I

Model scale, $\frac{1}{20}$; gross weight, 150,000 lb; center-of-gravity location, 25 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
9	50	111	400	--------	1½	h t p t
Damaged model						
4	50	124	500	5	1½	u p t
†9	50	111	300	5	2	u p
9	50	111	300	6	2	u p t
14	50	98	250	6	1½	b
14	50	98	250	7	1½	b t

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
t turned sharply—the model pivoted quickly about a vertical axis
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The most pronounced ditching characteristic of this bomber model was its tendency to turn or yaw. Construction of the airplane is such that extensive damage is to be expected and it probably will be difficult to find ditching stations where crew members can adequately brace themselves and be reasonably sure of avoiding an inrush of water.

TABLE 10

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER J

[Model scale, $\frac{1}{20}$ and $\frac{1}{30}$; gross weight, 255,000 lb; center-of-gravity location, 29 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched area).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged 1/30-scale model						
1	40	124	1,000	--------	½	u h
1	40	124	1,000	--------	½	u s
5	40	106	650	--------	1	h
9	0	119	650	--------	1	h
9	40	95	1,000	--------	½	h
13	0	108	1,000	--------	½	p
13	40	87	650	--------	½	h
Damaged 1/20-scale model						
1	40	124	-----	4	--------	b
†9	40	95	-----	2	--------	h

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.

Remarks: The behavior of the model was generally good. No violent motions such as diving occurred, and the maximum longitudinal deceleration recorded was about 4g.

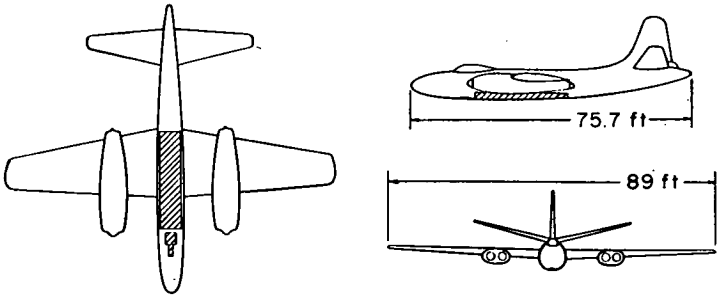


TABLE 11

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER K

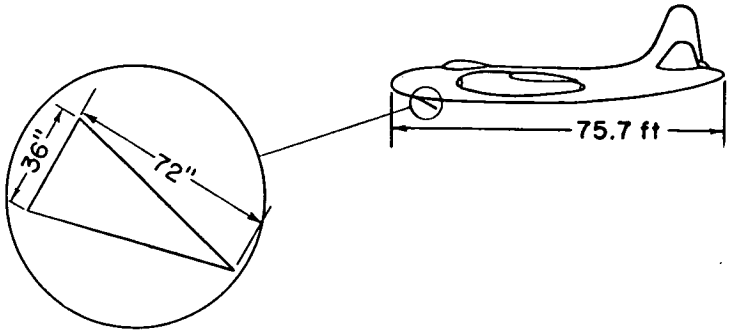
[Model scale, $\frac{1}{18}$; gross weight, 82,600 lb; center-of-gravity location, 29 percent M.A.C.; all values full scale]

(a) Without hydroflap.

Damage simulated by removal of parts and covering of openings with aluminum foil (hatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
2	40	131	950	1½	1	u h
6	40	119	850	1	½	u h
Damaged model						
2	40	131	200	9½	4	d_1
†6	40	119	300	5	2	d_1

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
h ran smoothly—the model made a very stable run
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The scale-strength bomb-bay doors and nose-wheel doors consistently failed on the model. The dives that occurred were very violent. Additional data have indicated that if the bulkhead and part of the fuselage bottom aft of the bomb bay fail in a ditching, diving may not occur.

TABLE 11—Concluded

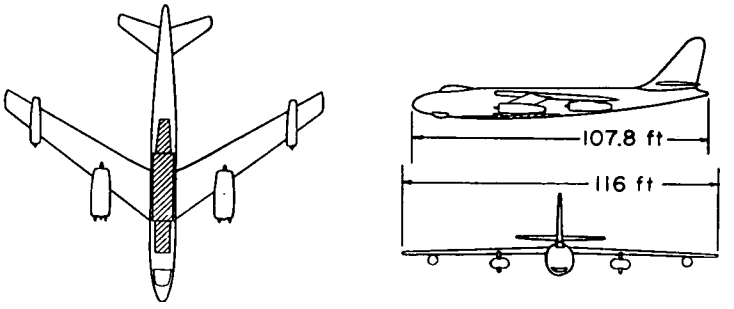
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER K

(b) With hydroflap.

Damage same as shown in three-view sketch. Hydroflap as indicated.

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
2	40	131	720	3½	1	s p
†6	40	119	540	3½	1	s p

*In this column, the letters indicate the following motions:
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
†Recommended ditching attitude and flap setting.



Remarks: The hydroflap stopped the diving and reduced the deceleration. It also kept the nose-wheel doors from failing.

TABLE 12

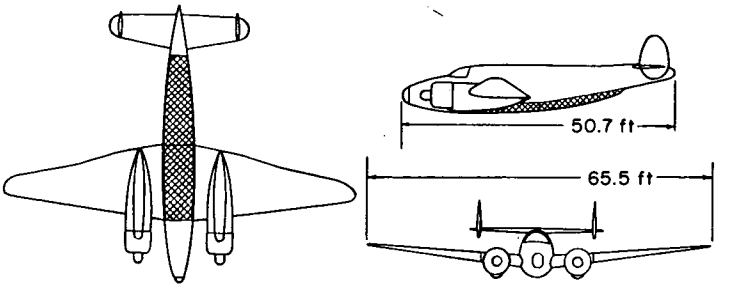
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER L

[Model scale, $\frac{1}{24}$; gross weight, 125,000 lb; center-of-gravity location, 20 percent M.A.C.; all values full scale]

Damage simulated by removal of parts and covering of openings with aluminum foil (hatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
5	35	134	650	2	1	u s p
10	0	155	700	3	1½	h
10	35	120	650	2	1	h
15	35	115	550	1½	1	h
Damaged model						
5	35	134	650	3	1	b
†10	35	120	550	2½	1	h
15	35	115	450	3	1½	b

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: Additional tests with the nacelles attached at scale strength indicated that the nacelles will probably be torn off in a ditching but will have little or no effect on behavior. The simulated main-wheel doors failed.

TABLE 13

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER M

[Model scale, $\frac{1}{11}$; gross weight, 26,500 lb; center-of-gravity location, 30 percent M.A.C.; all values full scale]

Damage simulated by removal of part (crosshatched area).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
2	38	113	450	4	1	s p
7	0	122	650	------	1	s t
7	38	87	450	1½	1	p
12	0	104	700	1	1	h
12	38	87	350	2	1	h
Damaged model						
2	38	122	400	------	1½	s p
7	38	87	300	------	1	p
†12	38	87	300	------	1	p

*In this column, the letters indicate the following motions:
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
t turned sharply—the model pivoted quickly about a vertical axis
†Recommended ditching attitude and flap setting.

Remarks: From examination of full-scale ditching reports on this airplane, it is believed that the fuselage bottom section aft of the bomb bay will be torn away in a ditching with the results indicated above. If this section does not fail, violent dives occur.

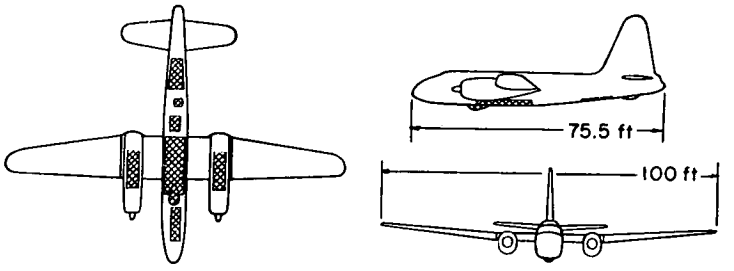


TABLE 14

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER N

[Model scale, $\frac{1}{16}$; gross weight, 45,000 lb; center-of-gravity location, 29 percent M.A.C.; all values full scale]

(a) Without hydroflap or hydro-skis.

Damage simulated by removal of parts (crosshatched areas).

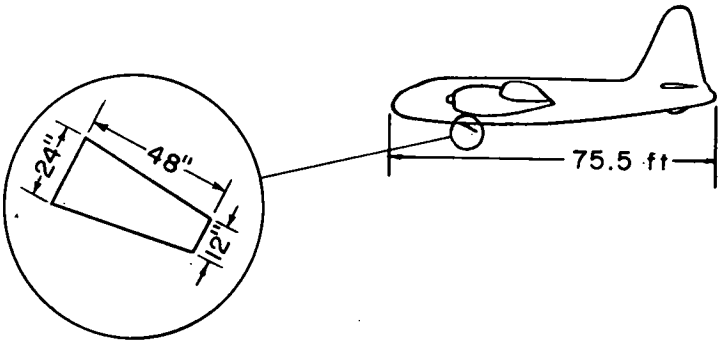
10	32	71	100	3½	2½	d_1

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
h ran smoothly—the model made a very stable run
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



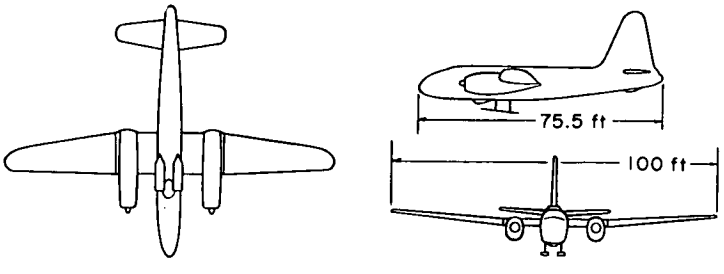
Remarks: Data obtained from the manufacturer indicates that the fuselage bottom is extremely weak so that considerable damage with this airplane could be expected. The diving caused by simulated damage was very violent.

TABLE 14—Concluded

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER N

(b) With hydroflap.

Damage same as shown in three-view sketch except nose-wheel doors not removed. Hydroflap as indicated.



Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
2	32	89	450	3	1	p h
†6	32	78	300	3½	1	p h
10	32	71	250	4	1	p h

*In this column, the letters indicate the following motions:
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with water
†Recommended ditching attitude and flap setting.

Remarks: The location of the hydroflap on this airplane was critical. When located forward of the nose-wheel doors, it did not stop the diving.

(c) With hydro-skis.

No damage simulated. Skis as indicated.

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
2	32	89	1, 350	1	½	h
6	32	78	950	--	½	h
10	32	71	500	½	½	h

*In this column, the letters indicate the following motions:
h ran smoothly—the model made a very stable run

Remarks: The ditching behavior with the hydro-skis was very good. It is possible that critical damage can be eliminated from ditchings by using a hydro-ski ditching gear, and thus the chances of survival and rescue would be greatly increased.

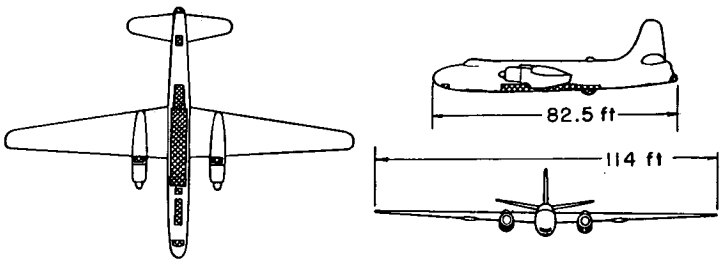


TABLE 15

SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER O

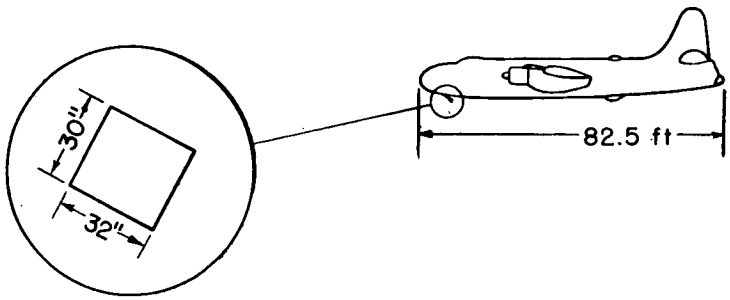
[Model scale, $\frac{1}{18}$; gross weight, 55,000 lb; center-of-gravity location, 22 percent M.A.C.; all values full scale]

(a) Without hydroflap.

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
1	40	98	300	------	1½	h
7	0	108	400	------	1½	p
7	40	88	300	------	1	p
13	0	98	300	------	1½	h
13	40	82	300	------	1	h
Damaged model						
1	40	95	100	4½	4	d_2
†7	40	89	200	3	2	p
†7	40	89	100	4½	3½	d_2
13	40	82	150	3½	2	d_2
13	40	82	150	3½	2	t

*In this column, the letters indicate the following motions:
d_2 dived slightly—the model stopped abruptly in a nose-down attitude with the nose of the model submerged
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
t turned sharply—the model pivoted quickly about a vertical axis
†Recommended ditching attitude and flap setting.



Remarks: The behavior of the damaged model varied inconsistently.

TABLE 15—Concluded

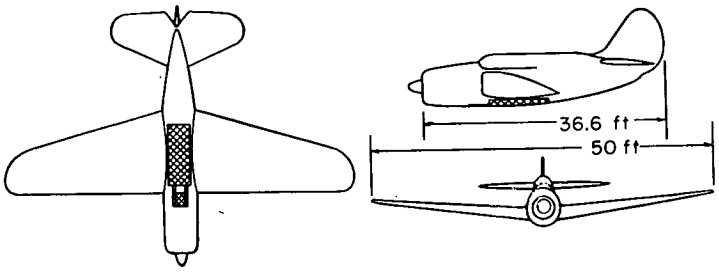
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER O

(b) With hydroflap.

Damage same as shown in three-view sketch. Navigator's escape hatch (open at an angle of 30° to the thrust line) used as hydroflap.

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
1	40	95	150	3	2½	p
†7	40	85	150	2½	2	p
13	40	82	150	3	2	p

*In this column, the letters indicate the following motions:
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with water
†Recommended ditching attitude and flap setting.



Remarks: The hydroflap is recommended as a ditching aid on this airplane to stop the diving that sometimes occurred. It also reduced the decelerations slightly.

TABLE 16

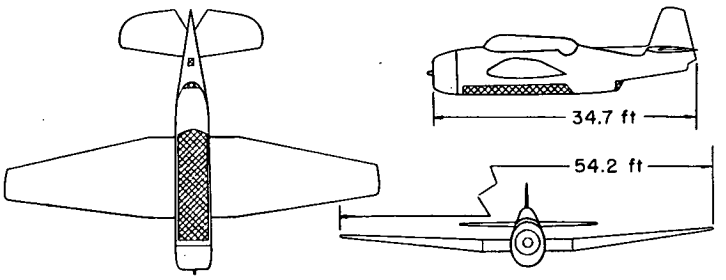
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER P

[Model scale, $\frac{1}{8}$; gross weight, 13,060 lb; center-of-gravity location, 30 percent M.A.C.; all values full scale]

Damaged simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Damaged model						
2	30	113	150	8	4	d_1
2	60	104	100	5½	5	d_1
2	60	104	---	------	------	s
8	0	113	400	6½	1½	s
8	0	113	---	------	------	p
8	30	95	200	5	2	d_1
8	60	87	150	7	2	d_1
8	60	87	---	------	------	s
15	0	87	200	4½	1½	d_1
15	0	87	---	------	------	b
15	30	78	150	5	2	d_1
15	60	69	200	4	1	d_1
15	60	69	---	------	------	s b

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water



Remarks: The landing flaps were very strong on this scout bomber. When they failed, the model skipped or made a deep run; when they did not fail, the model dived.

TABLE 17

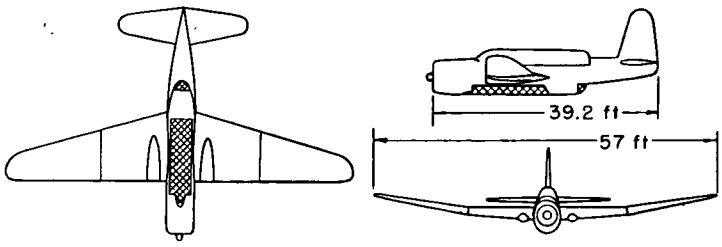
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER Q

[Model scale, $\frac{1}{9}$; gross weight, 13,795 lb; center-of-gravity location, 26 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
3	45	80	500	------	½	p h
7	0	86	550	------	½	s h
7	45	76	400	2	½	p h
11	0	85	500	1½	½	p h
11	45	68	450	1	½	p h
Damaged model						
3	45	77	100	4½	2½	d_1
†7	45	76	150	3½	1½	d_1
11	45	66	100	------	2	d_1

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
†Recommended ditching attitude and flap setting.



Remarks: Full-scale reports have indicated that all personnel aboard this airplane have a good chance to survive a ditching, and if the radioman moves to the upper part of the fuselage, his chances will be improved.

TABLE 18

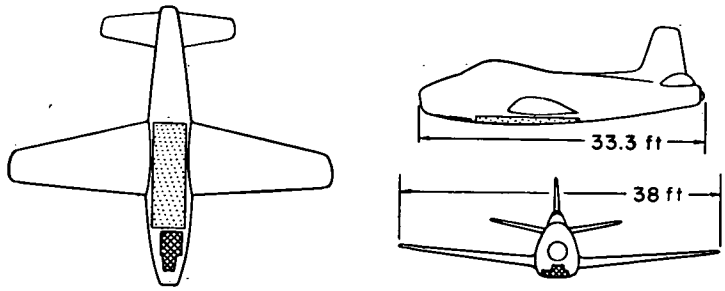
SUMMARY OF MODEL-DITCHING INVESTIGATION OF BOMBER R

[Model scale, $\frac{1}{9}$; gross weight, 16,925 lb; center-of-gravity location, 32 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
2	50	96	600	------	½	s
7	0	108	800	------	½	s
7	50	85	500	------	½	s
12	0	89	550	------	½	p
12	50	78	550	------	½	p
18	0	85	500	------	½	s p
18	50	71	450	------	½	p h
Damaged model						
2	50	100	80	------	5½	d_1
7	50	87	100	------	3½	d_1
†12	50	78	100	------	2½	d_1
18	50	71	100	------	2	d_1

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water.
†Recommended ditching attitude and flap setting.



Remarks: This airplane closely resembles bomber Q. The ditching behavior of the models was similar, but the higher landing speeds of bomber R gave higher average decelerations.

TABLE 19

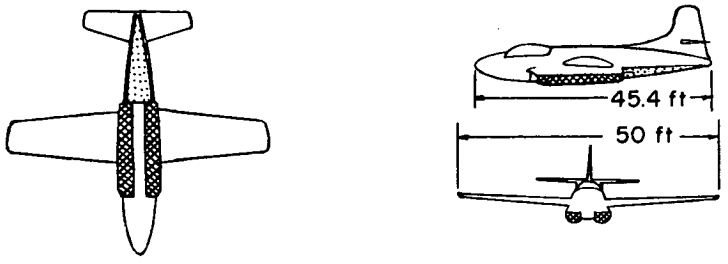
SUMMARY OF MODEL-DITCHING INVESTIGATION OF FIGHTER A

[Model scale, $\frac{1}{10}$; gross weight, 12,151 lb; center-of-gravity location, 23 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas) and installation of crumpled parts (dotted areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
2	40	128	650	9½	1	u s d_1
8	40	104	1, 000	4	½	u s h
12	0	118	900	6	½	u s p
12	40	94	700	2½	½	u s p h
Damaged model						
2	40	128	900	5	1	u s h
8	40	104	700	3	½	u s p h
†12	40	94	600	2½	½	h u p h

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The undamaged model trimmed up and skipped violently when it contacted the water. Simulation of damage improved the ditching behavior by reducing the trimming up and skipping.

TABLE 20

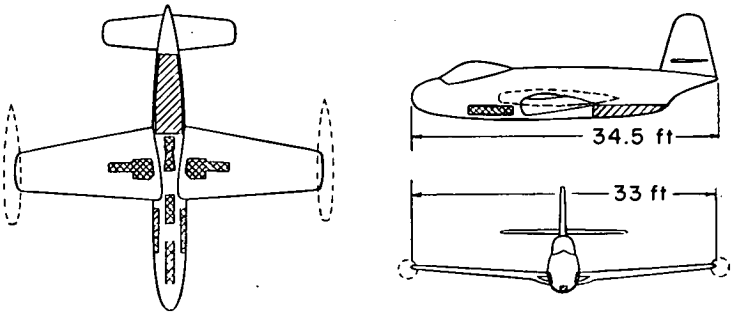
SUMMARY OF MODEL-DITCHING INVESTIGATION OF FIGHTER B

[Model scale, $\frac{1}{12}$; gross weight, 25,000 lb; center-of-gravity location, 22 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas) and installation of crumpled parts (dotted areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
4	40	127	550	------	1½	s t
8	0	139	1, 150	5	½	s p
8	40	111	600	2	1	u h
12	0	122	1, 200	4½	½	s p
12	40	101	650	2	½	u o
Damaged model						
4	40	127	650	------	1	s p
8	0	139	600	11	1½	h
†8	40	111	550	2	1	h
12	0	122	550	5	1	h
12	40	101	500	3	1	h

*In this column, the letters indicate the following motions:
h ran smoothly—the model made a very stable run
o oscillated—the model oscillated about the longitudinal or vertical axis
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
t turned sharply—the model pivoted quickly about a vertical axis
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The jet engines located below the fuselage did not cause diving in this installation, but a very high maximum longitudinal deceleration was obtained at one condition. Simulation of damage stopped the model from trimming up.

TABLE 21

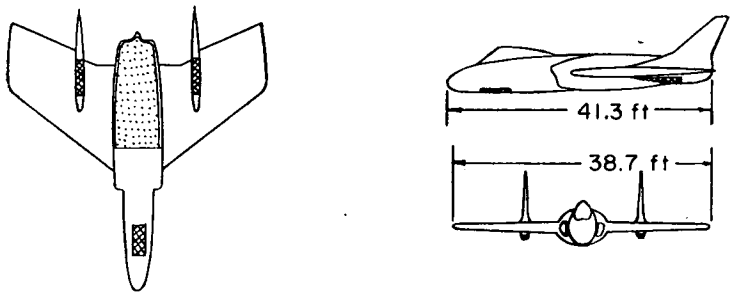
SUMMARY OF MODEL-DITCHING INVESTIGATION OF FIGHTER C

[Model scale, $\frac{1}{8}$; gross weight, 9,706 lb; center-of-gravity location, 31 percent M.A.C.; all values full scale]

Damage simulated by use of scale-strength parts (hatched areas) and removal of other parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
4	27	124	500	2	1½	u s p
8	27	107	550	1	1	u s p
12	27	97	400	2	1	u p
Damaged model						
4	27	124	200	9	3½	p d_2
8	27	107	150	10	3½	d_1
†12	27	97	100	7	4	d_1

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
d_2 dived slightly—the model stopped abruptly in a nose-down attitude with the nose of the model submerged
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The trimming up and diving of this model was extremely severe. The pilot should make sure that the safety harness is securely fastened in order to withstand the decelerations.

TABLE 22

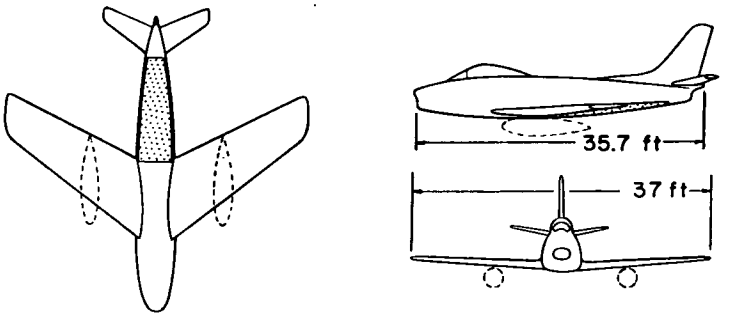
SUMMARY OF MODEL-DITCHING INVESTIGATION OF FIGHTER D

[Model scale, $\frac{1}{11}$; gross weight, 22,800 lb; center-of-gravity location, 12 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas) and installation of crumpled parts (dotted areas).

Landing attitude, deg	Ailavator setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
18	−20	131	940	------	1	u s
23	−30	117	870	2	½	s p
28	−40	106	720	1½	½	s p
Damaged model						
18	−20	131	600	------	1½	u s
23	−30	117	540	3½	1	s p
28	−40	106	500	3½	1	p

*In this column, the letters indicate the following motions:
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water



Remarks: The airplane can land at extremely high attitudes and should be ditched at the lowest speed and highest attitude consistent with adequate control.

TABLE 23

SUMMARY OF MODEL-DITCHING INVESTIGATION OF FIGHTER E

[Model scale, $\frac{1}{10}$; gross weight, 13,311 lb; center-of-gravity location, 22 percent M.A.C.; all values full scale]

Damage simulated by installation of crumpled part (dotted area).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
4	38	132	300	8	2½	d_1
9	38	109	800	1	½	h
14	0	113	700	2½	1	p s
14	38	98	650	1½	½	h
Damaged model						
4	38	132	200	7½	4	d_1
9	38	109	600	3	1	h
†14	38	98	600	3	½	h

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
†Recommended ditching attitude and flap setting.

Remarks: Extreme care should be taken to avoid the violent dive at the low attitude. The tanks under the wing should be jettisoned before ditching.

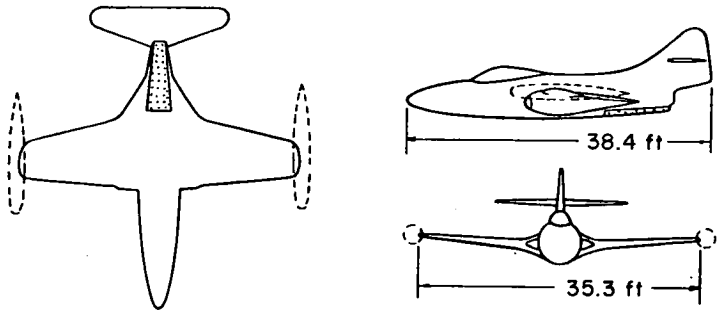


TABLE 24

SUMMARY OF MODEL-DITCHING INVESTIGATION OF FIGHTER F

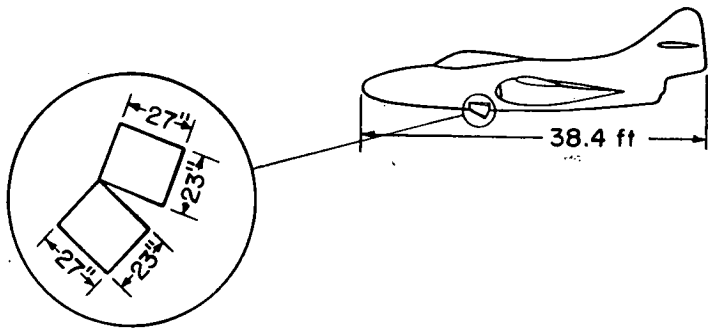
[Model scale, $\frac{1}{10}$; gross weight, 12,100 lb; center-of-gravity location, 27 percent M.A.C.; all values full scale]

(a) Without hydroflap.

Damage simulated by installation of crumpled part (dotted area).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
4	Inboard 20 Outboard 55	133	740	5	1	s p
8	Inboard 20 Outboard 55	115	760	3	1	s p
12	Inboard 20 Outboard 55	102	590	2	1	s p
Damaged model						
4	Inboard 20 Outboard 55	133	760	5	1	s p
8	Inboard 20 Outboard 55	115	685	3	1	s p
†12	Inboard 20 Outboard 55	102	700	2	½	s p

*In this column, the letters indicate the following motions:
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
†Recommended ditching attitude and flap setting.



Remarks: This model made rather long runs with severe skipping.

TABLE 24—Concluded

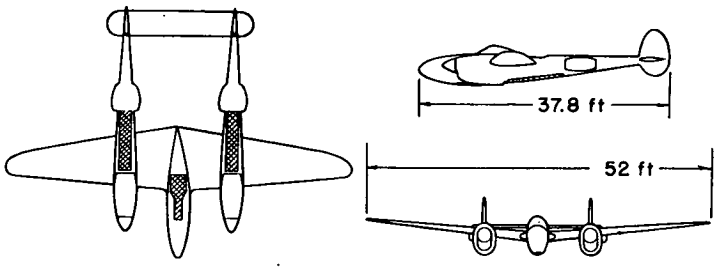
SUMMARY OF MODEL-DITCHING INVESTIGATION OF FIGHTER F

(b) With hydroflap.

Damage same as shown on three-view sketch. Speed brake (open at angle of 30° to thrust line) used as hydroflap.

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
8	Inboard 20 Outboard 55	115	765	2	1	s p
†12	Inboard 20 Outbaord 55	102	595	2	1	p s p

*In this column, the letters indicate the following motions:
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
†Recommended ditching attitude and flap setting.



Remarks: The severity of the skipping was reduced by using the hydroflap.

TABLE 25

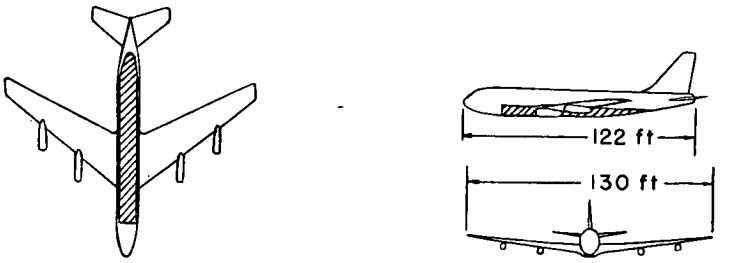
SUMMARY OF MODEL-DITCHING INVESTIGATION OF FIGHTER G

[Model scale, $\frac{1}{9}$; gross weight, 14,900 lb; center-of-gravity location, 28 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
5	37	100	250	6	2	s
9	0	115	250	------	2½	b
9	37	88	200	4	1½	s o
13	0	100	250	8	2	b
13	37	79	200	------	1½	s
Damaged model						
2	37	113	100	------	5½	s d_2
5	37	100	200	------	2	s
†9	37	88	200	------	1½	s
†13	37	79	250	------	1	s

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
d_2 dived slightly—the model stopped abruptly in a nose-down attitude with the nose of the model submerged
o oscillated—the model oscillated about the longitudinal or vertical axis
s skipped—the model rebounded from the water
†Recommended ditching attitude and flap setting.



Remarks: The landing speed was the most important variable affecting performance of this airplane. At high speeds, the highest deceleration and the most violent behaviors were encountered. A tail-down attitude (from 9° to 13°) is recommended.

TABLE 26

SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT A

[Model scale, 0.043; gross weight, 130,000 lb; center-of-gravity location, 26 percent M.A.C.; all values full scale]

Damage simulated by scale-strength parts (hatched area) and scale-strength nacelle struts.

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model with scale-strength nacelle struts						
6	0	146	1,100	2½	1	s b
6	50	113	1,040	2½	½	h
9	0	127	1,090	2½	½	h
9	50	104	850	1½	½	h
12	0	119	890	1½	½	h
12	50	100	640	2	½	h
Damaged model with scale-strength nacelle struts						
6	0	146	700	6½	1½	b
6	50	113	450	6	1½	h
9	0	127	500	5½	1½	h
9	50	104	420	5	1	h
12	0	119	480	6½	1½	h
†12	50	100	470	5	1	h

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
s skipped—the model rebounded from the water
†Recommended ditching attitude and flap setting.

Remarks: One or more of the nacelles were frequently torn off in a ditching but had little or no effect on behavior.

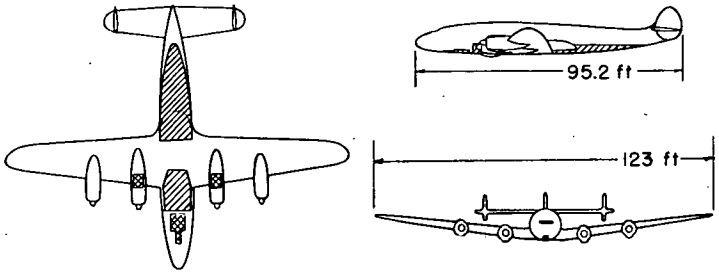


TABLE 27

SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT B

[Model scale, $\frac{1}{18}$; gross weight, 83,000 lb; center-of-gravity location, 25 percent M.A.C.; all values full scale]

(a) Without cargo container or hydro-ski.

Damage simulated by use of scale-strength parts (hatched areas) and removal of other parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
4	0	148	900	6	1	s h
4	40	91	250	4	1½	d_2
9	0	115	600	2	1	u h
9	40	79	400	4	½	b
12	0	102	600	1	1	h
12	40	74	250	3	1	b
Damaged model						
4	40	91	200	4	2	b d_2
†9	40	79	350	3	1	b d_2
12	40	74	200	4	1	h b

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
d_2 dived slightly—the model stopped abruptly in a nose-down attitude with the nose of the model submerged
h ran smoothly—the model made a very stable run
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.

Remarks: The fuselage will probably be damaged and leak substantially.

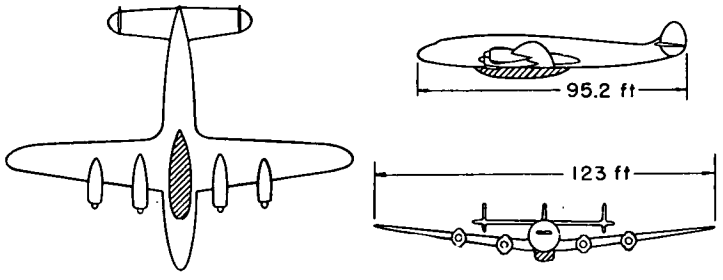

TABLE 27—Concluded

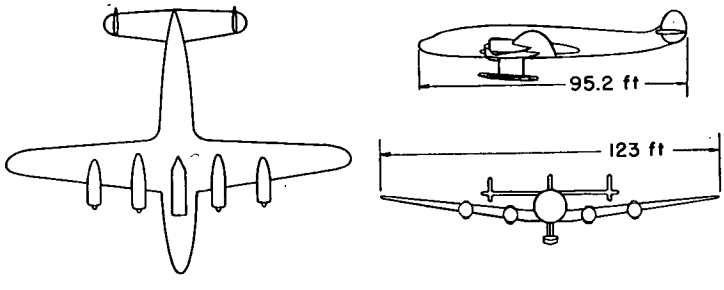
SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT B

[Gross weight of airplane plus cargo container, 93,000 lb; all values full scale]

(b) With cargo container

Model undamaged. Scale-strength cargo container (hatched area) attached as indicated.



Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
4	40	95	650	--	½	h d_2
†9	40	85	500	1½	½	h b
12	40	78	250	2	1	h b

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
d_2 dived slightly—the model stopped abruptly in a nose-down attitude with the nose of the model submerged
h ran smoothly—the model made a very stable run
†Recommended ditching attitude and flap setting.

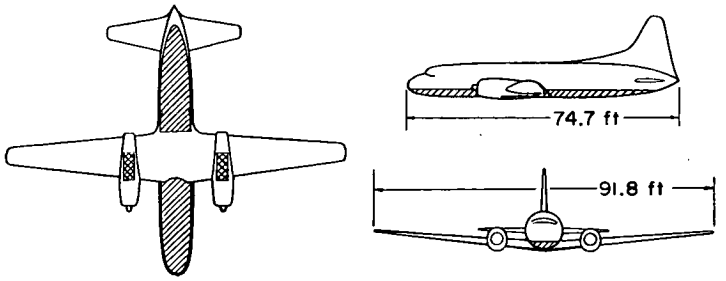
Remarks: The bottom of the cargo container was damaged considerably and evidently absorbed some of the landing loads. The decelerations were less and the behavior of the model was more favorable. The cargo container also protected the fuselage bottom.

(c) With hydro-ski.

No damage simulated. Ski as shown.

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
4	40	91	1,220	½	½	h
9	40	79	720	--	½	h p

*In this column, the letters indicate the following motions:
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water



Remarks: The ditching behavior with the hydro-ski was very good. It is possible that critical damage can be eliminated from ditchings by using a hydro-ski ditching gear, thus greatly increasing the chances of survival and rescue.

TABLE 28

SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT C

[Model scale, $\frac{1}{15}$; gross weight, 43,500 lb; center-of-gravity location, 22 percent M.A.C.; all values full scale]

Damage simulated by use of scale-strength parts (hatched areas) and removal of other parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model

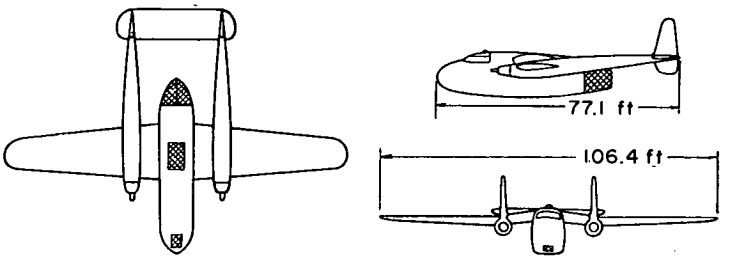
5	39	88	300	3½	1	h
9	0	105	300	6	1½	h
†9	39	82	300	3	1	h

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The landing flaps were an important factor in the ditching behavior of this model. Failure of the scale-strength flaps was simulated by the flaps rotating up or being torn from the model. When the flaps rotated up, the model dived; but when the flaps were torn away, the model performed as indicated above.

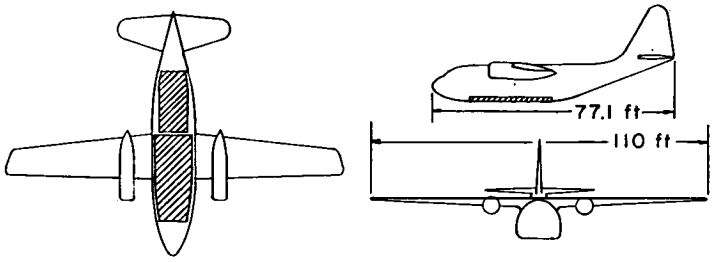
[Model scale, $\frac{1}{15}$; gross weight, 50,000 lb; center-of-gravity location, 25 percent M.A.C.; all values full scale]

Damage simulated by removal of parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
2	40	109	700	1	1	u s p
7	40	90	300	2	1	u b
12	40	78	350	1	1	u b
Damaged model						
2	40	109	450	2½	1	u b
7	40	90	350	2	1	b
†12	40	78	300	1	1	b

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The undamaged model trimmed up considerably when it contacted the water. Damage to the fuselage bottom greatly reduced the trimming up and caused the cargo compartment to flood rapidly, and thus to become a very hazardous ditching station.

TABLE 30

SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT E

[Model scale, $\frac{1}{14}$; gross weight, 44,000 lb; center-of-gravity location, 22 percent M.A.C.; all values full scale]

Damage simulated by scale-strength parts (hatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
4	45	80	385	------	½	u s
9	45	71	350	------	½	u h
14	45	65	350	------	½	u h

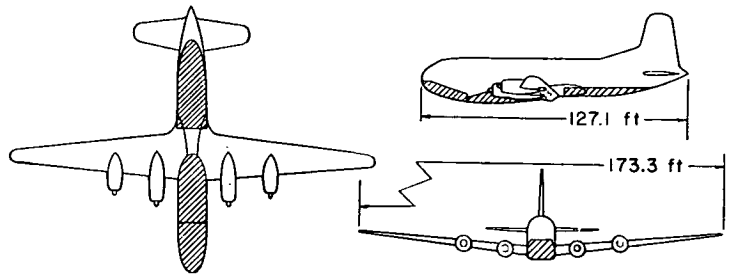
4	45	80	450	2	½	s p
9	45	71	450	1½	½	h
†14	45	65	415	1	½	p

*In this column, the letters indicate the following motions:
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The fuselage bottom will probably be damaged and the fuselage will fill with water and sink to the wing level.

TABLE 31

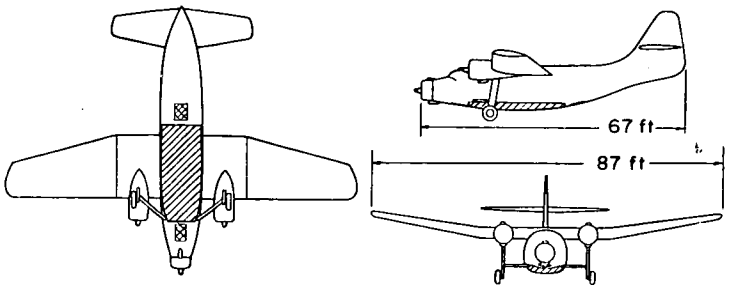
SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT F

[Model scale, $\frac{1}{24}$; gross weight, 175,000 lb; center-of-gravity location, 27 percent M.A.C.; all values full scale]

Damage simulated by use of scale-strength parts (hatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
2	40	109	750	2	½	u h
7	0	157	1, 150	2	1	u h
7	40	96	800	1	½	u h
12	0	123	900	2	½	h
12	40	91	700	2½	½	h
Damaged model						
2	40	109	550	4	1	h
†7	40	96	500	2½	1	h
12	40	91	500	4½	1	p

*In this column, the letters indicate the following motions:
h ran smoothly—the model made a very stable run
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The large clamshell doors in the nose of this airplane and the unusual shape of the fuselage bottom forward of the wing were of particular interest. With the scale-strength parts installed, only slight damage occurred to the clamshell doors and aft fuselage bottom, but considerable damage was sustained by the region just forward of the wing. However, the high location of the main floor should provide adequate ditching stations.

TABLE 32

SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT G

[Model scale, $\frac{1}{14}$; gross weight, 35,123 lb; center-of-gravity location, 31 percent M.A.C.; all values full scale]

Damage simulated by use of scale-strength parts (hatched areas) and removal of other parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
0	55	64	150	2½	1	d_1

4	55	60	200	2	1	d_2
8	0	87	150	4	2	d_1
8	55	56	150	2	1	d_2
Damaged model						
0	55	64	150	4	1	d_1
4	55	60	150	2	1	d_2
†8	55	56	150	2	1	d_2

*In this column, the letters indicate the following motions:
d_1 dived violently—the model stopped abruptly in a nose-down attitude with most of the model submerged
d_2 dived slightly—the model stopped abruptly in a nose-down attitude with the nose of the model submerged
f flipped over—the model rotated about the transverse axis and stopped in an inverted position
†Recommended ditching attitude and flap setting.

Remarks: The fixed landing gear on this model caused diving and flipping over. When the gear was removed the model either ran smoothly or skipped and porpoised.

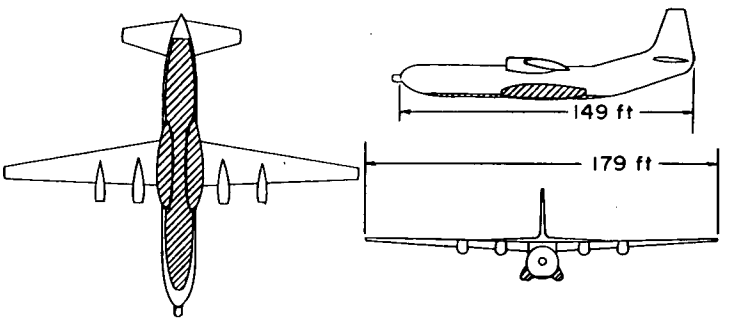

TABLE 33

SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT H

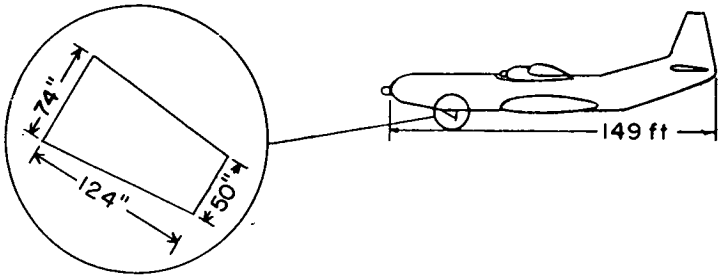
[Model scale, $\frac{1}{25}$; gross weight, 255,000 lb; center-of-gravity location, 25 percent M.A..C.; all values full scale]

(a) Without hydroflap.

Damage simulated by use of scale-strength parts (hatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
1	45	120	1, 270	2	½	u s h
5	0	155	1, 400	2½	1	s o
5	45	110	690	1½	1	u h
10	0	137	1, 490	2½	½	s
10	45	102	980	1½	½	u h
Damaged model						
1	45	120	570	2	1	b u h
5	0	155	810	5	1½	d_2 u h
5	45	110	580	3	1	b u h
10	0	137	740	5½	1	d_2 u h
†10	45	102	550	3	1	b u h

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
d_2 dived slightly—the model stopped abruptly in a nose-down attitude with the nose of the model submerged
h ran smoothly—the model made a very stable run
o oscillated—the model oscillated about the longitudinal or vertical axis
s skipped—the model rebounded from the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: With scale-strength fuselage bottoms installed, the model had a tendency to dive during the first part of the ditiching run, but recovered and ran smoothly. The landing-gear nacelles did not affect the ditching behavior. The fuselage is likely to flood rapidly and sink to the level of the wing.

TABLE 33—Concluded

†Recommended ditching attitude and flap setting.

Remarks: The damage sustained by the scale-strength sections was not severe in calm water ditchings.

TABLE 36

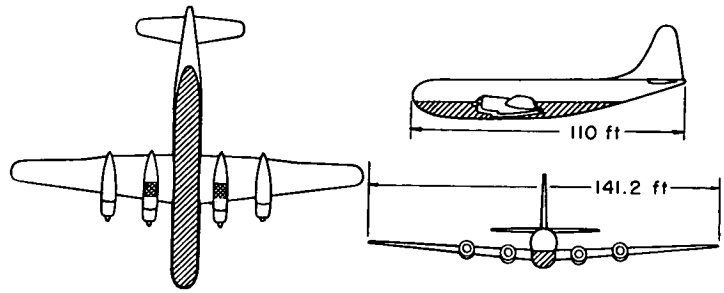
SUMMARY OF MODEL-DITCHING INVESTIGATION OF TRANSPORT K

[Model scale, $\frac{1}{24}$; gross weight, 160,000 lb; center-of-gravity location, 40 percent M.A.C.; all values full scale]

Damage simulated by use of scale-strength parts (hatched areas) and removal of other parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
1	45	90	450	1	1	u h
5	0	115	800	2	½	h
5	45	79	450	½	½	u h
9	0	96	600	1	½	h
9	45	72	450	1	½	h
Damaged model						
1	45	90	300	2½	1	b
†5	45	79	300	2	1	b h
9	45	72	300	2	1	b

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.



Remarks: The scale-strength sections did not sustain severe damage. Most damage usually occurred near the part of the fuselage that contacted the water first. It is likely that the cargo floor will not fail and that the interior of the airplane will be relatively safe in a ditching.

TABLE 37

SUMMARY OF MODEL DITCHING INVESTIGATION OF TRANSPORT L

[Model scale, $\frac{1}{20}$; gross weight, 130,000 lb; center-of-gravity location, 25 percent M.A.C.; all values full scale]

Damage simulated by use of scale-strength parts (hatched areas) and removal of other parts (crosshatched areas).

Landing attitude, deg	Flap setting, deg	Landing speed, knots	Length of run, ft	Maximum longitudinal deceleration, g units	Average longitudinal deceleration, g units	Motions of model (*)
Undamaged model						
3	45	109	650	2	1	u h
6	45	102	500	2	1	u h
9	0	129	800	3	1	u p
9	45	97	450	2	1	u o h
Damaged model						
3	45	109	400	3	1½	h
†6	45	102	400	4	1	p h
9	45	97	350	4	1	b h

*In this column, the letters indicate the following motions:
b ran deeply—the model settled deeply into the water with little change in attitude
h ran smoothly—the model made a very stable run
o oscillated—the model oscillated about the longitudinal or vertical axis
p porpoised—the model undulated about the transverse axis with some part of the model always in contact with the water
u trimmed up—the attitude of the model increased while running in the water
†Recommended ditching attitude and flap setting.

Remarks: The scale-strength sections sustained damage. The lower compartment of this airplane will probably fill with water. However, the strong cargo floor should provide protection for the upper deck and the low wing should provide enough buoyancy to give personnel time to escape.

REPORT 1348

GROUND SIMULATOR STUDIES OF THE EFFECTS OF VALVE FRICTION, STICK FRICTION, FLEXIBILITY, AND BACKLASH ON POWER CONTROL SYSTEM QUALITY[1]

By B. Porter Brown

SUMMARY

Tests have been made on a power control system by means of a ground simulator to determine the effects of various combinations of valve friction and stick friction on the ability of the pilot to control the system. Various friction conditions were simulated with a rigid control system, a flexible system, and a rigid system having some backlash. For the tests, the period and damping of the simulated airplane were held constant.

The results show that, when valve friction was present in a rigid system, the introduction of stick friction was beneficial in that it restored some of the quality lost because of the valve friction. When flexibility was introduced between the pilot and the source of stick friction, stick friction was still beneficial but, with flexibility between the source of stick friction and the valve, no benefits were obtained from stick friction. When backlash was introduced between the pilot and the source of stick friction, the valve-friction effect was not so objectionable as in the rigid system; stick friction improved this system still further. With backlash between the stick and the valve (± 0.025 inch at the valve), even the frictionless system was undesirable, and the addition of any combination of the frictions reduced the control quality still further.

INTRODUCTION

The ability of the pilot to control an airplane is dependent on a great number of control-system variables such as friction, backlash, and flexibility. Insofar as is known, no systematic study has been made to determine the effects of these variables. The National Advisory Committee for Aeronautics therefore has built a dynamic ground simulator for the purpose of such a study. In view of the large number of variables involved, it is doubtful that a precise definition of the optimum combination of these variables can be established; however, it is believed that the results will lead to a better understanding of each effect and may suggest some general design rules.

Previous investigations (for example, ref. 1) have shown that servocontrol-valve friction can reduce the quality of a power control system to such an extent that sensitivity problems and, in some cases, pilot-induced oscillations will result. It was suspected that the valve-friction effect is greatly dependent upon the mechanical characteristics of the linkages between the pilot and the valve such as static friction, flexibility, and backlash. Therefore, tests were made to study the effects of various ratios of valve friction to stick friction. The term "stick friction" is used hereinafter to denote the static friction in the mechanical parts of the system between the pilot and the valve. Various friction ratios were tested with a rigid control system, a flexible control system, and a rigid control system with backlash. For these tests the period and damping of the simulated airplane, the power-control time constant, the stick-force gradient, and the control-surface sensitivity were held constant. The results in this report are therefore limited to the fixed values of these parameters.

SYMBOLS

t	time, sec
α	angle of attack, deg
δ	control-surface deflection, deg
$\dot{\gamma}$	rate of change of flight-path angle, deg/sec
θ	attitude angle, deg
ζ	damping ratio
ω_n	natural frequency, radians/sec
D	differential operator, d/dt
$\left(\frac{\alpha}{\delta}\right)_0$	steady-state ratio of α to δ

APPARATUS

Figure 1 shows a photograph of the simulator used in the tests and figure 2 presents a schematic drawing of the simulator. The simulator consisted of a chair that was designed

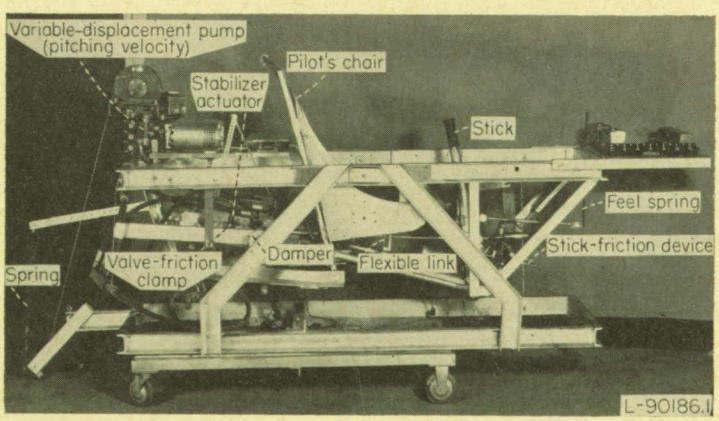


FIGURE 1.—Longitudinal power control simulator (Pitch chair).

[1] Supersedes NACA Technical Note 3998 by B. Porter Brown, 1957.

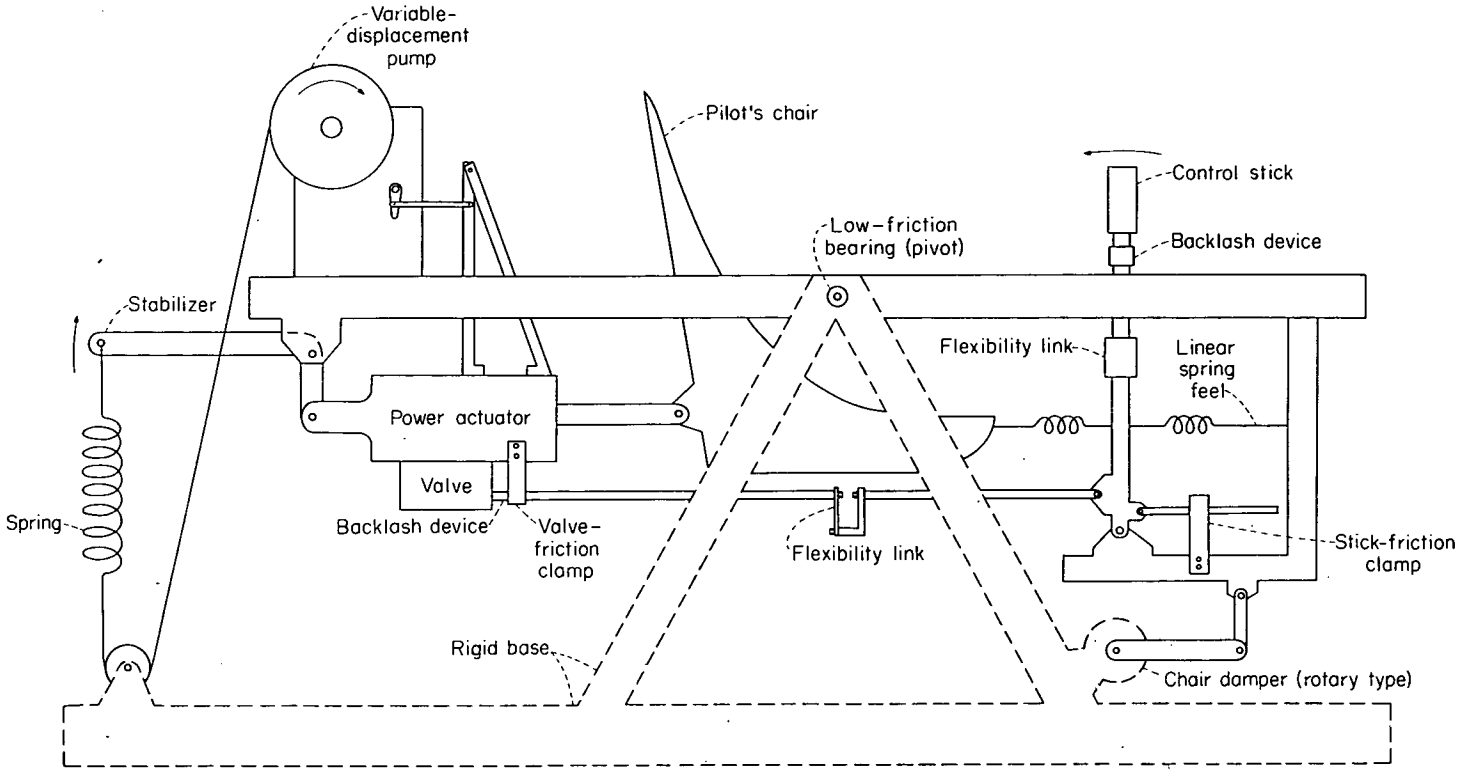

FIGURE 2.—Schematic drawing of simulator. Solid lines indicate movable parts. Arrows indicate direction of motion of stick, stabilizer, and pump drum associated with pull-up.

to pitch in response to control deflection. The pitching motion, which is closely associated with the short-period mode of an airplane, is expressed by the following equation:

$$\text{Chair angle}=\theta=\frac{\alpha}{\delta}\delta+\frac{\alpha}{\delta}\frac{\dot{\gamma}}{\alpha}\int_0^t \delta\, dt \qquad (1)$$

The term α/δ is the transfer function of a single-degree-of-freedom system with spring restraint and viscous damping. This transfer function may be written as follows:

$$\frac{\alpha}{\delta}=\left(\frac{\alpha}{\delta}\right)_0 \frac{{\omega_n}^2}{D^2+2\zeta\omega_n D+{\omega_n}^2} \qquad (2)$$

This expression neglects the effects of tail lift on the acceleration at the center of gravity. The term $\dot{\gamma}/\alpha$ is the transfer function relating rate of change of flight-path angle to angle of attack. If the tail lift and unsteady lift effects are neglected, this term is a constant for any given flight condition.

A slide-valve-type power control unit typical of those used in present-day fighter airplanes was installed to act as the driving unit to pitch the chair. The piston rod of the actuator was attached to the chair and the end of the cylinder body was attached to a spring through a bellcrank. As can be seen from figure 2, extension or retraction of the actuator moved the bellcrank. This bellcrank can be considered to be representative of an airplane's longitudinal control surface. Motion of this bellcrank δ, when multiplied by the transfer function α/δ, supplies the first term in equation (1).

A cable was attached to the other end of the spring and passed around a pulley connected to the rigid support. This cable was geared to a hydraulic motor which was driven by a variable-displacement pump. The input arm of the variable-displacement pump was mechanically linked to the output of the power control actuator. This linkage determines the steady-state value of the product $\frac{\alpha}{\delta}\frac{\dot{\gamma}}{\alpha}$ in equation (1). Since no followup system was attached to the variable-displacement pump, motion of the power control actuator not only moved the "tail surface" and caused an initial change in angle of attack but signaled the variable-displacement pump to rotate the drum at a rate proportional to the displacement of the power control actuator. Thus, the variable-displacement pump produces the integration of δ shown in equation (1). Since the variable-displacement pump also moves the chair through the same spring to which the power actuator is connected, the transfer function α/δ also appears in the second term of equation (1). The overall effect of the variable-displacement pump can be considered to represent the pitching motion associated with curvature of the flight path resulting from lift on the wing. As shown in figure 2, a rotary-type damper was used to provide damping to the chair. The short-period dynamic characteristics are adjustable so that any flight condition of any airplane can be simulated. For these tests, the airplane dynamics were held constant. A time history of the response characteristics of the chair and also the simulated response of angle of attack following a step stick deflection are shown in figure 3.

A control stick was mounted to the movable frame through a ball bearing and was connected directly to the control valve of the power control unit by a push-pull rod. The mechanical advantage between the stick and the valve (that

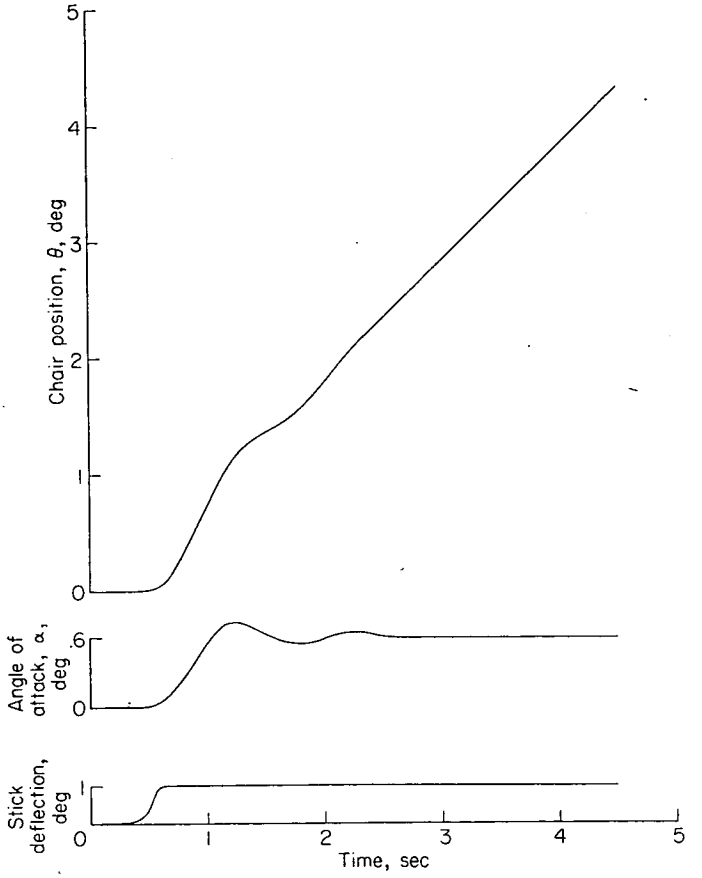

FIGURE 3.—Time history showing response of chair to step stick deflection.

is, the ratio between linear motion of the stick grip and the valve motion, the output being fixed) was about 4:1. The inertia of the stick and the push-pull rod was about 0.22 slug-feet^2 and the stick length was about 24 inches. The ratio between stick rotation and rotation of the output bellcrank δ was 1:5. Here again all attachment points were made as frictionless as possible. As indicated in figure 2, an adjustable friction clamp was used to vary the stick friction. A similar arrangement was installed on the control-valve stem so that valve friction could be varied.

For these tests a simple cantilever spring attached to the stick was used to provide the pilot with feel forces. This spring supplied linear forces with stick deflection; these forces resulted in a feel gradient of approximately 4 pounds per inch of stick displacement. No preload was provided in the feel device. The chair when disturbed would return to within 0.1 degree of its trim position. This condition was caused by the summation of the small amounts of friction in the main support bearings, the pulley, and the chair damper. The stick grip could be moved approximately ± 0.02 inch without causing any motion of the power control actuator. This dead spot in the stick motion was caused primarily by the dead spot in the control valve. The lost motion between the stick and the valve was not perceptible to the pilot. The flow-stroke characteristics of the valve were nonlinear, small deflections providing relatively slower control-surface rates. However, the time constant of the servo response was very short compared with the response time of the simulator and was not considered to be a significant factor in these tests. The control valve itself had some inherent friction which amounted to about 4 ounces in terms of stick force. This valve friction was eliminated for the zero-valve-friction tests by means of a small vibrator mounted on the valve stem as described in reference 2.

It should also be pointed out that the power control unit used incorporated a viscous damper on the valve for the purpose of eliminating valve chatter. This damper was not changed throughout the tests.

The light bulb, lens, and mirror were attached to the chair and arranged so that a spot of light was projected on a screen located in front of the pilot. Motions of the light spot indicated to the pilot the attitude angle of the chair. A second spot of light was also projected on the screen and was controlled by a cam. The cam-driven light spot moved from one vertical position to another on the screen, and the pilot attempted to make the light spot for the chair coincide with the cam-driven light spot.

Strain gages were mounted on the control stick to measure control forces, and slide-wire transmitters were used to measure stick position, chair angle, and cam position. These four quantities and time were continuously recorded on standard NACA recording instruments during the tests.

TESTS AND PROCEDURE

For these tests the dynamics of the simulator were adjusted to correspond approximately to those of a fighter airplane flying at an altitude of 10,000 feet and Mach number of 0.80. The period was set to be 1.0 second and the damping ratio, 0.45. The simulator was adjusted so that the stick deflection per degree of stabilizer deflection was made larger than its normal value to represent the gearing that would be provided by use of a mechanical-advantage changer in the airplane. With this arrangement, the steady-state ratio of angle of attack to stick deflection was approximately 0.60. The variable-displacement pump was adjusted to provide a steady-state value of about 1 degree per second per degree for the ratio of pitching velocity to stick deflection.

The pilots' task during the tests involved keeping the light spot for the chair lined up horizontally with the cam-driven light spot. The ease and precision with which the pilots could follow the cam-driven light spot provided the basis for the judging of the quality of the control system. In addition to the recorded data, the pilots' opinions were weighted heavily when the various configurations were evaluated.

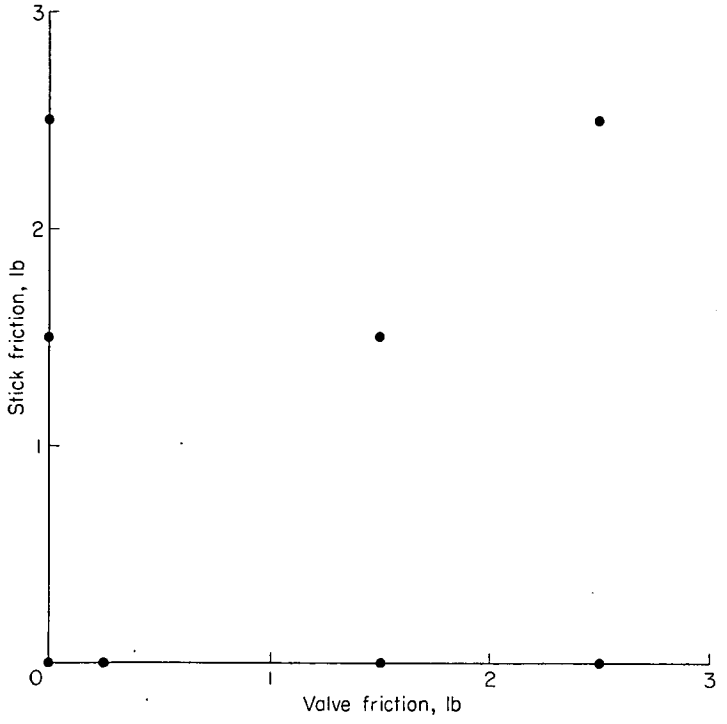
The friction conditions tested are shown in figure 4. All values of friction quoted in this report are given in terms of stick force. These conditions were tested with a rigid control system, a flexible control system, and a rigid control system having some backlash.

For each test configuration, at least two NACA test pilots obtained data.

RESULTS AND DISCUSSION

RIGID CONTROL SYSTEM

Examples of the data obtained are shown as time histories in figure 5 for various representative friction conditions.



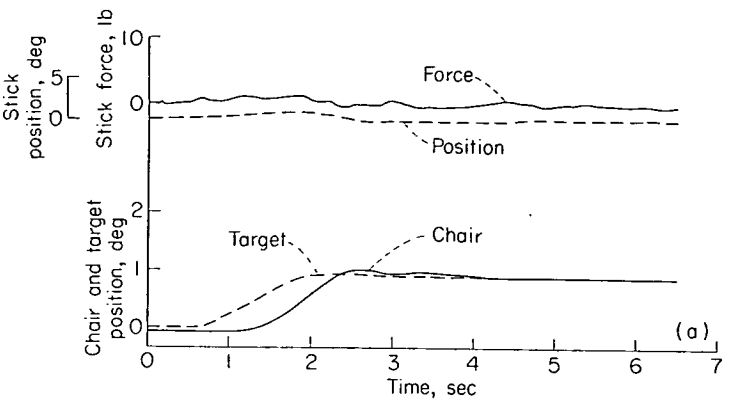


FIGURE 4.—Friction conditions tested.

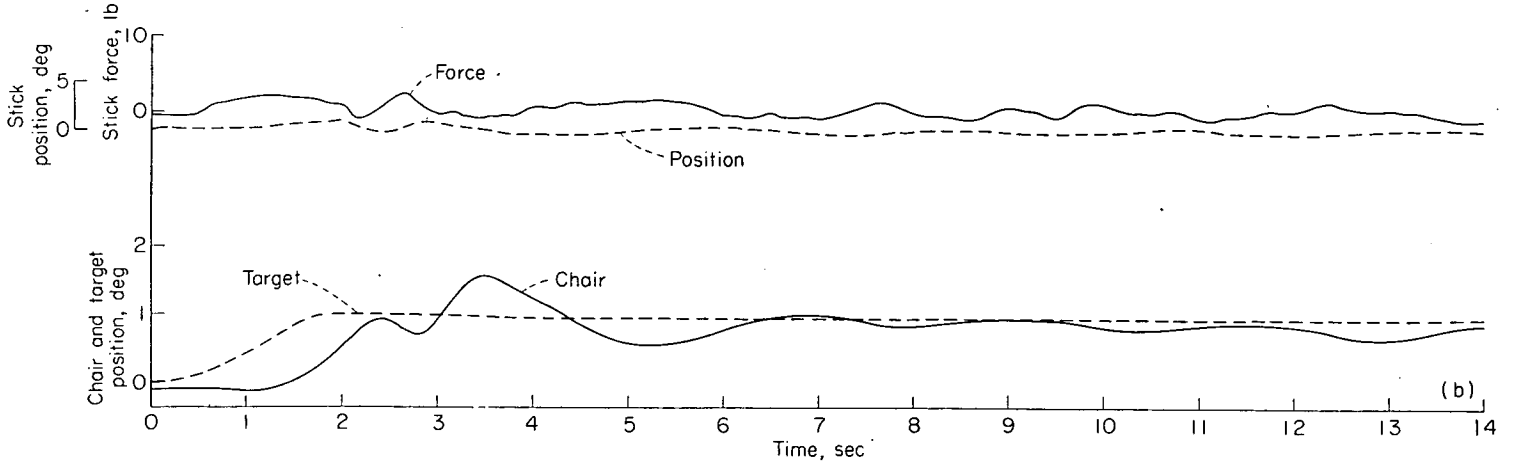
The quality of each configuration is indicated by the overshoots and oscillations in the chair record and also by the length of time required to make the chair record coincident with the target record. Coincidence of the two records indicates that the pilot was "on target."

Figure 5 (a) shows representative results obtained when the control system was essentially free of all friction. The absence of large overshoots and oscillations in addition to the relatively short length of time required to get on the target indicated that the pilot had little difficulty in performing the task. The pilots commented favorably on this system although they believed that the ½-pound limit of stick friction quoted in reference 1 would be necessary in flight. The small stick friction would be helpful in alleviating the small unintentional control inputs that may result from such things as the many duties of the pilot which momentarily divert his attention from the control of the airplane or rough-air conditions.



(a) No friction.

FIGURE 5.—Rigid control system.

Some tests were made with the vibrator removed from the valve stem. Without the vibrator the valve friction was about 4 ounces in terms of stick force. The pilots could not detect any effect of this small amount of friction and the records were very nearly identical to those shown in figure 5 (a). For this reason the tests with 4-ounce valve friction are not shown.

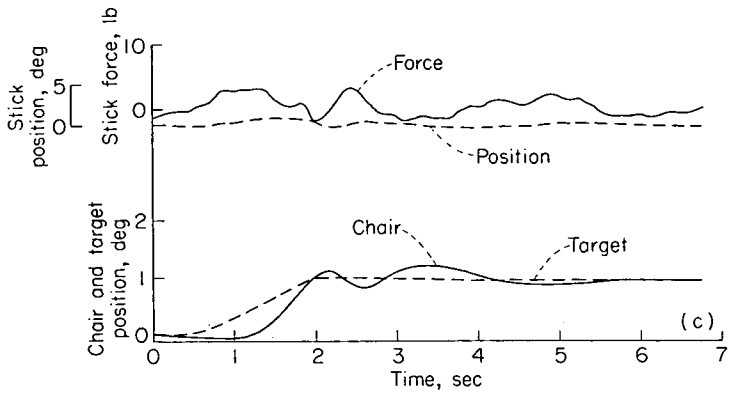


Figure 5 (b) shows the effects of 1½ pounds of friction in the control valve. The overshoots, oscillations, and the relatively long time required to get on the target are good indications of the amount of control system quality lost through the introduction of the valve friction. The latter portion of the record shows the extreme difficulties encountered in positioning the chair precisely on a given point. This effect has been measured in flight and is discussed in reference 1. During the simulator tests the pilots believed that 1½ pounds of valve friction were objectionable. They did not object on the grounds of the resulting increase in forces nor did they believe the system to be subject to violent pilot-induced oscillations. The objections were based simply on their inability to make fine corrections precisely and their feeling that the machine was flying the pilot.

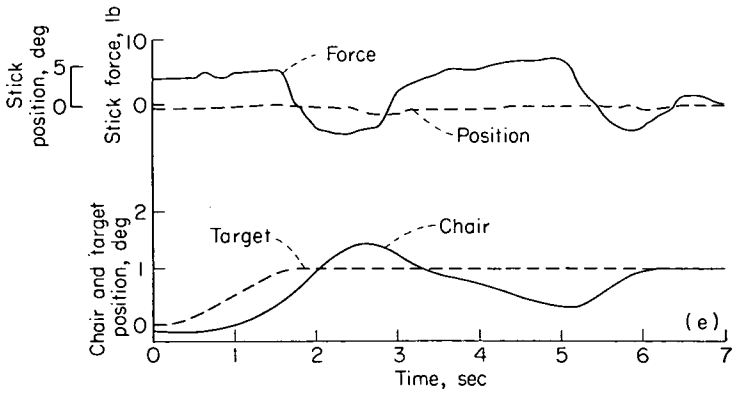
Figure 5 (c) shows the results obtained when the 1½ pounds of stick friction were used in conjunction with the 1½ pounds of valve friction. Although the total breakout force at the stick due to friction was increased, the overall performance

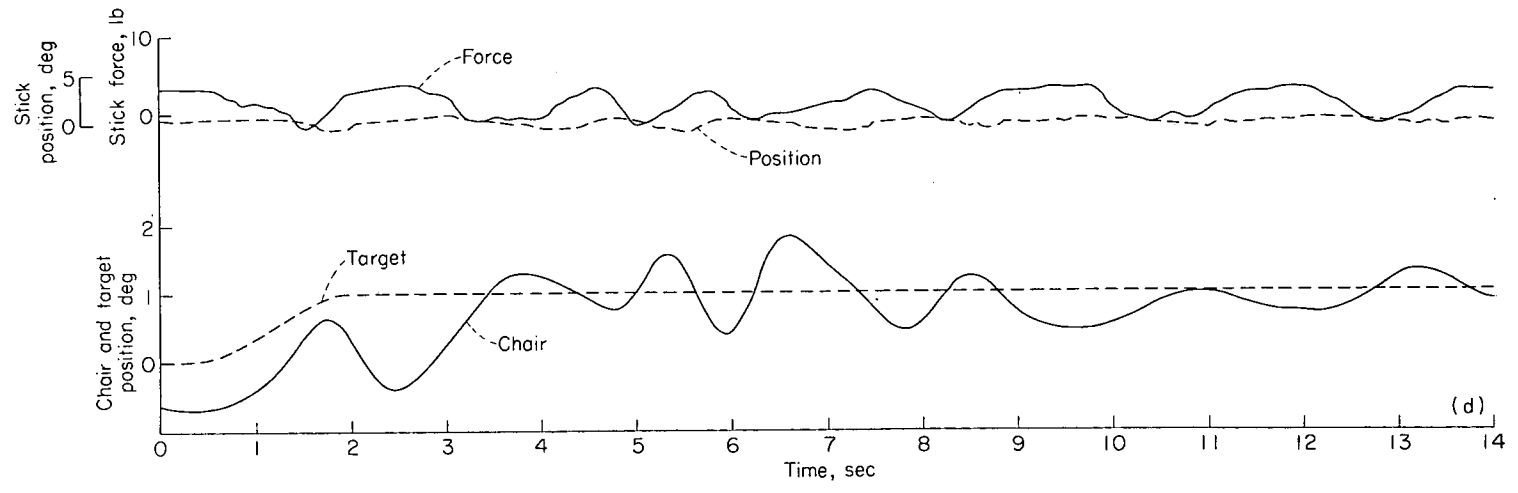


(b) 1½ pounds valve friction.

FIGURE 5.—Continued.

(c) 1½ pounds valve friction and 1½ pounds stick friction.
FIGURE 5. —Continued.

(e) 2½ pounds valve friction and 2½ pounds stick friction.
FIGURE 5.—Concluded.



was improved; the stick friction also restored the pilot's feeling that he had control of the machine. The stick friction locked the valve push-pull rod and thereby allowed the followup to return the valve to neutral.

Figure 5 (d) presents the results obtained with about 2½ pounds of valve friction. The records show that control through such a system is rather hopeless. The tendency for the chair amplitude to increase is a good indication of the actual danger associated with this amount of valve friction. It should be remembered that the simulator does not include the effects of rough air or the acceleration effects on the pilot or parts of the system. These factors which are present in flight will aggravate the oscillatory nature of the system and therefore will magnify the danger involved. The pilots noted that, even though these aggravating factors were absent in the simulator, the slightest distraction could very easily lead to violent pilot-induced oscillations. It seems safe to say that violent oscillations could be caused in flight by valve-friction values less than the 2½ pounds for the same flight conditions and stability parameters set up in the simulator.

Figure 5 (e) shows the results when 2½ pounds of stick friction were introduced in addition to the 2½ pounds of valve friction. Even though the figure shows that the pilot could get on the target, the large overshoots suggest difficulties that make precise control somewhat uncertain. The stick friction, however, was noticeably beneficial since the violent oscillatory tendencies were eliminated. The pilots verified these observations but objected to the system not only on the basis of precise control but also because of the amount of work involved. All pilots agreed that a total breakout force due to friction of about 3 pounds or less would be more desirable in flight for airplanes of the type being simulated.

Some tests were also made in which the valve friction was reduced to zero by means of a small vibrator and various amounts of stick friction were evaluated. The pilots could do a much better job with the highest stick friction tested (3 pounds) than they could with only 1½ pounds of valve friction. Actually, the best performance was achieved when the stick friction was in the range between ½ and 2 pounds and the pilots believed on the basis of these tests and on the basis of their previous experience that they would prefer such systems for actual flight.

Tests were also made in which the valve friction was held constant and the stick friction was varied. From these tests it was learned that, when valve friction was present, the best control quality was achieved when the stick friction was equal to or very slightly greater than the valve friction. An excess or deficiency in stick friction, however, resulted in some quality reduction; the system with more stick friction than valve friction was considered to be desirable provided

(d) 2½ pounds valve friction.
FIGURE 5.—Continued.

that the total breakout force due to friction did not exceed 3 pounds.

The results thus far discussed have been condensed into a plot of stick friction against valve friction (fig. 6) which shows the good, tolerable, and unsatisfactory combinations of these two types of friction. It should be pointed out that the conditions rated unsatisfactory were, in general, flyable but would be very objectionable from a precision control standpoint and would be very tiring to the pilot over long periods of time. Even though the figure shows that good performance can be obtained with as much as 1 pound of valve friction and 1 pound of stick friction, the designer should strive to decrease the valve friction as much as possible. This decrease would result in a smaller total friction force and a better performing control system. This point is extremely difficult to show graphically and no attempt was made to do so in figure 6; however, it is worth mentioning because the tests indicated that, as the system approached the condition of pure stick friction, performance and pilot impression improved.

Another point that should be brought out is that figure 6 applies only to the conditions of the tests and would not be expected to apply if other devices such as valve centering springs were used to attempt to compensate for the valve friction.

FLEXIBLE CONTROL SYSTEM

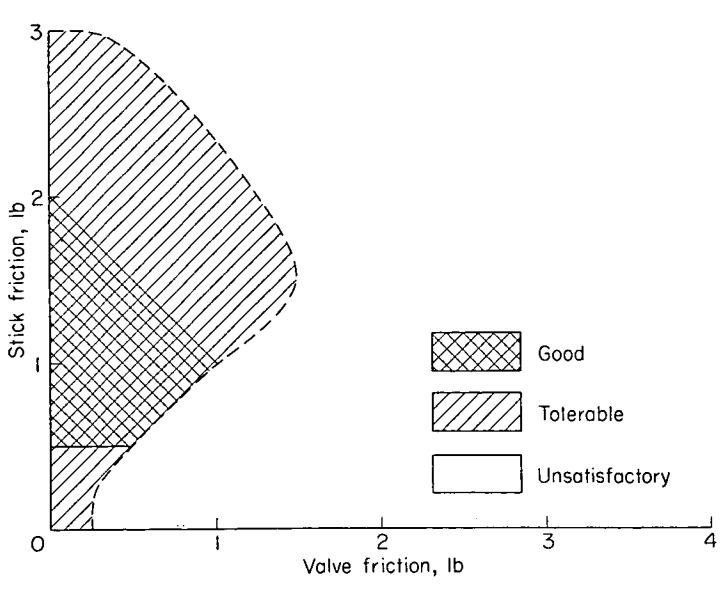
Since this report is concerned primarily with the effects of friction, the complete effects of flexibility are not treated here. Subsequent tests should be made to determine the effects of various combinations of flexibility and valve friction on control quality. Limited tests on flexibility are included in this report to illustrate the effect that it produces when introduced in the presence of stick friction and valve friction.

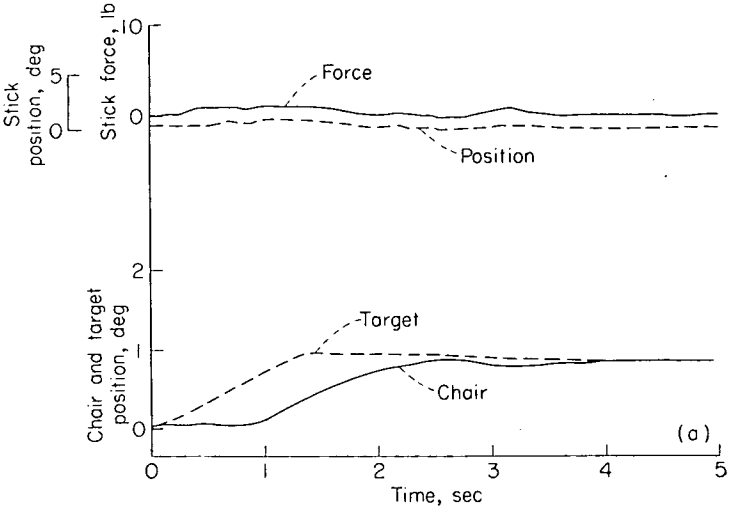
The rigid push-pull rod connecting the stick to the control valve was modified to include a flexible link to simulate a flexible control system. This modification also placed the flexibility between the feel device and the valve. The spring constant of the flexible link was set to a low value (4 pounds of stick force per degree of stick angle) so that the effect would be easily recognized. The same type of tests and friction conditions as described in the previous section were evaluated and representative records of these tests are presented in figure 7.

Figure 7 (a) shows the results with a frictionless system, and the similarity between figure 7(a) and figure 5 (a) shows that the flexibility had little or no effect. The pilots agreed that the flexibility was not detectable in this condition and therefore they rated this system the same as the rigid system. Here again the system was tried with 4 ounces of valve friction. The pilots believed that the friction effect was a little more noticeable in the flexible system than in the rigid system but they still considered the configuration to be tolerable. The flexibility magnifies the undesirable valve friction effect by allowing the valve to "motor" the control surface through a certain range, dependent on the amount of valve friction, by deflecting the flexible link. Also, the forces which the pilot applies in attempting to compensate for the motoring must be transmitted to the valve through the flexible link. When valve friction is present, therefore, the valve will not move until the pilot's force has deflected the flexible link to the point at which the spring force in the link overcomes the valve friction.

Figure 7 (b) shows the difficulties introduced by 1½ pounds of valve friction in conjunction with the flexibility. Even though figure 7 (b) does not differ much from figure 5 (b), an overall comparison of all the records obtained showed that the flexibility caused a very definite reduction in control quality. The pilots remarked that pilot-induced oscillations were possible with this system; however, they felt that such oscillations could be controlled somewhat by intense concentration. The skill and experience of the pilots involved in these tests were believed to be important factors in the prevention of violent oscillations with this system.

Figure 7 (c), which shows the results for 1½ pounds of stick friction and 1½ pounds of valve friction, proves that stick friction is not beneficial when flexibility exists between





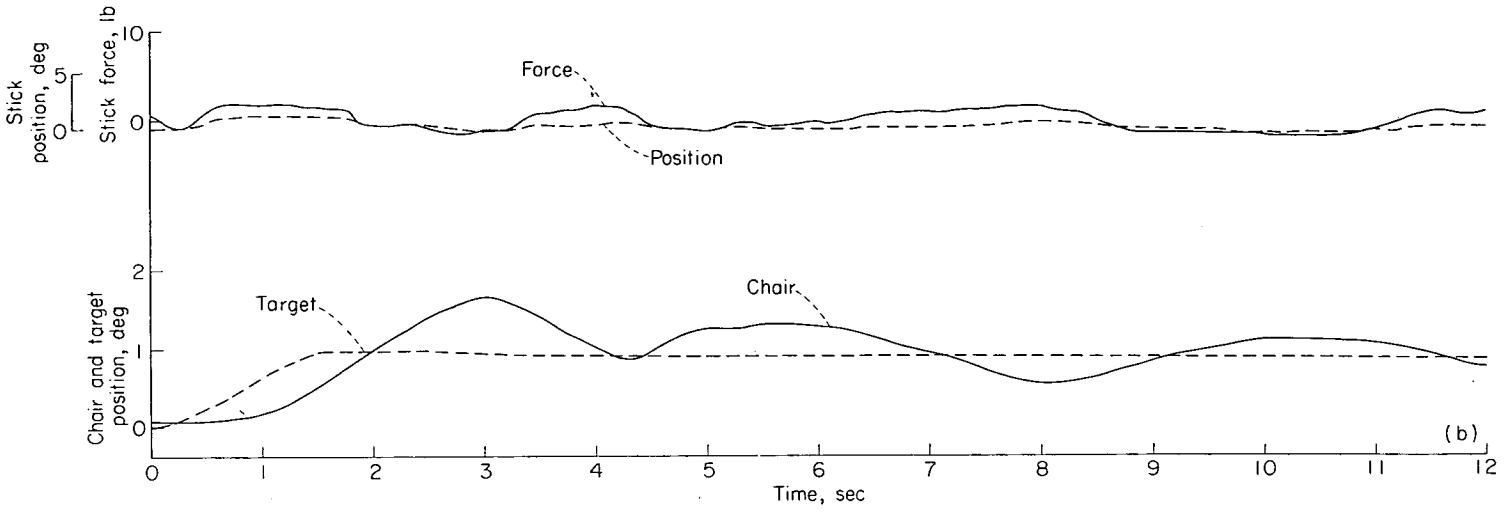


FIGURE 6.—Combinations of valve friction and stick friction for rigid control system.

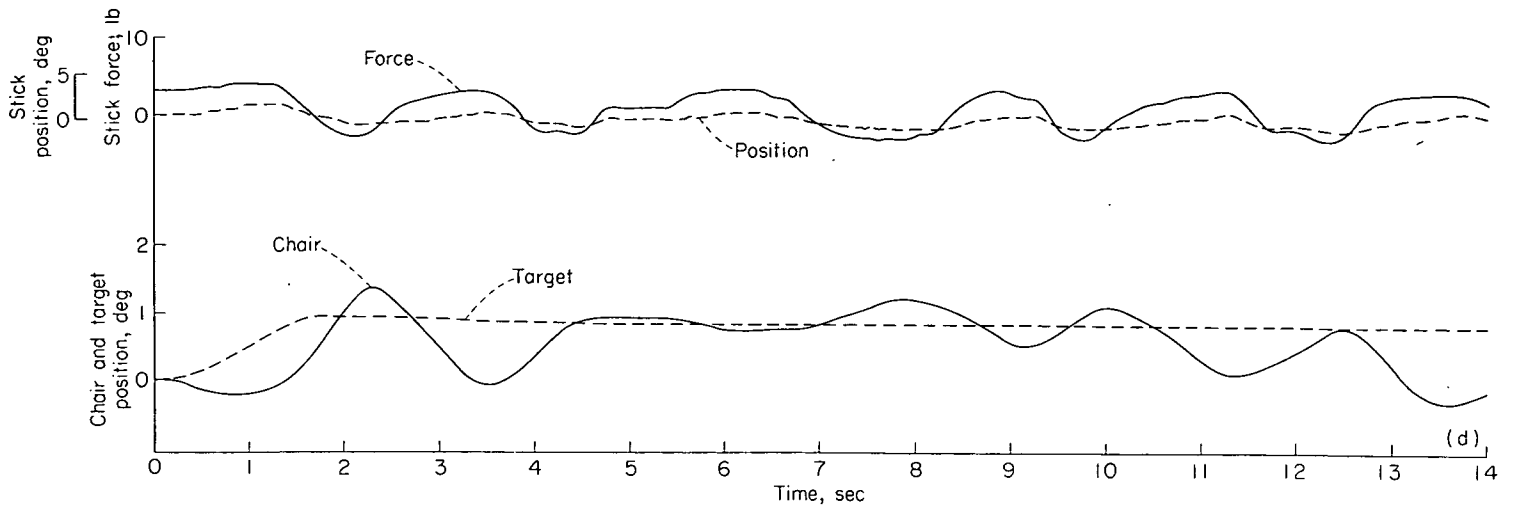
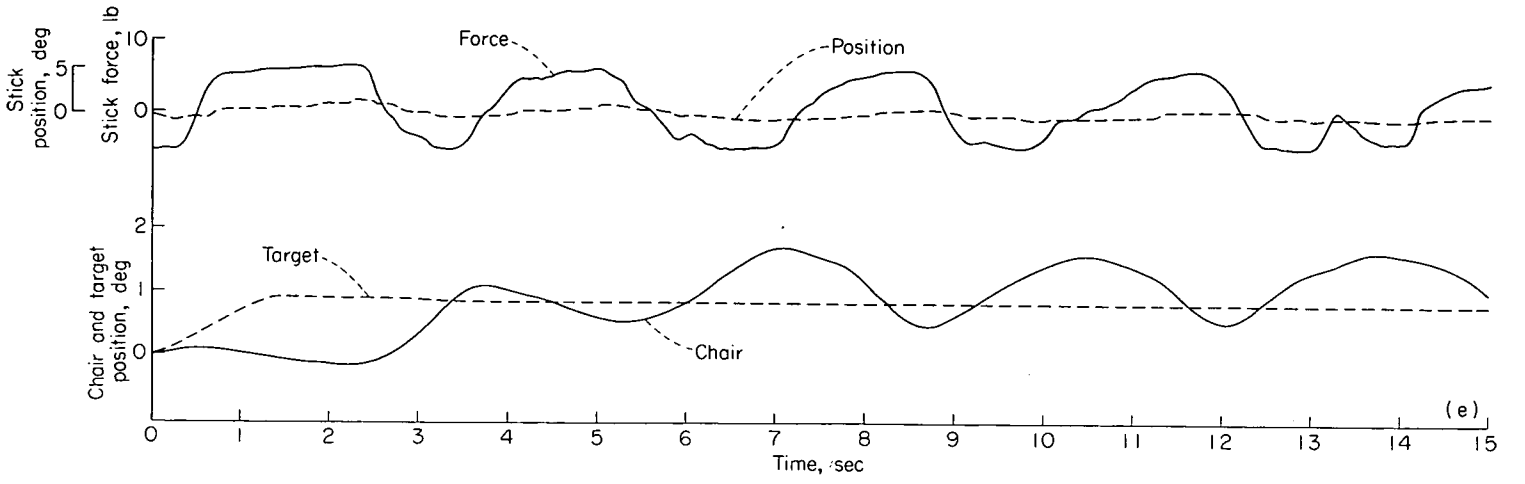
FIGURE 7.—Continued.



(c) 1½ pounds valve friction and 1½ pounds stick friction.
FIGURE 7.—Continued.



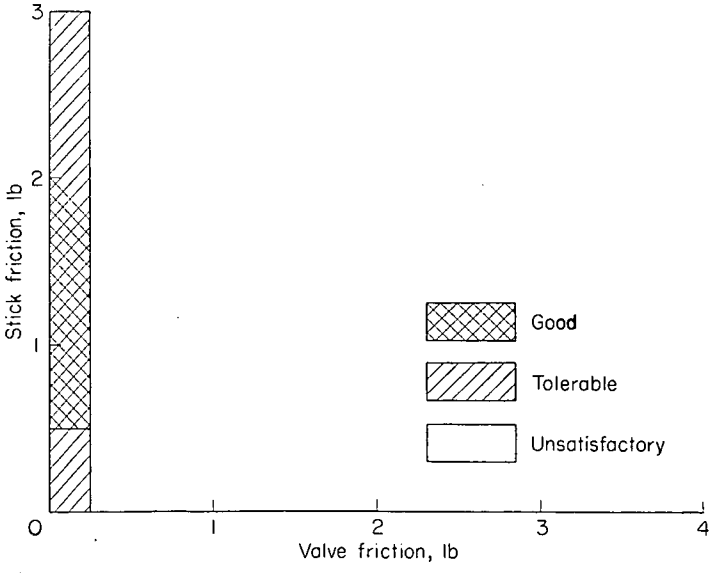
the stick and the control valve. In fact, the overall performance with this system seemed to be worse than that obtained with valve friction alone, and the pilots noted that the stick friction removed the small amount of control confidence that was present in the system with valve friction only. This result is understandable since the stick is no longer rigidly connected to the valve because of the flexible link; thus, the stick friction is prevented from "locking" the control push-pull rod and the valve is allowed to center itself. Stick friction in such a system only reduces the quality still further by causing a nonlinear relation between the stick force and stick motion. It is interesting to note that pilots having considerable experience in controlling systems involving valve friction alone can more or less cope with the difficulties and produce surprisingly good performance although they invariably comment that such systems are unsatisfactory. It is believed that these pilots are successful because they change their technique of flying, as explained in reference 1, from force consciousness to position consciousness because valve friction destroys the relationship between force application and control-surface position. This method of changing techniques is not successful, however, when flexibility is introduced in the presence of valve friction because the flexibility destroys the relationship between the stick position and the control-surface position.

Figure 7 (d) presents the results obtained with 2½ pounds of valve friction and figure 7 (e) shows the results obtained with 2½ pounds of stick friction and 2½ pounds of valve friction. The performance of both systems appears to be similar in that precise control is impossible; the pilots remarked that both systems were extremely susceptible to violent oscillations and they could not detect any benefits from the stick friction.

Figure 8 shows the ranges of good, tolerable, and unsatisfactory combinations of stick friction and valve friction when flexibility exists between the stick and the valve. This figure applies only to cases in which the flexibility is the same as that quoted previously. No doubt the limits will change depending upon the amount of flexibility present; however, the figure shows the detrimental effect on control quality since with this amount of flexibility only 4 ounces of valve friction could be tolerated.

(d) 2½ pounds valve friction.
FIGURE 7.—Continued.

(e) 2½ pounds valve friction and 2½ pounds stick friction.
FIGURE 7.—Concluded.



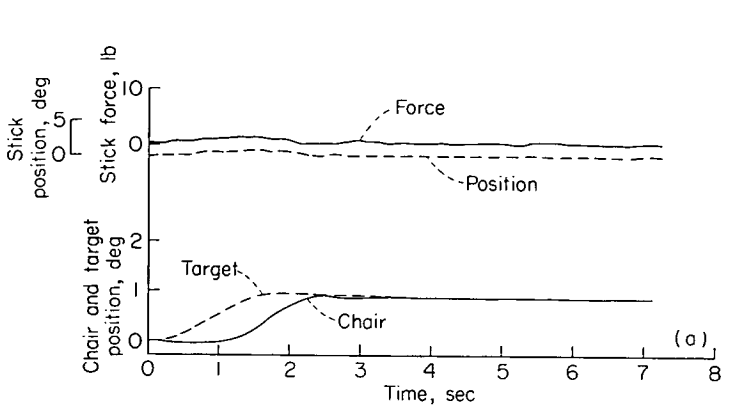


FIGURE 8.—Combinations of valve friction and stick friction with flexibility between the stick and the valve.

The control stick was modified to include a flexible link to simulate flexibility between the pilot and the point at which stick friction was applied. This modification also placed the flexibility between the pilot and the feel spring. The amount of flexibility in this system was the same as was introduced between the stick and valve. The stick was again connected to the control valve by means of a rigid push-pull rod.

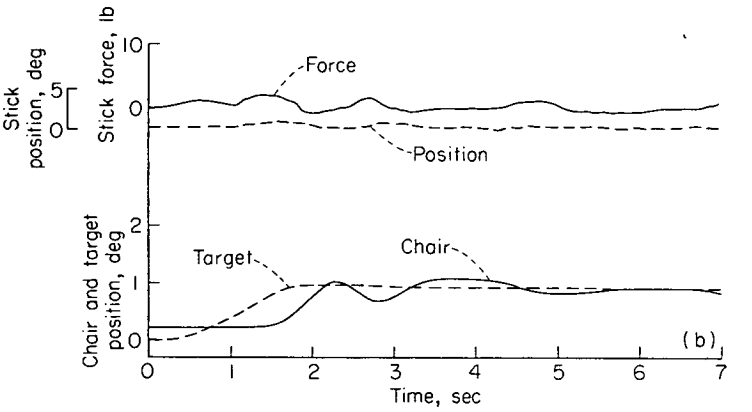

Figure 9 (a), which represents a frictionless system, shows no large differences from the rigid system of figure 5 (a) and the pilots could not feel any effects of the flexibility.

Figure 9 (b) presents the results with 1½ pounds of valve friction. Comparison with figure 5 (b) shows that a little less difficulty was encountered with this system than was experienced with the rigid system. The pilots' complaints, however, were very similar to those regarding the rigid system with 1½ pounds of valve friction in that precise control was difficult but violent oscillations were not probable.

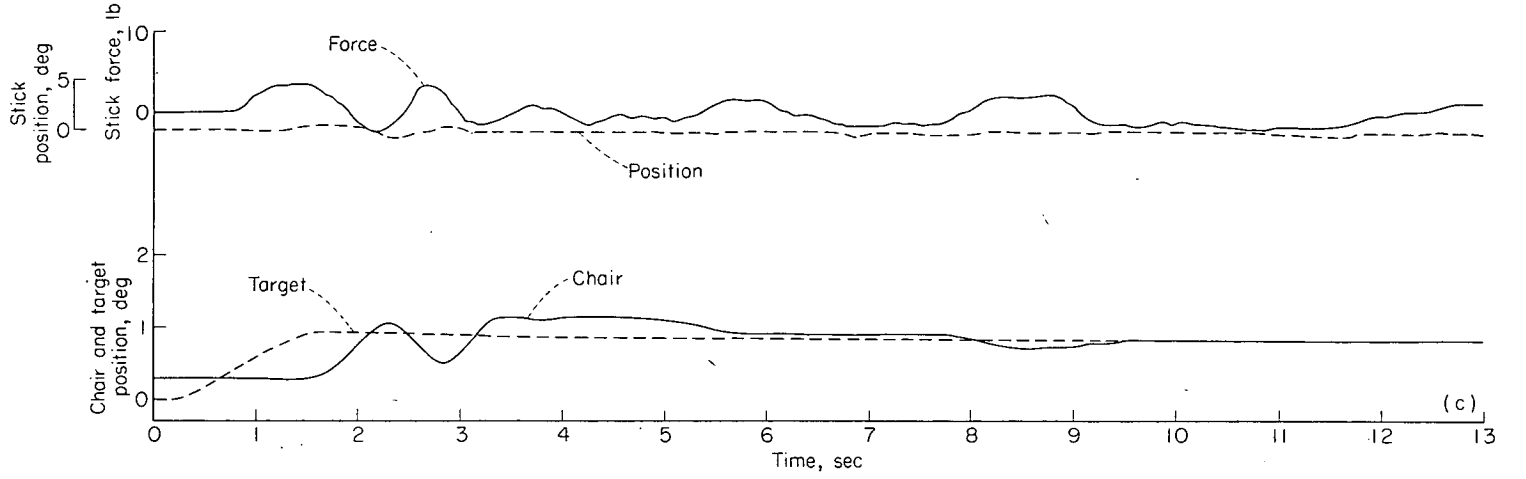

Figure 9 (c) shows the results of 1½ pounds of stick friction

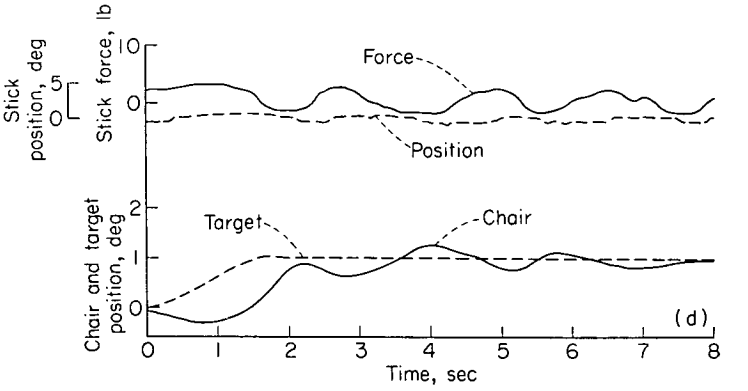
(a) No friction.

(b) 1½ pounds valve friction.

(c) 1½ pounds valve friction and 1½ pounds stick friction.

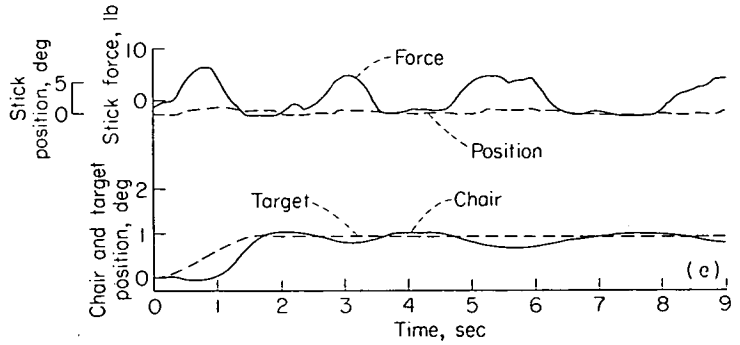
FIGURE 9.—Flexibility between the pilot and the stick friction.



and 1½ pounds of valve friction. This figure shows that, in spite of the increase in breakout force, the performance is very similar to that shown in figure 9 (b). The pilots, however, stated that the stick friction was helpful in restoring their feeling of control and therefore they rated this system above the system represented by figure 9 (b).

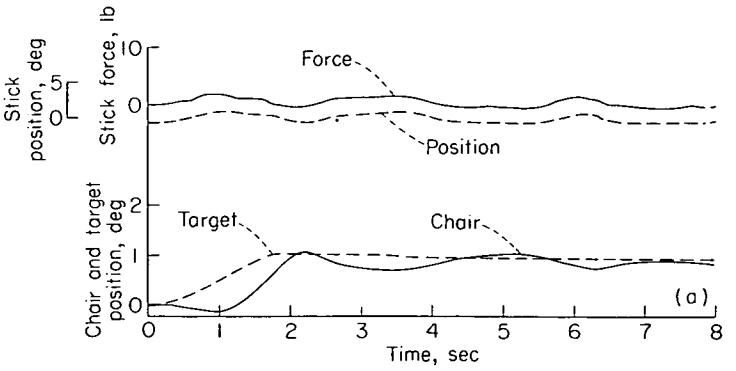
The effect of 2½ pounds of valve friction, which is shown in figure 9 (d), was to cause the system to be subject to violent oscillations and to make precise control impossible. Comparison of figure 9 (d) with figure 5 (d) shows that the valve-friction effect was, however, not so severe as that obtained with the original rigid control system. The addition of 2½ pounds of stick friction, shown in figure 9 (e), did not improve the precise control of the system. It did, however, restore the pilots' feelings of being able to prevent any violent oscillations.

No attempt was made to establish limits, as was done in figures 6 and 8, because, as mentioned previously, more detailed tests are needed to do so. Comparison of figures 7 and 9 does show, however, the importance of the location of the flexibility when valve friction is present. The pilots commented that flexibility between the pilot and the source of stick friction is far more tolerable from the pilots' standpoint than flexibility between the source of stick friction and the valve. In practice, this result means that stick friction can be beneficial even in a flexible system if the equivalent stick friction (friction between the valve stem and airplane structure) is introduced very close to the power control unit. Also, the feel device should be located between the source of flexibility and the valve.



CONTROL SYSTEM WITH BACKLASH

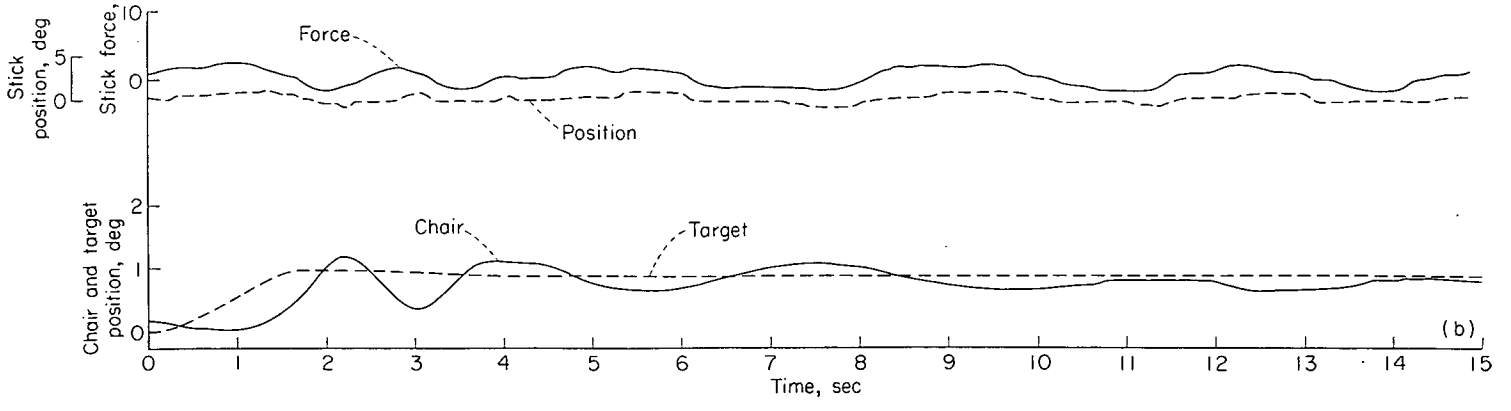
As in the case of the flexibility tests, the limited results regarding backlash are included in this report to show the general effects of backlash when introduced between the



(d) 2½ pounds valve friction.

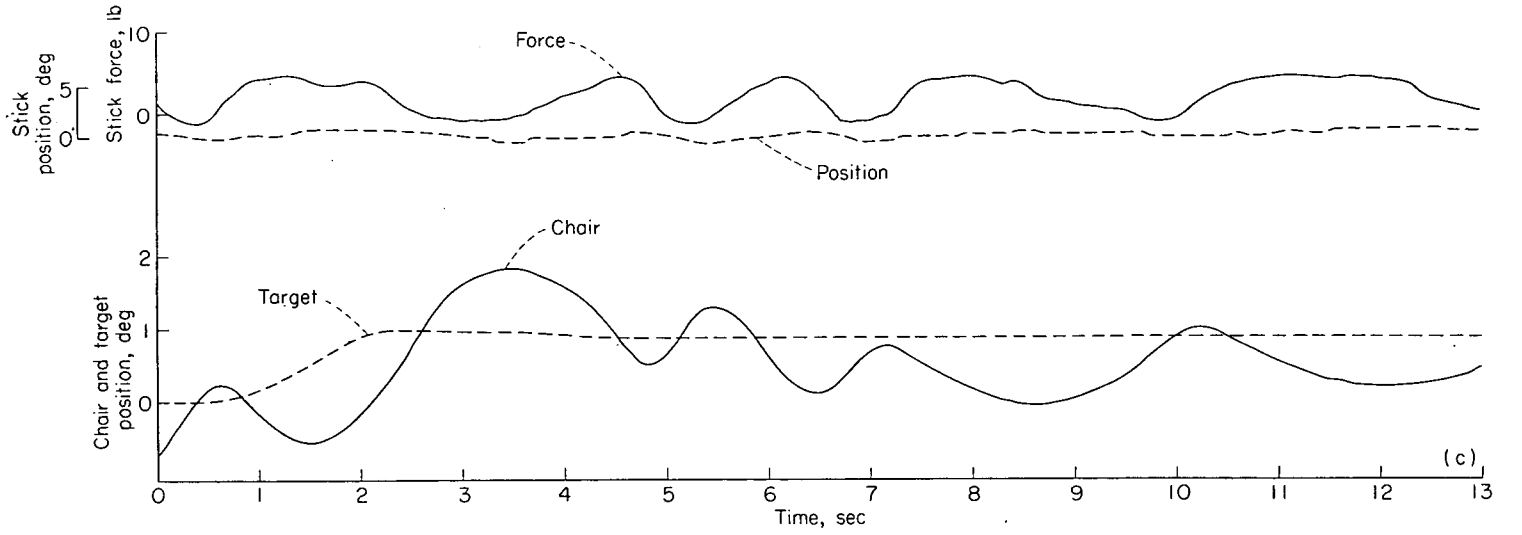
FIGURE 9.—Continued.

(e) 2½ pounds valve friction and 2½ pounds stick friction.
FIGURE 9.—Concluded.



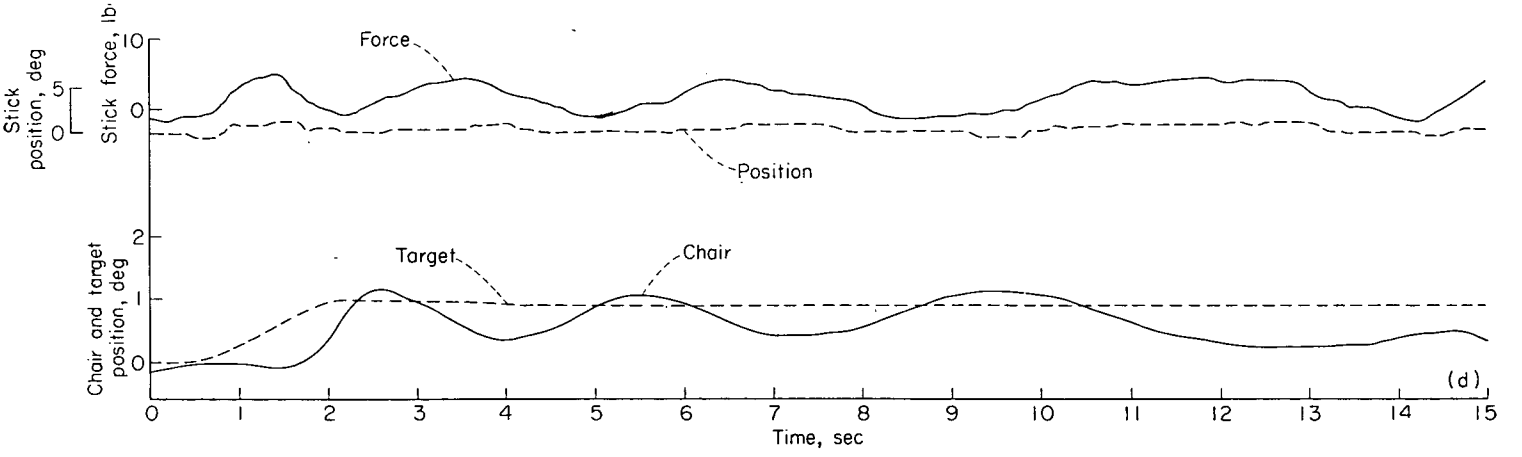
(a) No friction.
FIGURE 10.—Backlash between the stick and valve.

control stick and the valve and also between the pilot and the source of stick friction. The points at which the backlash was introduced are shown in figure 2.

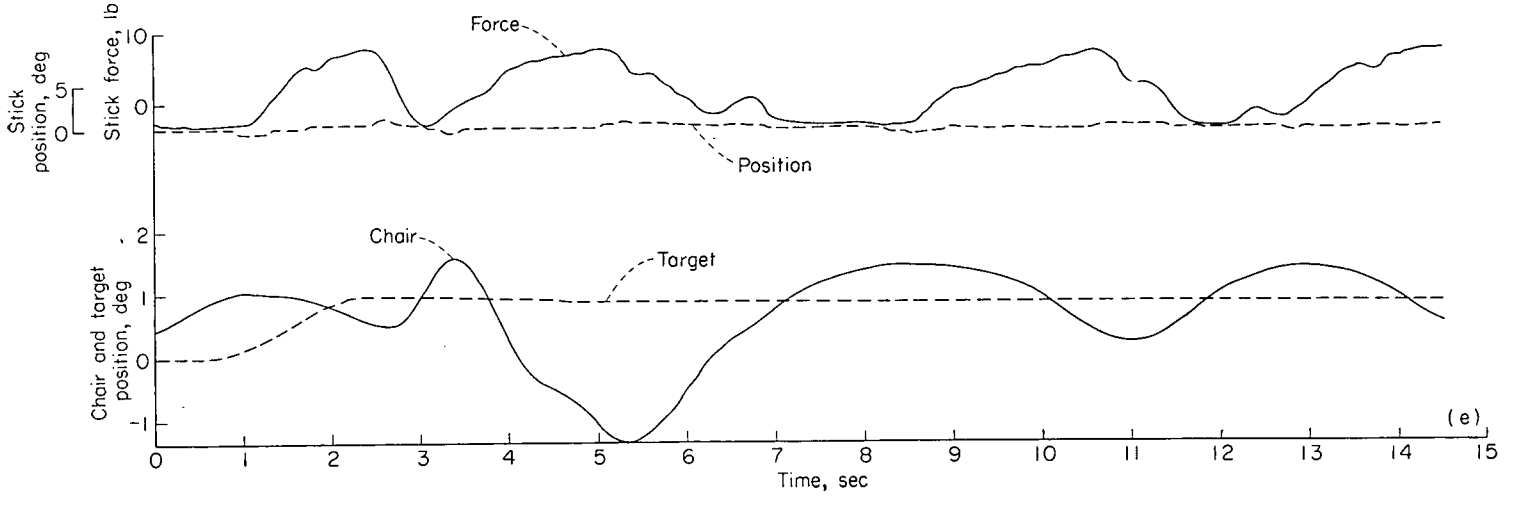


The push-pull rod connecting the stick to the valve was modified so that there was about ±0.025 inch of backlash, in terms of valve motion, between the stick and the valve. This modification also placed the backlash between the feel device and the valve. This backlash amounted to about ±0.10 inch of motion at the stick grip.

Figure 10 shows time histories of the effect of backlash between the stick and the valve for various friction conditions. These figures show that, even with a frictionless system, the pilots could not position the chair precisely and, as the breakout force was increased, the control quality deteriorated. The pilots noted that, even with the frictionless system, precise control was difficult and, as the valve friction was increased, the danger of oscillating became more pronounced. Stick friction also produced the same results but the pilots believed that the stick-friction effect was not so objectionable as the valve-friction effect. The important point is that none of the conditions were even tolerable with this amount of backlash at the valve.



The backlash between the stick and the valve was then removed and the same amount of backlash was introduced between the pilot and the point at which the stick friction was applied. This modification also placed the backlash between the pilot and the feel spring. The results from these tests are presented in figure 11. The frictionless system, as shown in figure 11 (a), was not too difficult to control even though the pilots could feel the backlash in the stick. With 1½ pounds of valve friction (fig. 11 (b)), the system performance was very similar to, but possibly a little better than, the original rigid control system with the same friction condition. Precise control was difficult but the system showed no tendency to produce violent oscillations. It should be remembered that this same friction condition when coupled with backlash between the stick and the valve produced a very dangerous system that was susceptible to severe oscillations. With backlash between the pilot and the source of stick friction, the stick friction improved the system. (See fig. 11 (c).) Even though the initial overshoot tended to be larger, the pilot could position the chair on the target. This improvement is in direct contrast to the detrimental effects of stick friction when the backlash was between the stick and valve. Figure 11 (d) shows the results of 2½ pounds of valve friction and figure 11 (e) shows 2½ pounds of valve friction and 2½ pounds of stick friction.



(b) 1½ pounds valve friction.
FIGURE 10.—Continued.

(b) 1½ pounds valve friction.

FIGURE 11.—Continued.

(c) 1½ pounds valve friction and 1½ pounds stick friction.

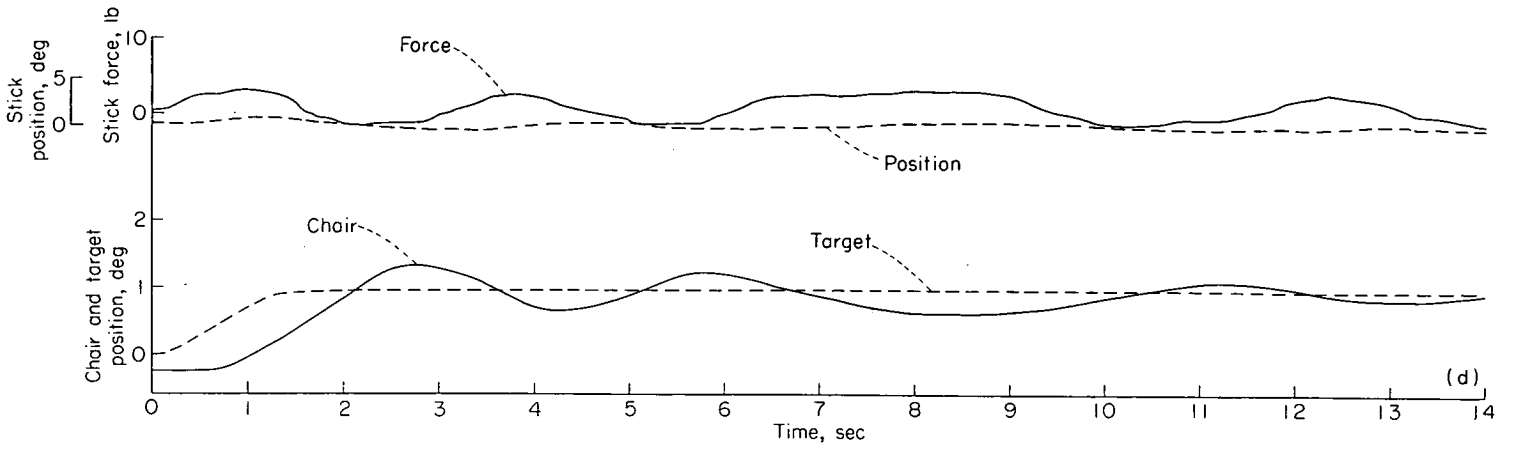

FIGURE 11.—Continued.

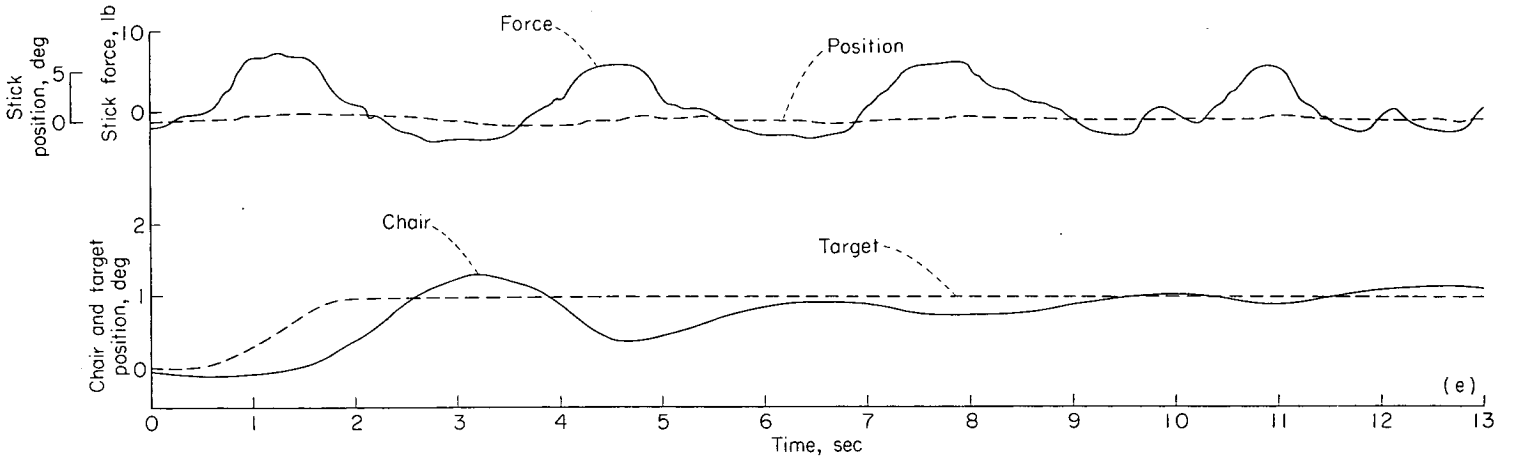
In each case the performance shows that no violent oscillations were ever encountered although precise control was extremely difficult. The pilots commented that with valve friction the system was subject only to mild oscillations and this tendency was completely removed by the addition of stick friction. These observations lead to the conclusion that the backlash between the pilot and source of stick friction is not nearly so dangerous as the backlash between the stick and the valve. In fact, the records and comments regarding the backlash between the pilot and stick friction indicate that valve friction was not so detrimental to this system as it was to the rigid control system with comparable friction conditions. It was noticed during the tests of the rigid system with valve friction alone that the pilots, when they wished to stop the chair motion, applied the necessary opposite force in a jerking manner that resulted in an instantaneous "kick" on the push-pull rod which centered the valve. It is possible that, with the backlash between the pilot and the source of stick friction, the stick acted as a convenient "hammer," within the backlash range, with which the pilots tapped the control rod to break the valve friction. More detailed tests are required, however, to establish a more definite explanation for the behavior of backlash in this particular location.

CONCLUSIONS



Tests have been made with a ground simulator incorporating a power control system. The purpose of the tests was to determine the effects of various combinations of valve friction and stick friction on the ability of the pilot to control the system. Various friction conditions were simulated with a rigid control system, a flexible system, and a rigid system having some backlash. From these tests the following conclusions can be drawn:

1. When valve friction is present in a rigid control system, stick friction is beneficial in restoring some of the quality lost because of the valve friction. The optimum quality is achieved when the stick friction is equal to or slightly greater than the valve friction measured at the stick.

(d) 2½ pounds valve friction.

FIGURE 11.—Continued.

(e) 2½ pounds valve friction and 2½ pounds stick friction.

FIGURE 11.—Concluded.

2. The total breakout force due to friction should not exceed 3 pounds in terms of stick force. Control-system quality improves as the valve friction is reduced; however, reducing the valve friction below 4 ounces did not yield any significant improvement.

3. When flexibility existed between the valve and the source of stick friction, the undesirable effects of valve friction were magnified by the flexibility, and the introduction of stick friction reduced the quality still further.

4. When flexibility was introduced between the pilot and the source of stick friction, stick friction was again beneficial in restoring some quality lost because of the valve friction.

5. With backlash between the stick and valve (±0.025 inch at the valve), precise control was difficult even with the frictionless system, and the quality deteriorated as valve friction or stick friction was increased.

6. With backlash between the pilot and the source of stick friction, the valve-friction effect was not as objectionable as it was in the rigid system, and the introduction of stick friction improved the system still further.

REPORT 1349

A LOW-SPEED EXPERIMENTAL INVESTIGATION OF THE EFFECT OF A SANDPAPER TYPE OF ROUGHNESS ON BOUNDARY-LAYER TRANSITION [1]

By Albert E. von Doenhoff and Elmer A. Horton

SUMMARY

An investigation was made in the Langley low-turbulence pressure tunnel to determine the effect of size and location of a sandpaper type of roughness on the Reynolds number for transition. Transition was observed by means of a hot-wire anemometer located at various chordwise stations for each position of the roughness. These observations indicated that when the roughness is sufficiently submerged in the boundary layer to provide a substantially linear variation of boundary-layer velocity with distance from the surface up to the top of the roughness, turbulent "spots" begin to appear immediately behind the roughness when the Reynolds number based on the velocity at the top of the roughness and the roughness height exceeds a value of approximately 600.

At Reynolds numbers even slightly below the critical value (value for transition), the sandpaper type of roughness introduced no measurable disturbances into the laminar layer downstream of the roughness. The extent of the roughened area does not appear to have an important effect on the critical value of the roughness Reynolds number.

INTRODUCTION

An extensive correlation of transition data for individual three-dimensional roughness particles was made by Loftin in reference 1. This correlation was made in terms of a local roughness Reynolds number based on the roughness height and the velocity at the top of the roughness, a form suggested by Schiller in reference 2 and employed by Tani in reference 3. Reasonably consistent values of the critical roughness Reynolds number were obtained by Loftin in reference 1, so long as the roughness was sufficiently submerged in the boundary layer to provide a velocity variation that was substantially linear with distance from the surface up to a height equal to the height of the roughness. Schwartzberg and Braslow in reference 4 showed that this critical value of the roughness Reynolds number was not greatly increased, even when the boundary layer was stabilized to small two-dimensional disturbances by the application of area suction. Similar correlations were obtained by Klebanoff, Schubauer, and Tidstrom (ref. 5).

The difference in character for transition as caused by three-dimensional roughness (spheres cemented to the surface) from that caused by two-dimensional roughness (full-span cylindrical wire laid on the surface parallel to the leading edge) is clearly shown by Klebanoff, Schubauer, and Tidstrom in reference 5. Most of the recent data dealing with the effects of two-dimensional roughness on boundary-layer transition have been summarized by Dryden (ref. 6) for the case of zero pressure gradient in the form of curves of the ratio of the transition Reynolds number in the presence of roughness to the transition Reynolds number for the model smooth plotted against the ratio of the height of the roughness to the boundary-layer thickness. In this type of plot, the assumption is made that transition will occur some distance downstream of the roughness and will gradually approach the roughness position as the Reynolds number is increased.

The data of reference 1 suggested, and those of reference 5 confirmed, the conclusion that three-dimensional roughness elements either had no effect on the boundary layer (subcritical condition) or, within a very narrow range of either speed or height of roughness, caused transition to move substantially up to the element itself.

A remaining problem is the question of the proper criterion for the effects of roughness when interaction between the elements is a possibility, as, for example, in the case of randomly distributed roughness. Such randomly distributed roughness corresponds to the practical case where the leading edge of the wing may in effect become sand blasted or covered with a sandpaper type of roughness. In this connection, it may be noted that the results of tests of airfoils with roughened leading edges (refs. 7 and 8) appeared to indicate the possibility that such roughness would have an effect on the airfoil characteristics only when the Reynolds number based on the roughness height and the free-stream velocity exceeded a critical value which seemed to be independent of the roughness size and the size and shape of the airfoil. It is not apparent that such a criterion is consistent with the concept of a constant critical value of the local roughness Reynolds number based on the velocity at the top of the roughness.

The present experiments were carried out for the purpose of determining the transition-triggering characteristics of such three-dimensional roughness particles when the roughness particles are randomly distributed in a close pattern such as in a sandpaper type of roughness, as well as of examining the relation between the two previously mentioned three-dimensional roughness criteria. It was also desired to obtain the necessary experimental information in such a way

[1] Supersedes NACA Technical Note 3858 by Albert E. von Doenhoff and Elmer A. Horton, 1956.

Preceding Page Blank

as to show the details of the transition phenomenon more clearly than would be indicated by time averaged velocity or total-pressure boundary-layer measurements.

The investigation was made in the Langley low-turbulence pressure tunnel at Mach numbers ranging from 0.15 to 0.25 by use of an 85-inch-chord NACA $65_{(215)}$–114 airfoil section that completely spanned the 36-inch-wide test section. This airfoil is the same model on which extensive laminar flow studies were reported in reference 9. The occurrence of transition at various chordwise positions for each roughness position was determined by means of a hot-wire anemometer. A great many qualitative indications of the nature of the flow in the boundary layer, as well as a few quantitative measurements of the level of the velocity fluctuations in the boundary layer, were obtained by this method.

SYMBOLS

y	distance normal to surface of airfoil
δ	total boundary-layer thickness where $\frac{u}{U}=1.0$ in the Kármán-Pohlhausen method
k	height of projection
c	chord of airfoil
x	distance from airfoil leading edge measured along the chord
s	distance from airfoil forward stagnation point measured along the airfoil surface
U_∞	free-stream velocity
U	local velocity just outside boundary layer
u	local streamwise component of velocity inside boundary layer
u_k	value of u at top of roughness projection
u'	root-mean-square value of the streamwise component of fluctuating velocity
q_∞	free-stream dynamic pressure
ν	coefficient of kinematic viscosity

t	Reynolds number at which transition takes place
min	minimum value

APPARATUS AND TESTS

The tests were made in the Langley low-turbulence pressure tunnel on an 85-inch-chord NACA $65_{(215)}$–114 airfoil section (fig. 1), which completely spanned the 36-inch width of the test section. The turbulence level of the tunnel at the speeds involved in this investigation is only a few hundredths of 1 percent. A description of the tunnel is given in reference 10 and a detailed description of the model is given in reference 11. The surface finish of the model was such that laminar flow could be maintained to the 50-percent-chord point up to a Reynolds number of 14×10^6, a value substantially the same as that obtained previously in references 9 and 11 with the same model.

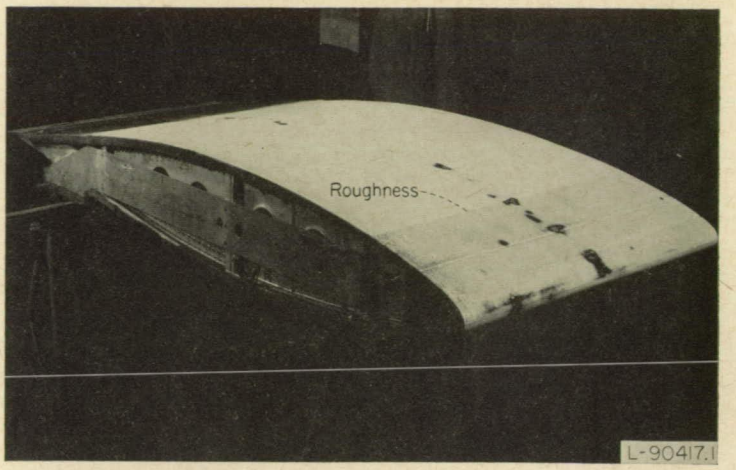

FIGURE 1.—Three-quarter view of 85-inch-chord NACA $65_{(215)}$–114 airfoil section with No. 60 carborundum grains from forward stagnation point to 12-inch station.

The pressure distribution of the model was measured from the leading-edge region back to approximately 65 percent of the chord by means of 0.008-inch-diameter pressure orifices drilled into the surface. Particular care was taken to provide numerous orifices near the leading edge so that the location of the forward stagnation point could be accurately determined. The nondimensional velocity distribution calculated from the measured pressure distribution along the upper surface is presented in figure 2.

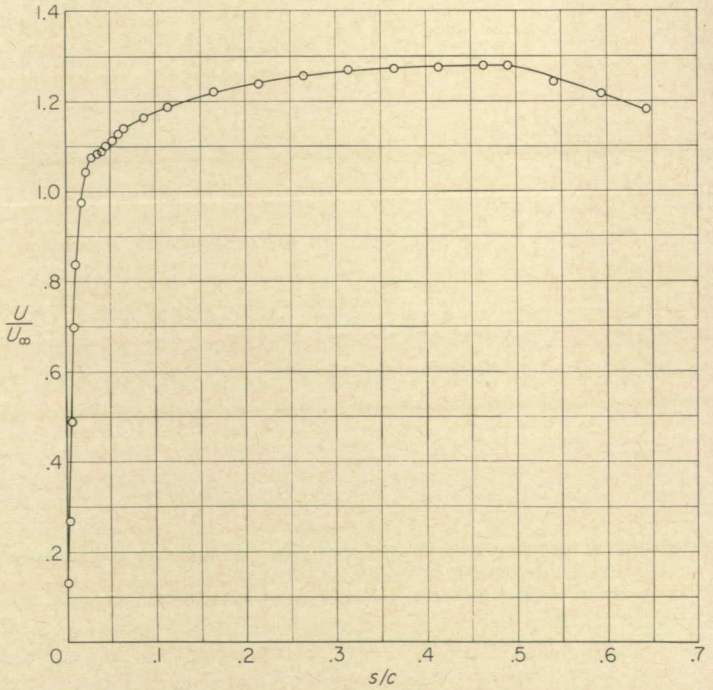

FIGURE 2.—Nondimensional velocity distribution outside of the boundary layer for NACA $65_{(215)}$–114 airfoil section at angle of attack of 0°.

The appearance of transition was determined by use of a hot-wire anemometer using a platinum iridium wire of 0.0003-inch diameter and of $\frac{3}{32}$-inch length. Figures 3 and 4 are photographs of the hot-wire holder. The output from the hot-wire anemometer was fed into an oscilloscope and the traces on the cathode-ray tube were recorded on 35 millimeter film by a special camera setup. The traces thus recorded were correlated with the tunnel velocity, wire position, and roughness location. The type of wire used in this investigation was one which was sensitive only to variations in the u-component of velocity. The wire was compensated for heat-capacity lag at one test condition, and this compensation setting was used for all observations. The cutoff frequency of the amplifier was about 12,000 cycles per second.

The tests were made with the leading edge of ¼-inch roughness strips 1 inch in span (fig. 4) located along the center line of the model at various positions from ¼ inch to 6¼ inches from the forward stagnation point measured along the surface and for full-span area-distributed roughness (fig. 1) from the forward stagnation point to 6 inches and to 12 inches back of the forward stagnation point. The roughness in all cases was provided by an application of either No. 60 or No. 120 carborundum grains, of grit sizes that met the specifications of reference 12. The grains were thinly spread over the surface to cover 5 to 10 percent of the surface area and were cemented by a thin coating of shellac applied before the roughness grains were spread. A closeup of the roughness as applied to the model is presented as figure 5.

In general, the No. 60 and No. 120 carborundum particles projected above the surface about 0.011 inch and 0.005 inch, respectively; however, the maximum particle height in each

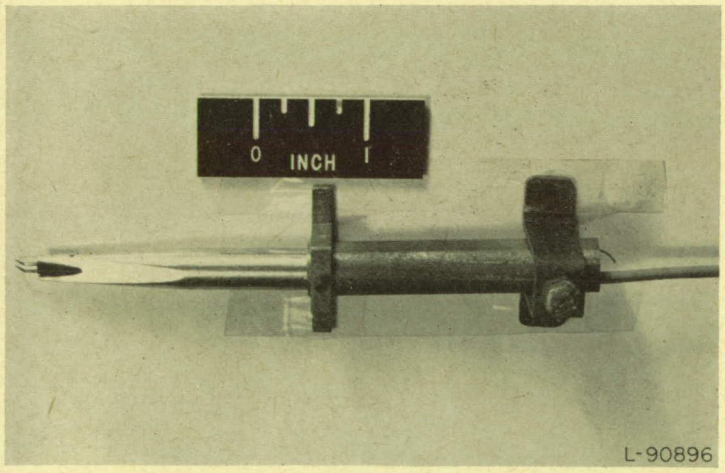

FIGURE 3.—Hot-wire holder used in investigation.

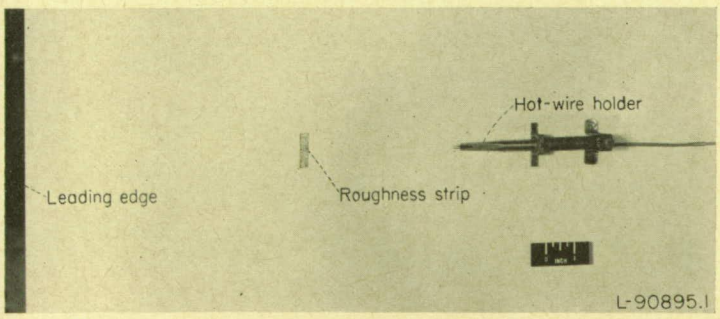

FIGURE 4.—View of hot-wire holder mounted on the airfoil surface relative to a typical ¼-inch by 1-inch roughness strip.

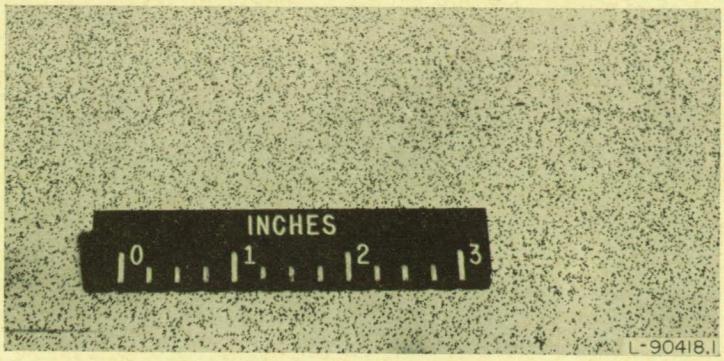

FIGURE 5.—Closeup of distributed No. 60 carborundum grains.

patch is also of interest. During the course of the investigation, although each roughness patch was examined carefully with the unaided eye, the height of the particles was not measured. Following completion of the tests, a series of ten patches ¼ inch by 1 inch of both sizes of grain were applied to a surface in the same manner used in applying the grains to the airfoil surface, and each of these patches was examined with a 15-power shop microscope to determine the actual particle height. The results of this examination are shown in figure 6, which shows the probability of finding at least one roughness particle of a given height in one patch of roughness. The curves of figure 6 show that, for No. 120 carborundum grain of 0.005-inch nominal size, it is virtually certain that each patch would have at least one particle projecting 0.008 inch above the surface, and about 50 percent of the patches would have at least one particle 0.009 inch high, whereas the chances of finding a particle 0.012 inch high would be very small. Similarly, for the No. 60 carborundum of 0.011-inch nominal size, it is virtually certain that every patch will contain at least one particle 0.016 inch high and approximately 50 percent of the patches will have at least one particle 0.018 inch high, whereas the chances of finding a particle 0.021 inch high in any patch is very small. The probable maximum height of a particle for No. 120 carborundum is

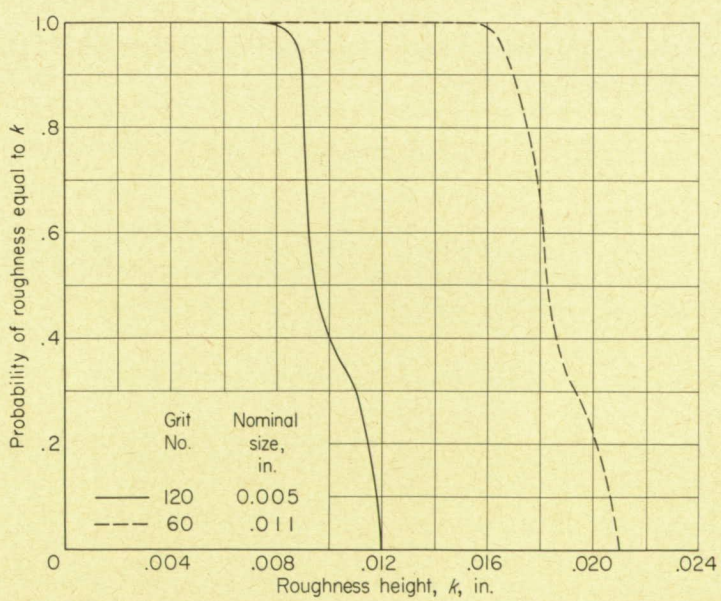

FIGURE 6.—Curves showing the probability of finding at least one grain of a given size of roughness in any ¼-inch by 1-inch roughness area when nominal size of carborundum grains is 0.005 or 0.011 inch.

therefore taken as 0.009 inch, and the probable maximum height of a particle for No. 60 carborundum is taken as 0.018 inch.

For each position of roughness, the hot-wire measurements were made at a sufficient number of chordwise positions back of the roughness to make possible determination of a curve of Reynolds number for transition as a function of chordwise position of the wire.

Some of the preliminary measurements were made with full-span strips of roughness ¼-inch wide. The relatively narrow width of the strip was chosen in order to permit correlation of transition with local boundary-layer conditions. When these measurements were made, it was found that, occasionally, the first indications of transition were obtained at a substantially lower tunnel speed for a downstream position than for more forward positions. In each such case, reexamination of the strip of roughness showed one or more particles in an off-center location projecting above the general level of the roughness. Because of the manner in which turbulent flow spreads, such unusually high projections affected the downstream observations but not the upstream ones. In order to facilitate inspection of the strip of roughness, its spanwise extent was reduced to 1 inch. Such small roughness strips were removed and reapplied two or more times, and the initial appearance of turbulence in each case occurred at very nearly the same Reynolds number; these results indicated that such roughness strips could be satisfactorily duplicated.

BOUNDARY-LAYER CALCULATIONS

In order to correlate the occurrence of transition with local boundary-layer conditions, it is of course necessary to know the velocity distribution in the boundary layer for all locations at which the roughness is placed. These laminar boundary-layer characteristics were calculated according to the method outlined in reference 13, that is, essentially by the Kármán-Pohlhausen method as modified by Walz (ref. 13, ch. 12, sec. B). This method is summarized in this section.

The momentum thickness θ of the boundary layer may be computed from the following equation:

$$\left(\frac{\theta}{c}\sqrt{R_c}\right)^2 \equiv \Theta^2 = \frac{0.470}{\left(\frac{U}{U_\infty}\right)^6}\int_0^{s/c}\left(\frac{U}{U_\infty}\right)^5 d\left(\frac{s}{c}\right) \tag{1}$$

The velocity distribution in the boundary layer may be obtained as follows: The form parameter K is defined as $\frac{\theta^2}{\nu}\frac{dU}{dx}$ or as

$$K \equiv \Theta^2 \frac{d\left(\frac{U}{U_\infty}\right)}{d\left(\frac{x}{c}\right)} \tag{2}$$

The form parameter K is related to the Pohlhausen shape parameter $\lambda = \frac{\delta^2}{\nu}\frac{dU}{dx}$ as follows

$$K = \left(\frac{37}{315} - \frac{\lambda}{945} - \frac{\lambda^2}{9072}\right)^2 \lambda \tag{3}$$

The parameter λ may also be written as

$$\lambda \equiv \Delta^2 \frac{d\left(\frac{U}{U_\infty}\right)}{d\left(\frac{x}{c}\right)} \tag{4}$$

where

$$\Delta \equiv \frac{\delta}{c}\sqrt{R_c}$$

Equation (3) is then solved for λ, and the velocity distribution in the boundary layer may be obtained by using the following expression

$$\frac{u}{U} = F(\eta) + \lambda G(\eta) \tag{5}$$

where

$$\eta \equiv \frac{y}{\delta}$$

$$F(\eta) \equiv 2\eta - 2\eta^3 + \eta^4$$

$$G(\eta) \equiv \frac{1}{6}\eta(1-\eta)^3$$

The measured velocity distribution over the airfoil used in these calculations is presented in figure 2. The boundary-layer parameters λ and Δ were calculated by the use of the aforementioned relations and the measured velocity distribution. The shape parameter λ is plotted against s/c in figure 7, and the nondimensional boundary-layer thickness

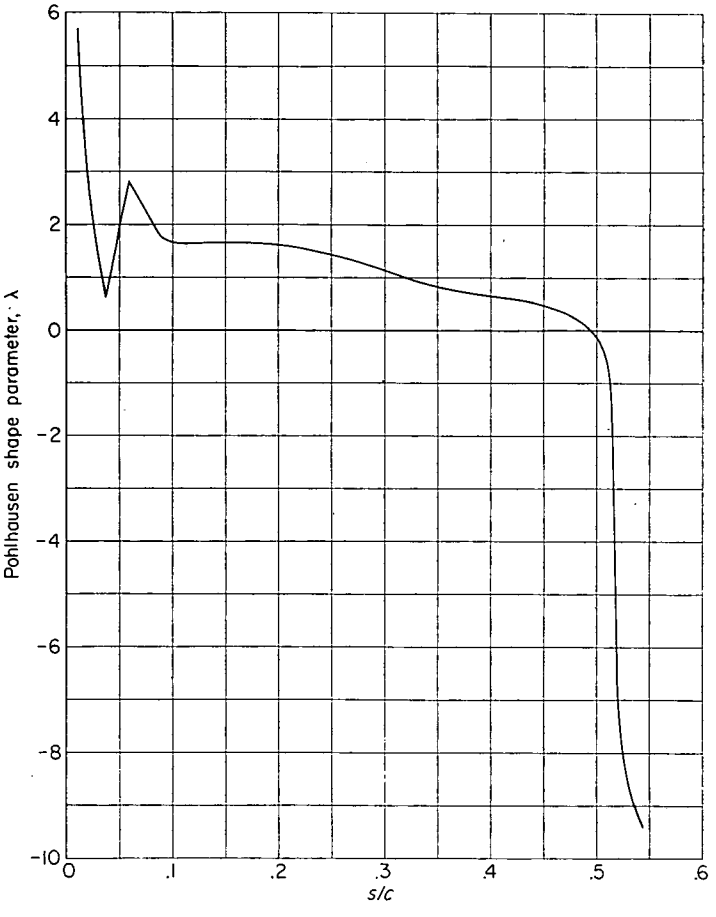

FIGURE 7.—Pohlhausen shape parameter λ for a laminar boundary layer on NACA $65_{(215)}$-114 airfoil section at angle of attack of 0°.

Δ or $\frac{\delta}{c}\sqrt{R_c}$ as a function of s/c is given in figure 8. In order to facilitate the calculations involved in the analysis of the data, the nondimensional velocity distribution u/U_∞ is also presented in figure 9 as a function of $\frac{y}{c}\sqrt{R_c}$ for various chordwise positions.

RESULTS AND DISCUSSION

Hot-wire traces of the time variation of velocity in the boundary layer as observed for various locations of the roughness are shown in figure 10. For each location of roughness, observations were made at various positions downstream throughout the range of speed necessary to include the transition phenomena at the point of observation. To the left of each hot-wire trace is a short tick which indicates the corresponding value of the Reynolds number per foot of chord as read on the vertical scale of the figure. The chordwise location of the point of observation of each group of hot-wire traces is indicated at the bottom of the figure, as is the height of the wire above the surface in thousandths of an inch. Also shown in the figure is the time scale for the traces. Time increases from left to right. It should be noted that the amplifier gain setting for the traces shown in figure 10 (a) was the same for all traces. This procedure resulted in substantially a straight line for the laminar traces. In parts (b), (c), (d), (e), and (f) of figure 10, however, the amplifier gain was increased for the conditions corresponding to completely laminar flow, and the traces for this condition, therefore, show some velocity fluctuations. These fluctuations, however, are of a completely different character from those corresponding to turbulent flow.

In general, transition appears to start as disturbances of very short duration that occur comparatively infrequently at a position just behind the roughness. As the position of observation moves downstream and the speed is kept constant, the frequency of the turbulent bursts does not appear to change, but the duration of each burst becomes longer. This phenomenon is shown very clearly in figure 10 (b) at

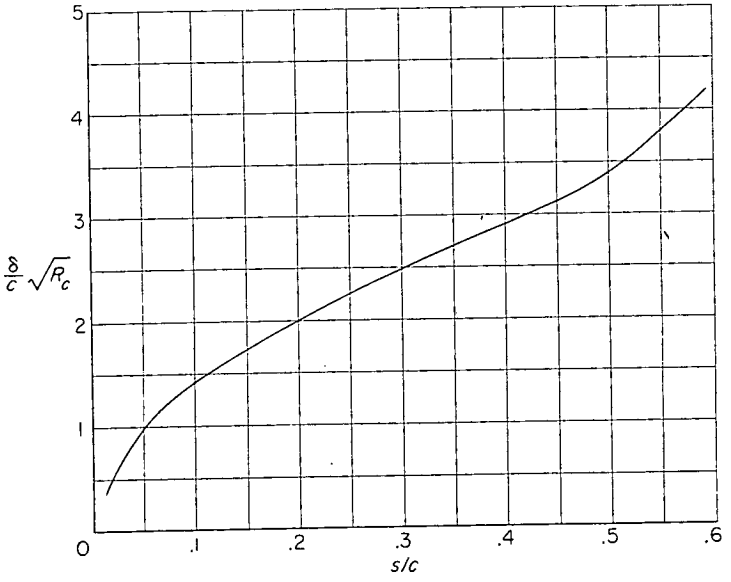

FIGURE 8.—Nondimensional laminar-boundary-layer thickness distribution for NACA $65_{(215)}$-114 airfoil section.

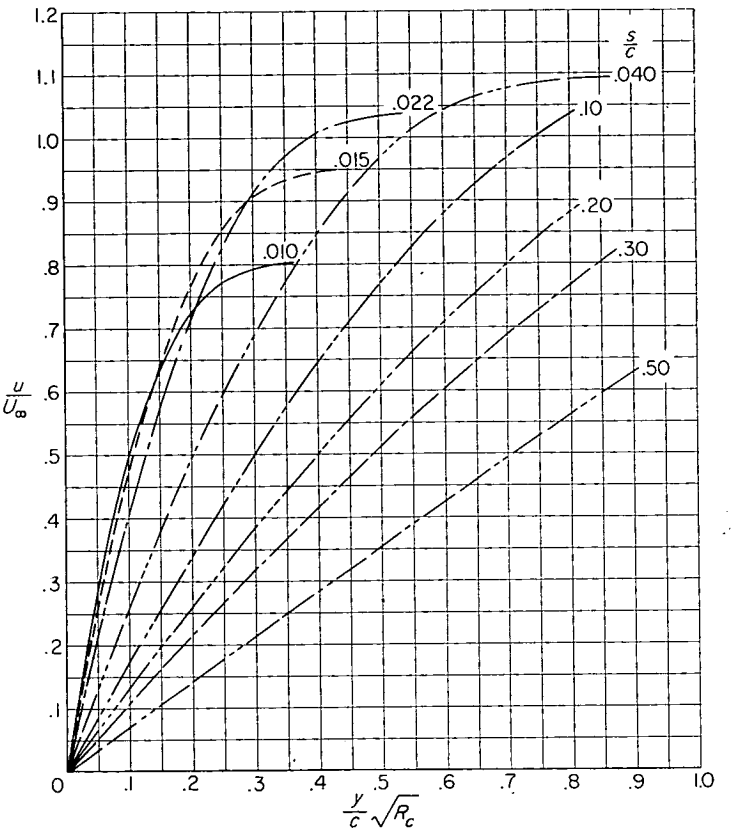

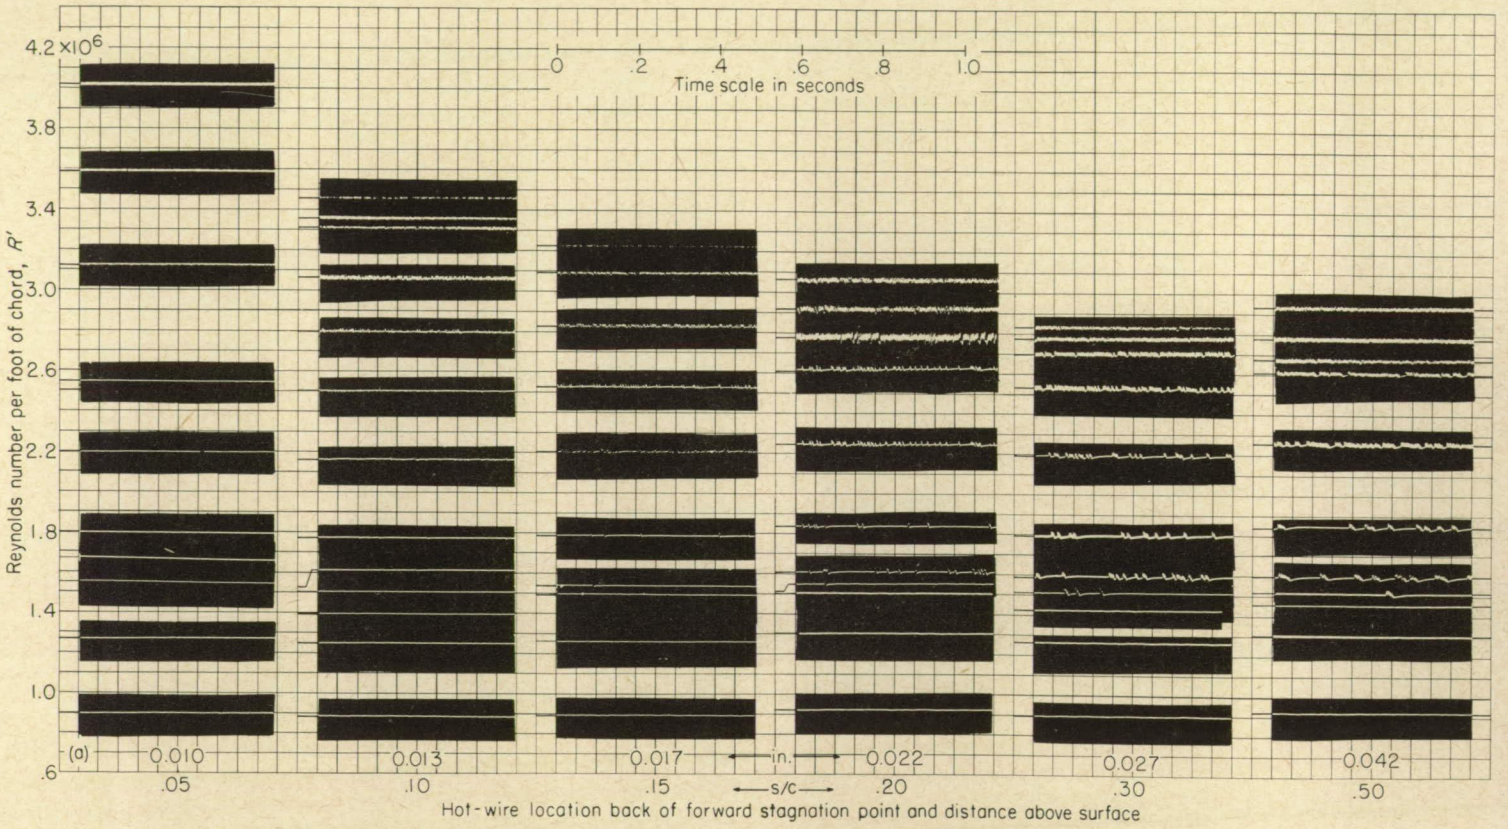

FIGURE 9.—Nondimensional velocity distribution within laminar boundary layer of NACA $65_{(215)}$-114 airfoil section for various positions along surface.

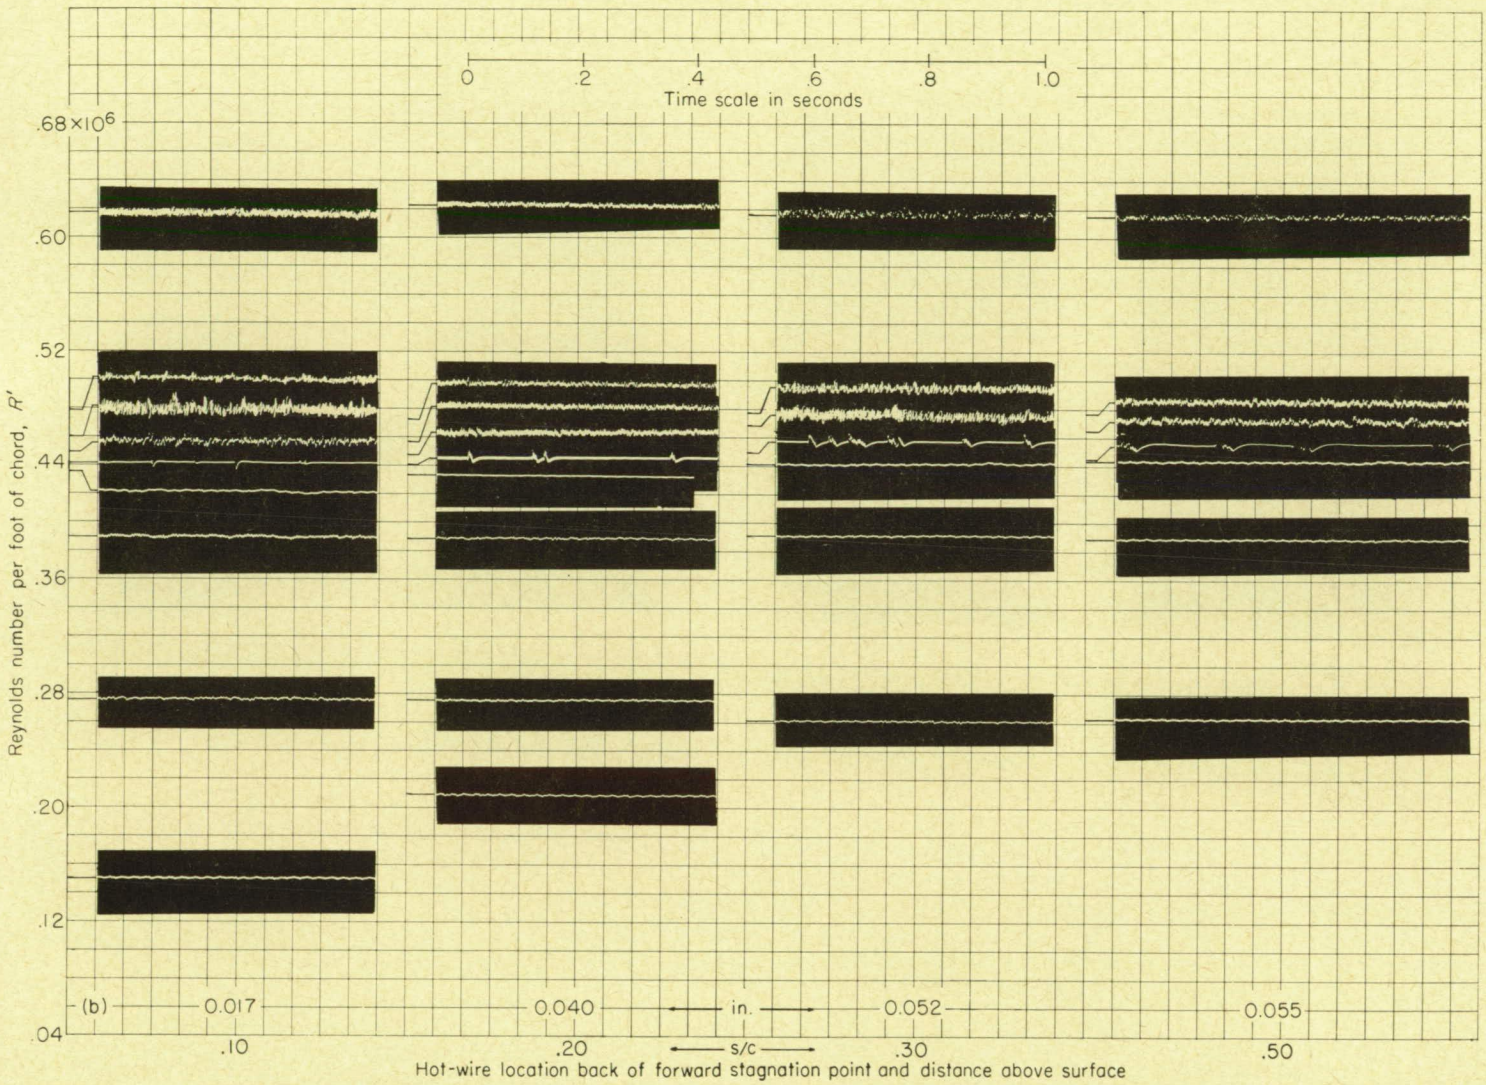

a Reynolds number of 0.44×10^6. Figure 10 also shows that each burst of turbulence is followed by a condition termed by Schubauer and Klebanoff (ref. 14) as a "logarithmic decrement" type of velocity variation. The increase in duration of individual bursts with distance downstream from the roughness is consistent with the description of the origin of transition given in reference 14; that is, it is consistent with the concept of transition beginning as turbulent spots that start in the vicinity of the roughness and grow as they move downstream.

A quantitative summary of the data of figure 10 is given by the data presented in figure 11. Each part of figure 11 consists essentially of a pair of curves. The lower curve of each pair gives approximately the lowest value of the Reynolds number per foot at which any turbulent bursts were observed for a given location of the roughness plotted against the observation position. The upper curve gives the maximum value of the Reynolds number per foot at which any traces of laminar flow could be detected. In other words, for conditions corresponding to the lower curve, the flow was nearly always laminar, and for those corresponding to the upper curve, the flow was nearly always turbulent. Examination of the various parts of figure 11 indicates that the lowest speed at which any turbulent flow could be found was substantially independent of the position of observation. This is generally true except for the most forward observation positions where, because of the extremely short duration of the bursts, they were difficult to observe and, as a result, these points may be plotted at too high a value of the unit Reynolds number.

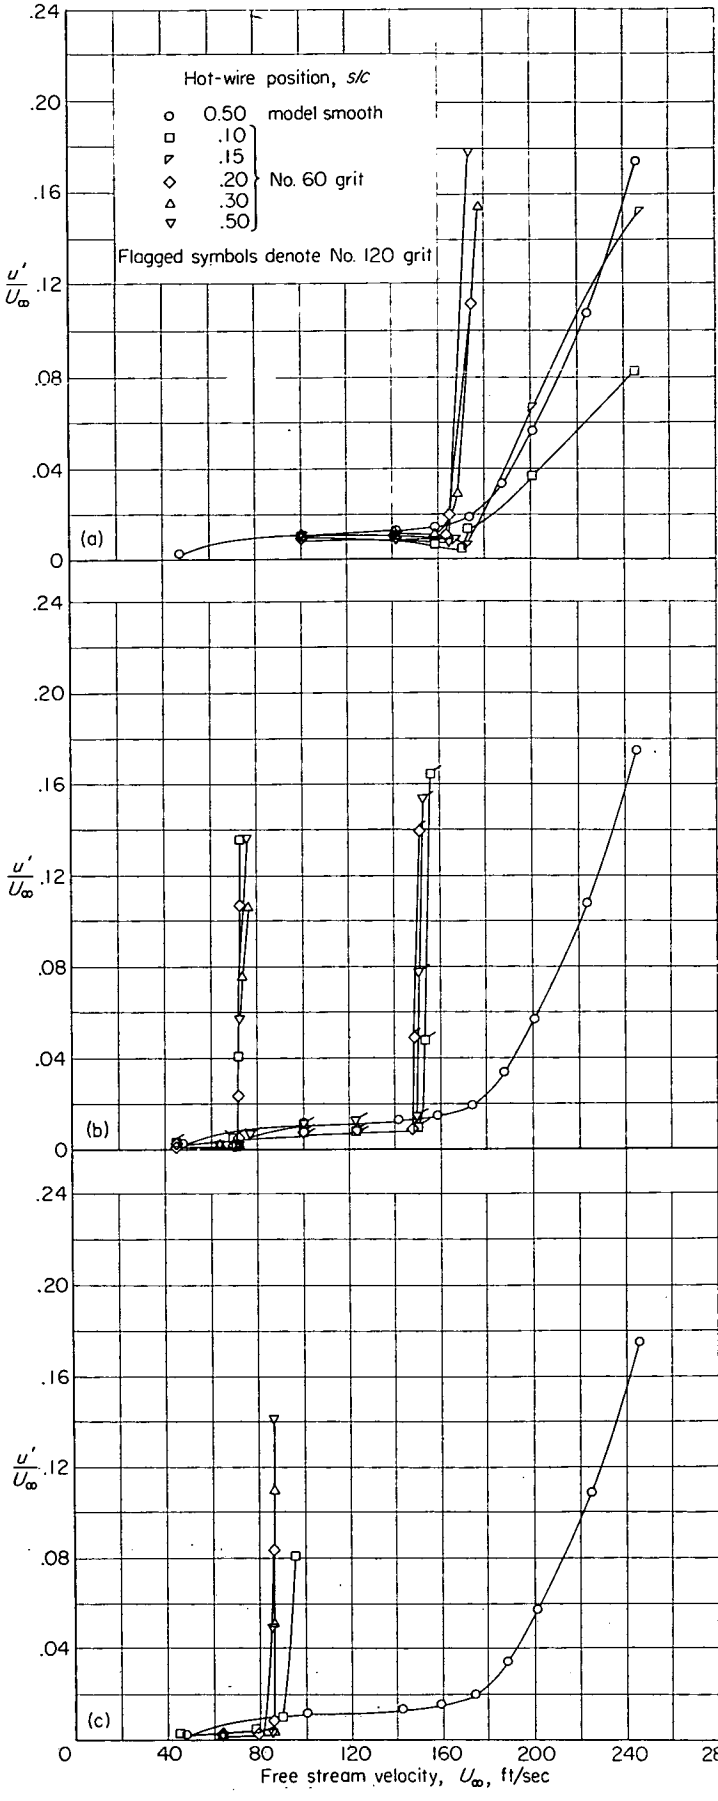
FIGURE 11.—Concluded.

The value of the speed at which the flow is nearly completely turbulent decreases appreciably as the point of observation moves downstream for the more forward roughness locations (figs. 11 (a) and (b)). This trend is as would be expected if turbulence began as a series of turbulent bursts originating at or near the roughness and increasing in size as they moved downstream. For the more downstream positions of the roughness (figs. 11 (c) to 11 (f)), the upper and lower curves almost coalesce; that is, the speed range between fully laminar and fully turbulent flow almost vanishes. The data on which figure 11 is based include many more observations than those presented in figure 10,



which are merely representative samples of the oscilloscope records.

Quantitative observations of the root-mean-square values of the fluctuations were made both with and without roughness through the speed range corresponding to that for which turbulence occurred when roughness was present. Typical examples of these measurements are presented in figure 12 as functions of the free-stream velocity. From figure 12, it is seen that the root-mean-square level of fluctuations in the laminar boundary layer, even at positions as far downstream as 50 percent of the chord, is as low on the airfoil with roughness present as on the smooth airfoil. It thus appears that, at speeds below those at which turbulent bursts occur, the presence of the roughness does not result in any measurable disturbance in the boundary layer that would hasten transition. It is therefore to be presumed that, at speeds below the critical speed for the roughness, no upstream movement of the transition region would occur even if the model were sufficiently long for transition to occur naturally in the region of favorable pressure gradient.

This type of phenomenon, therefore, appears to be strongly contrasted to the manner in which transition occurs when it is caused by two-dimensional disturbances. The data for the two-dimensional type of disturbance have been summarized in reference 6. This summary indicates that, for the case of two-dimensional disturbances, the roughness introduces into the boundary layer a measurable disturbance which grows until transition occurs.

If, as seems likely from an examination of the oscillograph records (see fig. 10), transition associated with the type of roughness of the present investigation results from the formation of discrete eddies or disturbances originating at the roughness particles, it should be possible to relate the occurrence of such disturbances to the characteristics of local flow about the roughness. That is, if all the roughness particles are regarded as being geometrically similar, and if the roughness is regarded as being sufficiently submerged in the boundary layer to provide substantially linear velocity variation from the surface to the top of the roughness, discrete eddies should form when the Reynolds number of the flow about the roughness reaches a critical value. This concept is not new; it was proposed by Schiller (ref. 2) and used by Loftin in analyzing the data presented in reference 1.

This view is supported by the data presented in figure 13, which is a plot of the critical Reynolds number $R_{k,t}$ based on the height of the roughness and the velocity at the top of the roughness as a function of the chordwise position of the roughness. The velocity at the top of the roughness was found either from the theoretical boundary-layer calculations previously described or, if the roughness projected completely through the boundary layer, from the measured pressure distribution. For all roughness positions more than $0.025c$ from the forward stagnation point, the critical roughness Reynolds number $R_{k,t}$ was substantially constant within rather close limits. For positions nearer the forward stagnation point than $0.025c$, the critical roughness Reynolds number $R_{k,t}$ increased markedly. It is to be noted that, for positions nearer the forward stagnation point than $0.025c$, the roughness protruded nearly through the boundary layer, and, for the three positions closest to the forward stagnation point, the roughness protruded completely through the boundary

yer. (See fig. 14.) It is entirely possible that for the range conditions of the present tests, the boundary layer over ie region of the airfoil in the vicinity of the forward stagnaon point was sufficiently stable to cause small eddies origating at the roughness to be damped out before they avelled downstream far enough to affect the less stable minar boundary layer farther downstream. At any rate, iese results indicate that if the height of the roughness article is so small that the roughness Reynolds number is ss than 600 based on maximum particle size or less than 50 based on nominal particle size, the roughness is not large nough to cause transition. This statement appears to be alid even for roughness heights several times the boundaryyer thickness. The order of magnitude of the critical roughess Reynolds number is within the range of those found by oftin (ref. 1) and is not much different from the value found y Schwartzberg and Braslow (ref. 4).

The extent of the roughened area does not appear to have n important effect on the height of roughness necessary to ause transition. When the grains of roughness were spread from the leading edge to 6 inches or 12 inches back of the leading edge (fig. 1), the airfoil Reynolds number at which transition occurred was substantially the same as for a spot of roughness 1 inch in span and ¼ inch in chord located from 2 to 2¼ inches from the forward stagnation point. This location (that is, the position at which, for given free-stream conditions, the value of the roughness Reynolds number R_k was a maximum) was approximately the most critical location for the height of roughness used.

APPLICATION OF RESULTS

An examination of the consequences of the inference drawn from the preceding discussion, namely, that transition occurs when the local roughness Reynolds number R_k exceeds a value of 600, is of interest. The nature of these consequences will be examined with particular reference to the airfoil studied in the present investigation by calculating the critical conditions for various heights of roughness. Figure 15 shows the variation of the roughness Reynolds number R_k for 0.018-inch roughness particles with position along the surface

(a) $R_{c,t}=11.8\times10^6$.
(b) $R_{c,t}=6.7\times10^6$.
(c) $R_{c,t}=5.4\times10^6$.
(d) $R_{c,t}=3.2\times10^6$.

FIGURE 14.—Illustration of height of roughness relative to laminar-boundary thickness for airfoil Reynolds number at which transition occurs for various positions of the roughness.

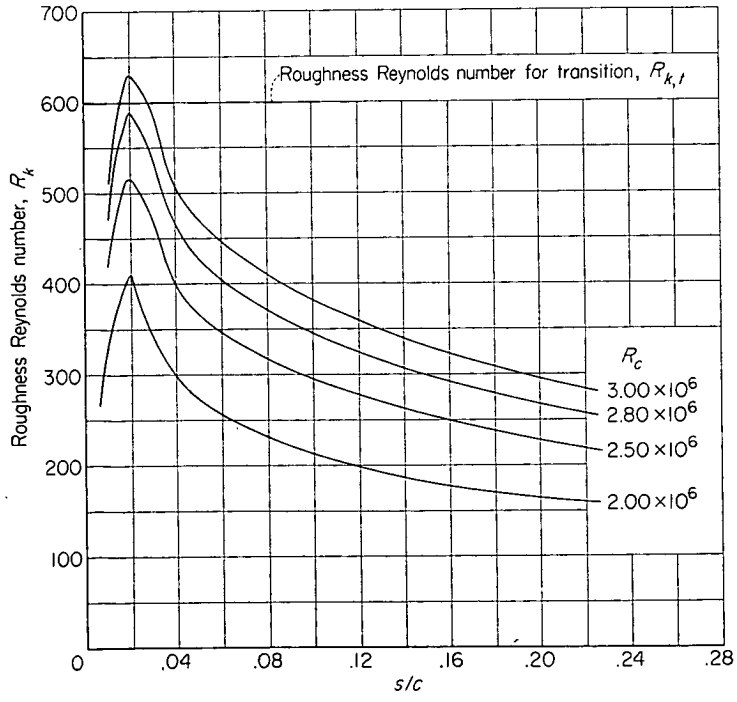

FIGURE 15.—The roughness Reynolds number R_k for roughness height of 0.018 inch as a function of roughness location for various airfoil Reynolds numbers R_c as calculated for an 85-inch-chord NACA $65_{(215)}$-114 airfoil section.

for several values of the airfoil Reynolds number. Th roughness position for maximum R_k does not vary rapidl with airfoil Reynolds number and occurs when the heigh of the roughness is slightly less than the total boundary-laye thickness. For far forward roughness positions, R_k is lo because of the low value of the potential flow velocity nea the forward stagnation point. For far rearward roughnes positions, R_k is low because the roughness is deeply buried in the boundary layer.

Several sets of calculations of this nature were made fo different heights of roughness. The results are summarize in figures 16 and 17. For each height of roughness, th position along the surface corresponding to a maximu value of R_k was found, and the value of R_c corresponding t a value of R_k of 600 at this location was then calculated This value of R_c is the smallest value at which a value of R of 600 can be obtained with the roughness of a given heigh situated at any position along the surface. Figure 16 give the relation between the minimum critical airfoil Reynold number and the most sensitive location of the roughnes with the height of the roughness as a parameter for a fixe value of the critical roughness Reynolds number of 60 Figure 17 plots the same information in a slightly differen manner. Here the minimum value of the critical airfo Reynolds number for a roughness Reynolds number $R_{k,t}$ 600 for roughness situated at the most sensitive location plotted against the ratio of the roughness height to airfo chord. From figure 17, it is seen that the curve of $R_{c,min}$ fo $R_{k,t}=600$, when plotted as a function of k/c on log log pape

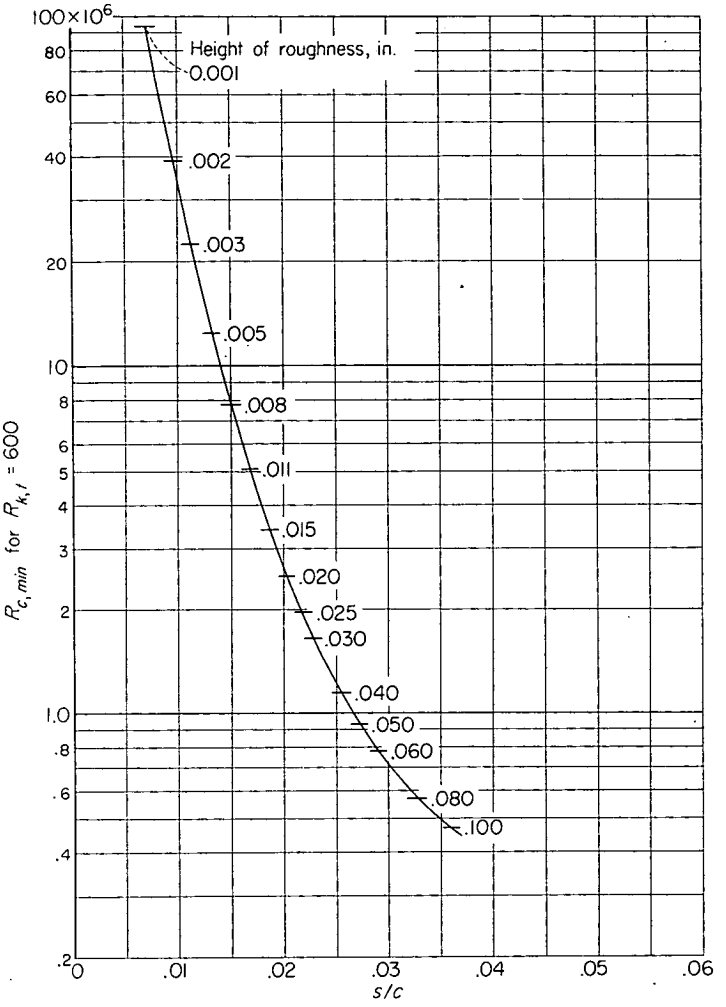

FIGURE 16.—The theoretical location, for various heights of roughness on an 85-inch-chord NACA $65_{(215)}$-114 airfoil section, at which, for a value of $R_{k,t}$ of 600, the airfoil Reynolds number R_c will be a minimum.

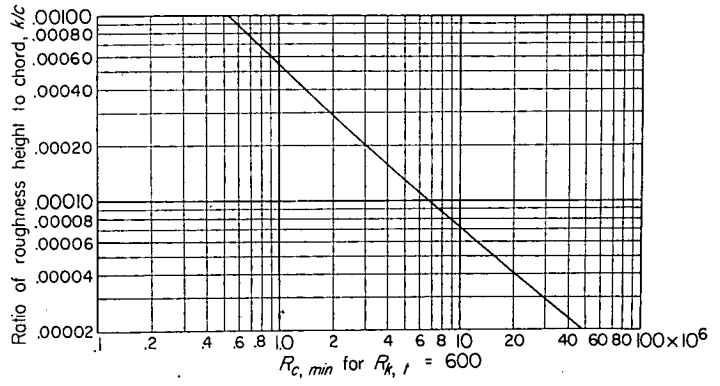

FIGURE 17.—Variation of the minimum airfoil Reynolds number $R_{c,min}$, for critical roughness Reynolds number $R_{k,t}$ of 600, with roughness height as calculated for an 85-inch-chord NACA $65_{(215)}$-114 airfoil section.

is nearly a straight line with a slope of −1. This result, of course, indicates that $R_{k,\infty}$, which is the product of k/c and $R_{c,min}$, is approximately constant and equal to about 680. If this value of $R_{k,\infty}=680$ is used as a criterion for transition, it becomes a simple matter to determine whether a given height of distributed roughness will cause transition for a given airfoil Reynolds number. If this criterion is expressed in terms of the nominal size of the roughness grain, the corresponding critical value of $R_{k,\infty}$ is 415. This criterion agrees very well with the data presented in references 7 and 8.

Although a particular pressure distribution was involved in the determination of the simple criterion $R_{k,\infty}=680$, it seems reasonable that the critical value should not be very sensitive to the particular type of pressure distribution. In general, if it is assumed that the value of $R_{k,t}$ is 600 for the case where the height of the roughness is less than the total boundary-layer thickness and is at least as large or larger for roughness that projects through the boundary layer, this condition will correspond to a value of $R_{k,\infty}$ of about 680 if the airfoil has a reasonably extensive region of low pressure gradient with a velocity outside the boundary layer approximately equal to the free-stream velocity. Consider, for example, the case of a flat plate with uniform pressure. If the roughness is so far forward that it projects through the boundary layer, the value of R_k will not change with further forward movement of the roughness. The data of figure 13 seem to indicate, however, that the value of $R_{k,t}$ has its lowest value when the roughness is just completely immersed in the boundary layer. For this case, the value of $R_{k,t}$ is 600 and the corresponding value of $R_{k,\infty}$ for a flat plate would be only slightly greater than this value and thus would not differ greatly from the value of 680 found for the present airfoil.

The minimum size of roughness that can be easily detected or the size of the splattered remains of insects are relatively fixed values completely independent of wing size. In view of these conditions, the significance of the unit Reynolds number $\left(R'=\frac{U_\infty}{\nu}\right)$ immediately becomes clear. For example, if k is the height of the splattered remains of insects, then if R' is so small that $R_{k,\infty}$ is less than about 680, the remains of the insects should not cause premature transition. If, for the sake of discussion, it is assumed that the height of the insect remains or the minimum size of roughness that can be easily detected is about 0.001 inch, the critical value of R' will be about 8.2×10^6. This value of the unit Reynolds number R' for transition is in general agreement with values considered acceptable on the basis of wind-tunnel experience in the Langley variable-density and low-turbulence pressure tunnels. In the variable-density-tunnel tests, in which R' was usually about 7×10^6, a fair amount of difficulty was experienced in maintaining the leading edge of the airfoils smooth enough to obtain consistent results for the maximum lift coefficients. In the low-turbulence-pressure tunnel, essentially no difficulty was experienced in obtaining the design laminar flow for a unit Reynolds number $R'=1.5\times10^6$ and only occasional difficulties for $R'=3\times10^6$; however, for R' above these values, the difficulty of obtaining extensive laminar flows increased markedly.

Figure 18 translates this criterion into more easily appreciated terms. The critical size of roughness for an assumed free-stream Mach number of 1.0 has been computed as a function of altitude by using NACA standard atmosphere (ref. 15). At sea level, the critical size is about 0.001 inch. This increases to about 0.002 inch at 20,000 feet and 0.010 inch at 60,000 feet. For altitudes above 30,000 or

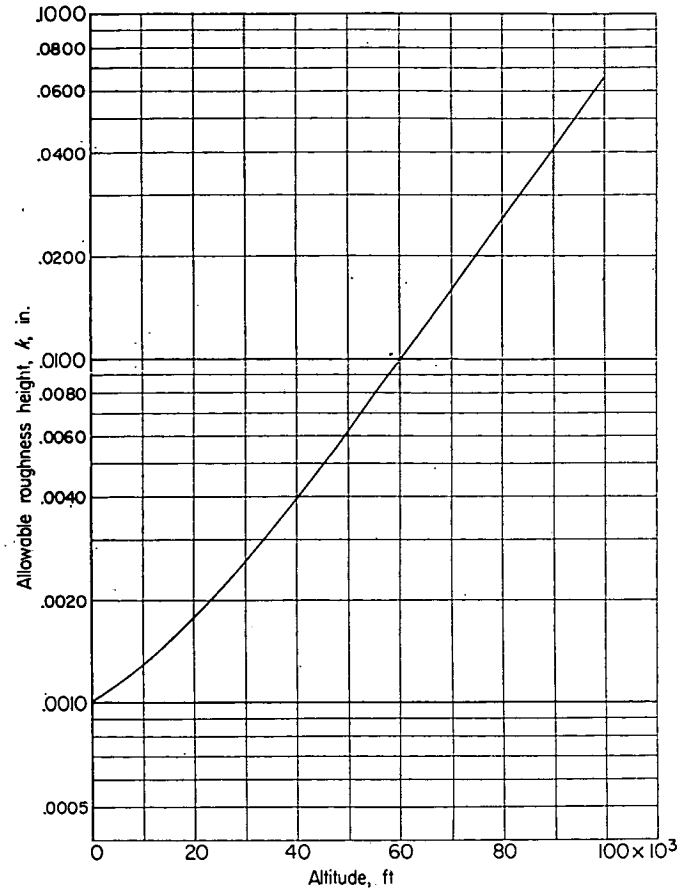

FIGURE 18.—Allowable roughness height for critical roughness Reynolds number, $R_{k,t}$ of 600, as function of altitude for Mach number of 1.0.

40,000 feet, it does not seem likely that accidental surface roughness should make it difficult to obtain extensive laminar flows. Of course, built-in roughness such as lap or butt joints, surface waviness, or rivet heads might still be sufficiently large to cause transition.

CONCLUSIONS

A low-speed investigation in the Langley low-turbulence pressure tunnel to determine the effect of grain height and location on the transition characteristics of sandpaper type of roughness on an NACA 65-series airfoil section indicates the following conclusions:

1. If the roughness is sufficiently submerged in the boundary layer to give substantially linear variation of the boundary-layer velocity with distance from the surface up to the height of the roughness, turbulent spots begin to appear immediately behind the roughness when the Reynolds number R_k, based on the velocity at the top of the roughness and the roughness height, exceeds a critical value $R_{k,t}$ of approximately 600.

2. At Reynolds numbers even slightly below the critical value, the sandpaper type of roughness introduced no measurable disturbances into the laminar layer downstream of the roughness.

3. The most sensitive position for roughness grains of a given size, that is, the roughness position for which the critical value of the model Reynolds number is least, is that at which the roughness height is slightly less than the total laminar boundary-layer thickness.

4. The chordwise extent of the roughened area does not appear to have an important effect on the critical value of the roughness Reynolds number $R_{k,t}$.

5. If the airfoil has a reasonably extensive region of low pressure gradient with a velocity outside the boundary layer approximately equal to the free-stream velocity and roughness so distributed over the leading-edge region as to include the most sensitive position, the condition $R_{k,t}=600$ may be approximately replaced by the more easily calculated condition $R_{k,\infty}=680$, where $R_{k,\infty}$ is the Reynolds number based on the size of the roughness and the free-stream velocity.

REPORT 1350

METHODS FOR OBTAINING DESIRED HELICOPTER STABILITY CHARACTERISTICS AND PROCEDURES FOR STABILITY PREDICTIONS [1]

By F. B. GUSTAFSON and ROBERT J. TAPSCOTT

SUMMARY

In the first part of this report a brief review is presented of methods available to the helicopter designer for obtaining desired stability characteristics by modifications to the airframe design. The discussion is based on modifications made during the establishment of flying-qualities criteria and includes sample results of theoretical studies of additional methods.

The conclusion is reached that it is now feasible to utilize combinations of methods whereby stability-parameter values are realized which in turn provide the desired stability characteristics.

Part II reviews some of the methods of predicting rotor stability derivatives. The procedures by which these rotor derivatives are employed to estimate helicopter stability characteristics have been summarized. Although these methods are not always adequate for predicting absolute values of the stability of the helicopter, the effects on stability of changes in individua derivatives can generally be estimated satisfactorily.

INTRODUCTION

The problems relating to stability of helicopters have been the subject of numerous published works. Requirements established by the military services for satisfactory helicopter stability are specified in reference 1. Some of the pertinent work on this subject by the National Advisory Committee for Aeronautics is described in references 2 to 21. The purpose of part I of this report is to summarize some of the physical methods available to the designer for obtaining desired stability values by changing the airframe design. Although the direct application considered is that of meeting flying-qualities criteria, it may be worth pointing out that other reasons often arise for designing a configuration so that specific amounts of stability are provided; for example, the most efficient combination of autopilot and airframe design may be desired.

In order to predict helicopter stability, as for example to estimate theoretically whether a proposed helicopter will meet the flying-qualities requirements, both the applicable equations of motion and the necessary stability derivatives must be determined.

Processes for applying the equations of motion have been well established as a result of the extensive stability analysis made for airplanes, and the modification of these procedures for use with helicopters has been found a secondary problem in comparison with the provision of values of stability derivatives. In the past few years, sufficient information has been provided to permit the most pertinent rotor derivatives to be predicted with fairly good accuracy in applications where no stall is present. A summary of this work is presented in part II of this report.

I—METHODS FOR OBTAINING DESIRED HELICOPTER STABILITY CHARACTERISTICS

The scope of the discussion in part I is outlined in the following table:

Characteristic	Rotor type investigated
Damping in roll	Single and tandem
Maneuver stability	Single and tandem
Speed stability	Single and tandem
Lateral oscillation and turn characteristics	Tandem

Available results on static directional (weathercock) stability of tandem helicopters are not included in this discussion because of thorough coverage in reference 2. For helicopter types other than single-rotor or tandem-rotor configurations, no direct information is provided herein but much can be inferred from the more appropriate of the two types covered.

For each of the stability characteristics covered, modifications made to the design in the process of exploring a range of characteristics during the establishment of criteria for desirable flying qualities are discussed. The value of these examples lies in the fact that they are demonstrated cases for which stability parameters have been measured. Optimum design generally requires the choice of a method or combination of methods; therefore, sample results of theoretical studies of additional methods are included in each case.

DAMPING AND CONTROL POWER IN ROLL

The ratio of control power to damping, which frequently tends to reach values that lead to a major problem in the hovering characteristics of small low-inertia helicopters, is treated in table I. The test vehicle was a two-place single-rotor helicopter. As used herein, "control power" is the rolling moment per unit stick deflection and "damping" is the resisting moment per unit angular velocity of the helicopter. Since changes in control power are restricted by trim requirements, this discussion is concerned solely with changes in damping.

The requirement of the current military specification (ref. 1) is that the rate of roll per inch of stick displacement (often referred to as "sensitivity") be less than 20° per second. The test helicopter provided the opportunity to explore a fair-sized range of values, always on the satisfactory side, by adjusting a mechanical gyroscopic device. The value of 14 for L_δ/L_p is obtained with the device locked out, and the value of 5.2 is obtained with the device as far beyond the production setting as feasible. Both from theory and from flight measurements on other helicopters, it is known that, with lighter blades and no special device, the requirements of reference 1 would not have been met.

TABLE I

RATIO OF CONTROL POWER TO DAMPING
[Single rotor; 2,200-lb gross wt]

Parameter	Value to meet MIL-H-8501	Range tested	Method used
$\frac{\text{Control power}}{\text{Damping}}$, $\frac{L_\delta, \text{deg/sec}}{L_p, \text{in.}}$	<20	14 to 5.2	Available gyro device; L_δ fixed

Additional methods (L_δ fixed)	Amount for range tested
Increase in I_1 via tip wt. 	$\Delta W_b = 0.6$
Hinge offset with $\gamma = 4.7$ 	2 % R
Aero servos 	----------

In addition, and of perhaps even greater importance, studies made subsequent to the establishment of the existing specifications have demonstrated the direct value of increased damping irrespective of L_δ/L_p. (For example, see ref. 20.) Therefore, examination of several additional methods for changing the damping is advisable.

Increasing the blade inertia is one method of changing the damping. If use of a tip weight is considered, calculations indicate that 60 percent of the blade weight is needed to duplicate the full change in L_δ/L_p from 14 to 5.2.

Offsetting the flapping hinge will increase damping, but if this method is used the control linkage has to be changed to prevent increase in control power, or else little change in L_δ/L_p will result. With the heavy blades of the test helicopter, an offset of only 2-percent radius would be needed to change L_δ/L_p from 14 to 5.2; with light blades, an offset of 5-percent radius would be enough.

A third design approach which makes possible increased damping is the use of aerodynamic servocontrols. Sketches of two types, as viewed from above the rotor, are shown in table I. One type uses a surface behind the outer part of the blade and the other uses a surface attached at right angles at the blade root. Such devices apparently can be designed to provide increases in damping sufficient to cover the test range. Some methods permit increase in both control power and damping, a combination which is sometimes desirable; examples are flapping-hinge offset and aerodynamic servocontrols as just discussed.

Damping and control power in roll for the tandem helicopter require no separate discussion since, in roll, it is possible simply to consider two single rotors instead of one.

MANEUVER STABILITY OF SINGLE-ROTOR HELICOPTERS

Two separate maneuver-stability (or divergence) problems with single-rotor helicopters at cruising speed are treated in table II. With one helicopter, the variations were made by way of angle-of-attack stability, and with the other, by way of damping in pitch. For the first case, a change to a value of angle-of-attack stability of 300 pound-feet per radian was enough to cause the requirement to be met. The range covered went from the unstable value of 7,000 pound-feet

TABLE II

MANEUVER STABILITY
[Single rotor; gross wts.: (1) 5,000 lb and (2) 2,200 lb; cruise speed]

Major parameter varied	Value to meet MIL-H-8501	Range tested	Method used
(1) M_α, $\frac{\text{lb-ft}}{\text{radian}}$	<300	7,000 to −2,100	Tail surface 
(2) M_q, $\frac{\text{lb-ft}}{\text{radian/sec}}$	<−1,200 (rotor)	−710 to −1,930	Available gyro device

Parameter	Additional methods	Amount for 1/2 range tested
M_α	Increased rpm	33 %
	Forward c.g. with offset hinges	Δc.g. = 2.5% R with 5% offset
M_q	Similar to roll sensitivity	

er radian to the stable value of −2,100 pound-feet per adian. (Minus is stable in accepted stability theory.) he test conditions actually extended somewhat farther an the value of −2,100 pound-feet per radian on the stable de but the M_α values were not recorded.

The tail assembly used has been discussed in published apers, particularly reference 3. It may bear repeating, owever, that a total tail area of 0.5 percent of the rotor area ould make the difference between the helicopter's diverging xcessively in a few seconds and being able to fly through ough air without the longitudinal control being moved. his result was obtained after linking the tail to the cyclic ontrols, which so reduced the design compromises as to ermit use of a somewhat more effective tail.

Tests were made with a different helicopter (labeled (2) table II), wherein the damping in pitch was varied in such way as to bracket the condition for which the requirement as met. The value of −1,200 pound-feet per radian eeded to cause the specification to be met falls about mid-ay in the range of −700 to −1,900 pound-feet per radian overed. Damping is another quantity where the minus gn is indicative of a stable condition. As to the method sed, the investigation was the same as that which provided ne damping-in-roll values given in table I.

As to alternate methods, for large changes in angle-of-ttack stability M_α, there do not seem to be many which will over the range singlehanded. Increase in rotor speed is sted because the effect of such an increase is calculated to be ufficient to warrant thought of some compromise with esign for optimum power. It will be understood that otational speed is appropriate because in all other respects ne design is fixed; more fundamentally, what is implied is ower values of pitch and tip-speed ratio. A 33-percent ncrease in rotor rotational speed is estimated to give half ne range covered and would not have been enough, in itself, o meet the specification. The effects are not linear and uch greater increase in stability by this method would ause extreme compromise with performance.

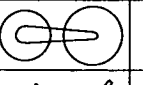
If offset flapping hinges are used, then the aircraft center-f-gravity position affects angle-of-attack stability. An esti-nate for this helicopter is that, with the hinges at 5 percent lade radius, moving the center of gravity 7 inches (2.5 per-ent of the rotor radius) forward from the rotor shaft would roduce as much change as the 33-percent increase in rotor otational speed. With the same offset, a center-of-gravity ift of 14 inches, if such is tolerable, would produce the hange to the −2,100 value and thus would permit the re-uirements to be exceeded.

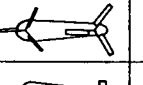
For alternate methods of varying the rotor damping in itch M_q, the methods given in the roll-sensitivity discussion gain apply.

The discussion of this section is in terms of existing criteria hich in turn relate most specifically to normal-acceleration haracteristics in maneuvers. It might be remarked that in ertain instances, when the normal-acceleration criteria for naneuver stability are just met, the pitching velocity still ows appreciable divergent tendencies. Consideration of the problem suggests that when such situations arise, by carrying somewhat farther the methods that have just been described, logical development with time should be achieved for pitching velocity as well as normal acceleration, so that no fundamentally new problems seem to be represented.

MANEUVER STABILITY OF TANDEM-ROTOR HELICOPTERS

Maneuver stability of the tandem helicopter, again at cruising speed, is treated in table III. The parameter considered is again pitching moment per unit angle-of-attack change, and with the test helicopter the unstable value of 57,000 pound-feet per radian corresponded to a value that would just barely meet the requirements set forth in the specification. While a change of only 15,000 pound-feet per radian would have sufficed to just reach the marginal value of 57,000, a change of 88,000 in the direction of increased stability was explored. It is desirable to be able to make these larger changes. The test method used was not altogether appropriate for this discussion because so much of the range was obtained by choice of power setting. The available center-of-gravity range produced a useful but subordinate change, a forward center of gravity being the more stable.





Because the test method was not altogether appropriate for large changes, calculations are again used to illustrate other methods. Changes which affect the relative lift-curve slopes of the front and rear rotors seem especially effective. It is estimated that, if the front-rotor radius is decreased and the rear-rotor radius is increased to provide a total difference of 10 percent of the mean radius, the test value of stability increase would be realized. If, instead, a differential in rotor solidities were effected by putting wider blades on the rear rotor and narrower ones on the front rotor, this same stability increase could be obtained with a solidity differential of 45 percent of the mean value.

The size of horizontal-tail surface necessary to contribute the same range was computed, in order to illustrate the indication in reference 9 that a horizontal tail is relatively less effective for tandems than for single rotors. A value of 4 percent of rotor area is indicated in distinction to the 0.5

TABLE III

MANEUVER STABILITY
[Tandem rotor; 7,000−lb gross wt.; cruise speed]

Major parameter	Value to meet MIL-H-8501	Range tested	Method used
M_α, $\frac{\text{lb-ft}}{\text{radian}}$	<57,000	72,000 to −16,000	c.g. and power setting

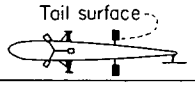
Additional methods	Amount for range tested
ΔR (same Ω) 	10%
$\Delta\sigma$ 	45%
Tail surface 	100 sq ft or 4% of total rotor area

percent indicated for the single-rotor helicopters. Although the two cases are not strictly comparable, the relative order of magnitude is considered to be reasonable.

SPEED STABILITY OF SINGLE-ROTOR HELICOPTERS

Table IV treats the speed stability of a single-rotor helicopter. For a helicopter to be stable with speed, it is required that, with fixed pitch and throttle, the stick be moved farther forward for trim with increase in speed. The parameter used to measure this change is the longitudinal cyclic pitch B_1 per unit velocity V (in knots). The range tested (B_1/V from 0 to 0.06 degrees per knot) was obtained by changes in horizontal-tail setting. When sufficient upload was provided on the tail surface, the stable contribution of the rotor could be cancelled; when download was provided, it could be increased. Incidentally, most of this exploration of near-zero speed stability was carried out with the tail linked to the cyclic stick, the reason being that a high, fixed, nose-up tail setting can be dangerous in the event of inadvertent speed increase.

The rotor tends to be stable, but counteracting factors must still be considered. Some fuselage shapes can be as destabilizing as a nose-up tail setting, although a range of 30 foot-pounds per knot would be rather unusual. A large rotor-blade-section diving moment could more than cancel the stable tendency of the rotor. The increment Δc_m of 0.06 actually was suggested by the dangerous characteristics which arose with autogiros having $c_m = -0.06$. A rough estimate indicated the value of 0.06 to be the right order of magnitude to produce the change under discussion as well.



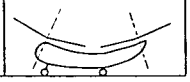
SPEED STABILITY OF TANDEM-ROTOR HELICOPTERS

Table V relates to speed stability of the tandem-rotor type of helicopter. The longitudinal control of this configuration is obtained primarily by changing the pitch-setting difference between front and rear rotors, and the parameter is written as $\Delta\theta/V$ to correspond. This quantity was varied from -0.01 to 0.003; thus, the requirement of at least zero is bracketed. This change was accomplished by changing the tilt angle between the front and rear rotor systems. The unstable setting was 0°; the stable one, 1.8° "toe-in."

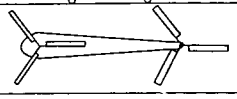
TABLE IV

SPEED STABILITY

[Single rotor; 5,000-lb gross wt.; cruise speed]



Parameter	Value to meet MIL-H-8501	Range tested	Method used
$\frac{B_1}{V}$, $\frac{\text{deg}}{\text{knot}}$	>0	0 to 0.06	Tail surface 



Additional factors	Amount for range tested
Moments, fuselage less tail	$\Delta\frac{\text{ft-lb}}{\text{knot}} = 30$
Blade section pitching-moment coefficient	$\Delta c_m \approx 0.06$

TABLE V

SPEED STABILITY

[Tandem rotor; 7,000-lb gross wt.; cruise speed]

Parameter	Value to meet MIL-H-8501	Range tested	Method used
$\frac{\Delta\theta}{V}$, $\frac{\text{deg}}{\text{knot}}$	>0	−0.01 to 0.003	$-1.8° \Delta a_g$ 

Additional factors	Amount for range tested
c.g. shift 	22%
$\Delta\sigma$ 	34%

Calculations indicate that a center-of-gravity shift from midway between the shafts to 22 percent ahead of the mid point should produce the equivalent range. The 22-percen value is based on total distance between shafts. Similarly giving the rear rotor higher solidity and the front less, with a total difference $\Delta\sigma$ of 34 percent of the mean, should achiev this same result. These values are for cruising speed; a low speeds the effect of center of gravity can even reverse whereas the solidity change becomes more effective. Th use of these methods in combination thus holds specia interest. It is also worth noting that these effects act i the same direction for speed stability as they do for maneuve stability.

LATERAL-OSCILLATION AND TURN CHARACTERISTICS OF TANDEM-ROTOR HELICOPTERS

Tandem-rotor lateral-oscillation and turn characteristic at cruise speed are treated in table VI. One of the mos effective parameters for both is rolling moment per uni sideslip velocity, or L/v, measured as foot-pounds of rollin moment per foot per second of sideslip velocity. Fortunately this quantity, which is the effective dihedral, is not critica in its own right, provided it stays on the stable side. (B convention, stable values are negative.) Most of the require change was obtained by attaching small wings (surface area

TABLE VI

Additional method	Amount for range tested
Vertical c.g. − c.p. relationship	9 in.

square feet) to the landing gear. The front view and side ew are shown. It was most convenient in these flying-ualities trials to extend the test conditions further by chang-g the flight conditions; but with so many designs beginning appear with moderate-sized wings (much bigger than the anels used in these tests), making the full change needed ay often require only the determination of the correct eometric dihedral.

One additional method is to change the vertical location the center of gravity relative to the side-view area. Only major change in power-plant location, such as a shift to verhead turbines, seems likely to make a change of the ecessary magnitude (9-inch shift in center of gravity). ontributing changes, though, including some ventral-fin rea, may often prove feasible.

Increasing the damping in roll is another effective approach hat can be considered. This method is discussed, along ith still other approaches, in reference 4.

CONCLUDING REMARKS FOR PART I

Examples have been presented to illustrate methods for nproving helicopter stability. It will be realized that any of the numerical values which have been given apply nly for the case studied. For example, a tandem helicopter ight already have lower effective dihedral or might some-ow be designed with less nose-down inclination of the rincipal inertia axis and, in either event, might meet the teral requirements without reduction in effective dihedral.

The cases presented are believed to illustrate that it is ow feasible to choose one or more important stability arameters from theoretical studies and, in turn, to find a ombination of methods whereby values of the parameters re realized which provide the desired stability character-tics.

The obtainment of desired stability characteristics with a inimum of design compromise requires first of all a high egree of fundamental understanding. To achieve this end workable theory must be available. It is believed that the xistence of such theory has been demonstrated. In addition such use of theory, the outstanding key to the obtainment desired characteristics with minimum design compromise eems to be the availability and use of a variety of physical ethods in combination with one another. It is hoped that he sample methods presented may be helpful in suggesting ill more approaches to the helicopter designer.

—PROCEDURES FOR PREDICTING HELICOPTER STABILITY

The prediction of stability derivatives requires a knowledge the contributions of both the rotor and the fuselage. uselage characteristics are not open to as specific an analysis s rotor characteristics, and preliminary estimates can be andled on the basis of data from previous designs and from ind-tunnel model tests. The fuselage seems to be subject greater modification up to the time production starts; onsequently, this discussion is confined primarily to the otor contributions to the derivatives.

SYMBOLS

W	gross weight of helicopter, lb
m	mass of helicopter, slugs
g	acceleration due to gravity, 32.2 ft/sec^2
R	blade radius, ft
c	blade-section chord, ft
c_e	equivalent blade chord (on thrust basis), $\frac{\int_0^R cr^2dr}{\int_0^R r^2dr}$, ft
b	number of blades per rotor
σ	rotor solidity, $bc_e/\pi R$
Θ	instantaneous blade-section pitch angle (angle between line of zero lift of blade section and plane perpendicular to rotor shaft), $\theta - A_1 \cos\psi - B_1 \sin\psi$, radians
θ	collective-pitch angle (average value of Θ around azimuth), radians
ρ	mass density of air, slugs/cu ft
γ	mass constant of rotor blade (ratio of air forces to mass forces), $\rho caR^4/I_1$; also, flight-path angle, radians
I_X	helicopter rolling moment of inertia about center of gravity, slug-ft^2
I_Y	helicopter pitching moment of inertia about center of gravity, slug-ft^2
I_Z	helicopter yawing moment of inertia about center of gravity, slug-ft^2
$\Delta\theta$	difference between collective-pitch angles of front and rear rotors, positive when collective-pitch angle of rear rotor is greater, radians; also, increment of θ
I_1	mass moment of inertia of blade about flapping hinge, slug-ft^2
ΔT	difference between thrusts of front and rear rotors, positive when thrust of rear rotor is greater, lb
$\Delta R, \Delta(\Omega R), \Delta\sigma$	definitions analogous to that for ΔT
$\Delta\alpha_d$	difference between angles of attack of front and rear rotors due to longitudinal swashplate tilt, positive when rear-rotor angle of attack is greater
A_1, B_1	coefficients of $-\cos\psi$ and $-\sin\psi$, respectively, in expression for Θ; therefore, lateral and longitudinal cyclic pitch, respectively, radians
δ	control motion, inches from trim
t	time, sec
V	true airspeed of helicopter along flight path, ft/sec
v	sideslip velocity of helicopter in Y-direction, ft/sec
α	rotor angle of attack (angle between flight path and plane perpendicular to axis of no feathering), positive when axis is inclined rearward, radians
Ω	rotor angular velocity, radians/sec
μ	tip-speed ratio, $\frac{V\cos\alpha}{\Omega R}\left(\text{assumed equal to } \frac{V}{\Omega R}\right)$
U_T	component at blade element of resultant velocity perpendicular to blade-span axis and to axis of no feathering, ft/sec

$u_T = U_T/\Omega R$

ψ blade azimuth angle (measured in direction of rotation from downwind position of blade if wind axes are used; measured in direction of rotation from position of blade when it is pointing rearward along longitudinal axis of helicopter if body axes are used), radians

a slope of curve of blade section lift coefficient plotted against section angle of attack, per radian

L rotor lift, lb; also, rolling moment, lb-ft

T rotor thrust (component of rotor resultant force parallel to axis of no feathering), lb

Q rotor-shaft torque, lb-ft

C_T rotor thrust coefficient, $\frac{T}{\pi R^2 \rho (\Omega R)^2}$

C_Q rotor-shaft torque coefficient, $\frac{Q}{\pi R^2 \rho (\Omega R)^2 R}$

β blade flapping angle at particular azimuth position, $a_0 - a_1 \cos \psi - b_1 \sin \psi$ . . ., radians; also, sideslip angle, radians

a_0 constant term in Fourier series that expresses β; therefore, rotor coning angle

a_1 coefficient of $-\cos \psi$ in expression for β; therefore, longitudinal tilt of rotor cone

b_1 coefficient of $-\sin \psi$ in expression for β; therefore, lateral tilt of rotor cone

a' projection of angle between rotor resultant force vector and axis of no feathering in plane containing flight path and axis of no feathering

b' projection of angle between rotor resultant force vector and axis of no feathering in plane containing axis of no feathering and perpendicular to plane containing flight path and axis of no feathering

p helicopter rolling velocity, radians/sec

q helicopter pitching velocity, radians/sec

r helicopter yawing velocity, radians/sec; also, radial distance to blade element, ft

ϕ angle of roll, radians

N yawing moment, lb-ft

M pitching moment, lb-ft

h height of rotor hub above helicopter center of gravity, ft

η angle between principal longitudinal axis of inertia of helicopter and flight path, positive when nose is up, radians

X, Y, Z stability axes

Dots over symbols indicate derivatives with respect to time.

ROTOR STABILITY DERIVATIVES

In general, calculation of the stability derivatives needed for a study of helicopter characteristics depends on the knowledge of the individual rotor derivatives shown in th following table:

$\frac{\partial(C_T/\sigma)}{\partial\alpha}$	$\frac{\partial(C_T/\sigma)}{\partial V}$	$\frac{\partial(C_T/\sigma)}{\partial\Omega}$	$\frac{\partial(C_T/\sigma)}{\partial\theta}$	$\frac{\partial(C_T/\sigma)}{\partial q}$
$\frac{\partial a'}{\partial\alpha}$	$\frac{\partial a'}{\partial V}$	$\frac{\partial a'}{\partial\Omega}$	$\frac{\partial a'}{\partial\theta}$	$\frac{\partial a'}{\partial q} = \frac{\partial b'}{\partial p}$
$\frac{\partial(C_Q/\sigma)}{\partial\alpha}$	$\frac{\partial(C_Q/\sigma)}{\partial V}$	$\frac{\partial(C_Q/\sigma)}{\partial\Omega}$	$\frac{\partial(C_Q/\sigma)}{\partial\theta}$	$\frac{\partial(C_Q/\sigma)}{\partial q}$
$\frac{\partial a_0}{\partial\alpha}$	$\frac{\partial a_0}{\partial V}$	$\frac{\partial a_0}{\partial\Omega}$	$\frac{\partial a_0}{\partial\theta}$	$\frac{\partial a_0}{\partial q}$
$\frac{\partial a_1}{\partial\alpha}$	$\frac{\partial a_1}{\partial V}$	$\frac{\partial a_1}{\partial\Omega}$	$\frac{\partial a_1}{\partial\theta}$	$\frac{\partial a_1}{\partial q}$
$\frac{\partial b_1}{\partial\alpha}$	$\frac{\partial b_1}{\partial V}$	$\frac{\partial b_1}{\partial\Omega}$	$\frac{\partial b_1}{\partial\theta}$	$\frac{\partial b_1}{\partial q}$

As shown, the rotor parameters considered are C_T/σ and a' the magnitude and angle of the thrust vector, respectively rotor torque C_Q/σ; blade coning angle a_0; and b_1 and a_1, th lateral and longitudinal flapping, respectively. These roto parameters are functions of five independent variables: roto angle of attack α, forward speed V, rotational speed Ω, col lective pitch θ, and pitching velocity q. The values of th derivatives are determined by the variations from trim o the rotor parameters with changes in each of the five vari ables. The total number of derivatives shown here is large however, for most applications it is generally possible to re duce the number considerably. For instance, if the roto under consideration has no flapping-hinge offset, the flappin coefficients are not significant; thus, the number of deriva tives to be considered is immediately reduced by abou one-half. If necessary, however, these derivatives can b determined from the equations of references 10 and 14.

Of the remaining derivatives, the lift due to pitching an torque due to pitching generally can be neglected. Fo most cases, then, the derivatives needed have been reduce to those enclosed within the lines in the preceding table All the C_T/σ, C_Q/σ, and a' derivatives can be obtained fron the figures or equations of references 8 and 10, as is show in the following discussion.

The thrust due to angle of attack and that due to collec tive pitch are presented as functions of tip-speed ratio i figure 1. If the solidity and tip-speed ratio for a given cas are known, these quantities can be read directly from th curves. The equations on which this figure is based and th processes by which they were derived are discussed i reference 8.

The change in thrust coefficient with tip-speed ratio i presented in reference 8 in the form of an equation fron which, when the flight condition is known, the rate of chang

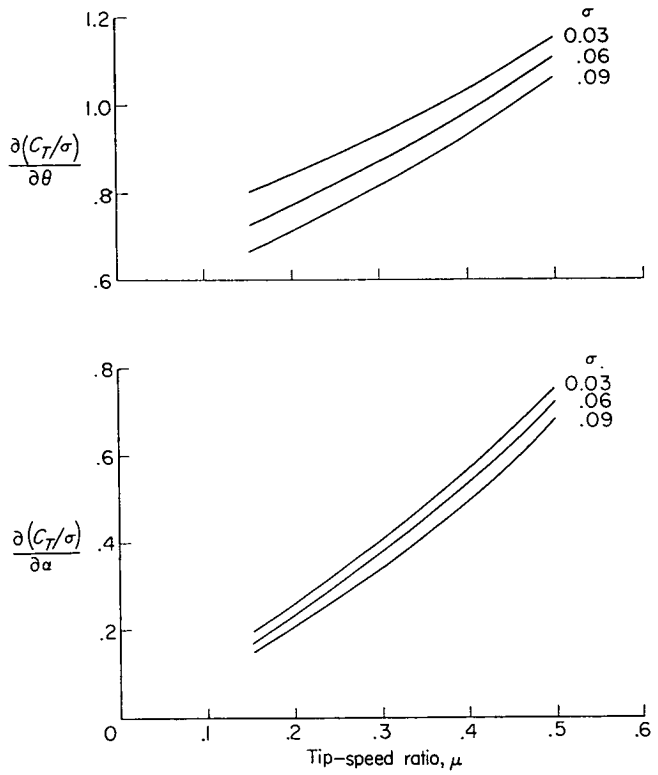

FIGURE 1.—Variation of C_T/σ derivatives with respect to μ.

of thrust coefficient with forward speed and rotational speed can be computed.

The change in inclination of the rotor force vector due to steady pitching or rolling velocity has been derived in reference 10. This derivative is shown in figure 2 as a function of the parameter $\frac{\theta}{C_T/\sigma}$. As the effect of tip-speed ratio μ is small, the formula shown in figure 2 is fairly accurate below a tip-speed ratio of 0.5 for both roll and pitch. The rotor damping moment is determined simply by multiplying the quantity obtained from the figure by $18/\gamma\Omega$ and by the rotor thrust and rotor height above the helicopter center of gravity; that is,

$$\frac{\partial M}{\partial q}=\frac{\partial a'/\partial q}{18/\gamma\Omega}\left(Th\,\frac{18}{\gamma\Omega}\right)$$

For the rotor-vector angle and rotor torque derivatives, charts such as those shown in figure 3 have been derived and are published in reference 8. These charts are given for a range of collective-pitch angles from 0° to 14° at 2° increments; the sample shown herein is for a collective pitch of 8°. In these charts, the longitudinal rotor-vector angle a' is plotted against the ratio of thrust coefficient to solidity for specified values of tip-speed ratio. Lines of constant power parameter $C_Q/C_T\mu$ are also plotted on the charts. Combinations of these parameters which result in angles of attack of 12° and 16° on the retreating blade are indicated by dashed lines; these lines, in effect, serve as limit lines above which account must be taken of stall. By using slopes or differences from these charts in conjunction with

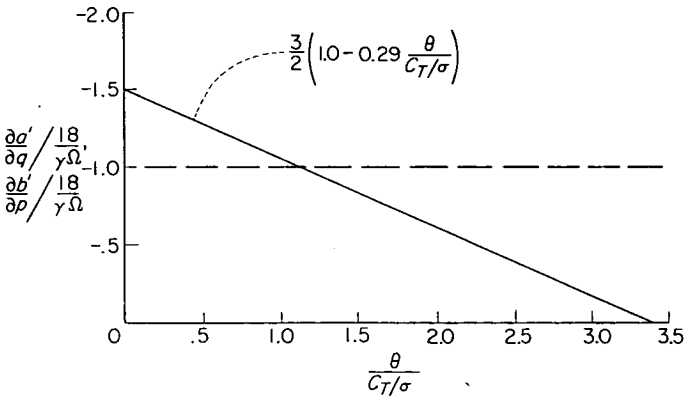

FIGURE 2.—Chart for determining rotor damping in pitch and roll.

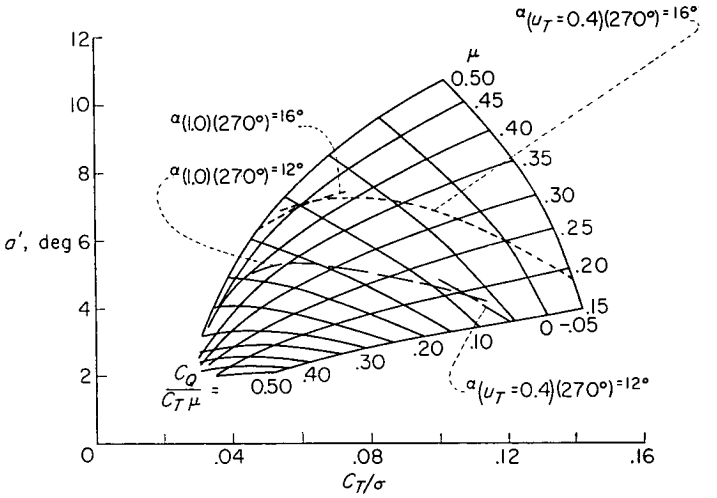

FIGURE 3.—Sample chart for determining derivatives of a' and C_Q/σ. $\theta=8°$.

other derivatives and some simple equations, the remaining derivatives of a' and of the torque coefficient can be obtained. As an example, consider the derivative of a' with respect to angle of attack. From charts such as figure 3, the rate of change of a' with thrust coefficient can be obtained at a given tip-speed ratio and thrust coefficient by scaling off the slope of the tip-speed-ratio line at the desired thrust coefficient. When this quantity is multiplied by the change in thrust coefficient with angle of attack, which has already been discussed, the result is the change in a' with angle of attack. The other a' and the torque coefficient derivatives can be obtained by similar procedures. These procedures are discussed in reference 8.

PREDICTION OF HELICOPTER STABILITY CHARACTERISTICS

It is believed that the rotor contribution to the essential helicopter derivatives can be predicted by using the rotor derivatives that have been discussed. These rotor derivatives are applicable, in most cases, to a study of the stability characteristics of either a single-rotor or a tandem-rotor configuration. Differences arise in using the rotor derivatives to determine the helicopter derivatives for use in the equations of motion and in accounting for the effects of flow

interference for a specific configuration. For most purposes, the lateral and longitudinal characteristics of the helicopter can be studied separately. Generally, equations of motion derived on the basis of constant forward speed are sufficient and are applicable to both single- and tandem-rotor configurations.

Longitudinal characteristics.—In a study of the longitudinal characteristics of the helicopter (refs. 5 and 11), an important criterion is that the time history of the normal acceleration shall be concave downward within 2 seconds after a step input to the longitudinal control; that is, the slope of the normal acceleration curve shall reach its maximum value and begin to decrease within 2 seconds. In order to assist in estimating theoretically whether a prospective helicopter will meet this criterion, the following equations of motion were devised:

$$\frac{\partial L}{\partial q}q+\frac{\partial L}{\partial \theta}\Delta\theta+\frac{\partial L}{\partial \alpha}\Delta\alpha-\frac{WV}{g}\dot{\gamma}=0$$

$$\frac{\partial M}{\partial q}q+\frac{\partial M}{\partial \theta}\Delta\theta+\frac{\partial M}{\partial \alpha}\Delta\alpha+\frac{\partial M}{\partial B_1}\Delta B_1-I_Y\dot{q}=0$$

$$\Delta\alpha=\int_0^t q\,dt-\Delta\gamma-\Delta B_1$$

These equations are based on stability axes and derived on the assumptions of constant forward speed, constant rotor speed, and constant stability derivatives. The assumption is also made that the dynamic maneuver can be represented by a series of static conditions; hence, the rotor parameters are always at their equilibrium values as determined by the instantaneous values of angle of attack, pitch angle, tip-speed ratio, and pitching velocity. The first and second equations shown represent, respectively, equilibrium normal to the flight path and equilibrium in pitch. The third equation simply relates the variables of the first two equations to permit a solution.

The form of these equations applies specifically to the single-rotor configuration. For the tandem configuration, the pitching moment due to control motion results primarily from differential collective pitch of the two rotors rather than from cyclic pitch; thus, the term in the equations expressing pitching moment due to control motion must be modified to account for this difference.

In reference 5, these equations of motion have been solved for the flight-path angle γ, which, in turn, permits an expression to be written for the time history of the normal acceleration. Values of combinations of derivatives have been determined which, when substituted into the expression for the time history of normal acceleration, will result in a time history that is concave downward at 2 seconds. These values have been presented in the form of a chart. (See fig. 4.) Thus the curve in figure 4 is a boundary line that separates combinations of significant longitudinal stability derivatives which result in satisfactory characteristics from those which result in unsatisfactory characteristics according to the criterion previously mentioned. Shown along

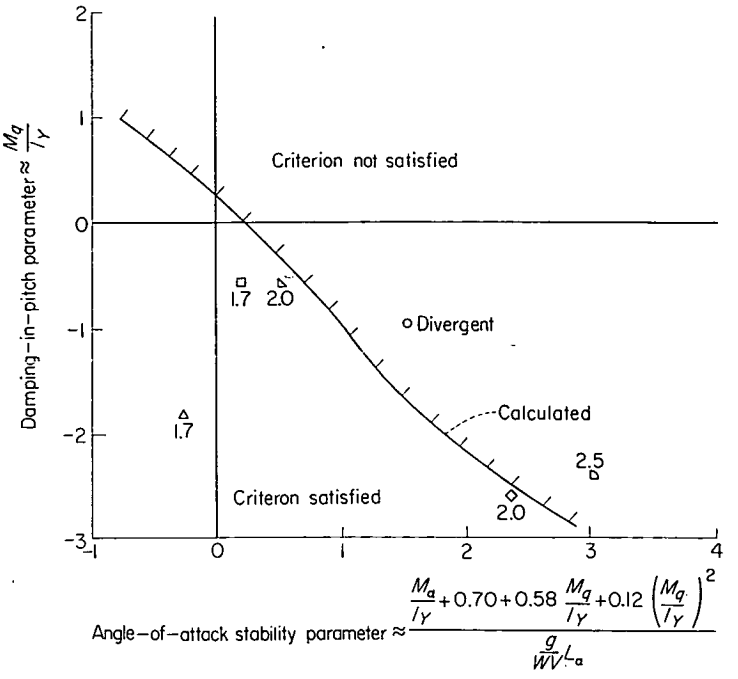

FIGURE 4.—Maneuver-stability chart for 2-second criterion.

with the theoretical curve are data points corresponding to five helicopter configurations. The derivatives for the configurations corresponding to the points shown were measured in flight and the adjacent number is the approximate time for the corresponding normal-acceleration time history to become concave downward. For both single- and tandem-rotor helicopters, the theoretical curve is indicated to be qualitatively correct for separating configurations which have satisfactory maneuver stability from those which have unsatisfactory maneuver stability according to the criterion; that is, the experimental points for which the normal-acceleration time history becomes concave downward in less than 2 seconds fall in the satisfactory region whereas, for times of more than 2 seconds, the points fall in the unsatisfactory region.

Figure 4 shows that an increase in the angle-of-attack stability or damping in pitch (that is, more negative M_α or M_q) or increases in the rotor lift-curve slope L_α are stabilizing. Also, it can be determined from this plot that an increase in the pitching moment of inertia I_Y can be destabilizing. Since the change in lift slope cannot be large and the lift slope is not expected to change sign, the primary changes in stability must be brought about by changes in the damping-in-pitch or angle-of-attack stability.

In the discussion of longitudinal stability so far, the forward speed has been assumed to be constant. For the tandem configuration, however, the downwash effects of the front rotor acting on the rear rotor cause an unstable variation in pitching moment with speed. A study of the speed stability of the tandem helicopter was made in reference 6. In that study, on the basis of the available derivatives discussed previously, an expression for the change of stick position with speed was derived. The equation, along with a plot of constants based on the rotor derivatives, is shown in

figure 5. These constants are presented for several values of rotor solidity over a range of tip-speed ratios. After a flight condition is selected and the tip-speed ratio and thrust coefficient are thereby established, the slope of the variation of stick position with speed can be determined. This equation takes into account the effects on speed stability of center-of-gravity position, differential rotor speed, differential rotor radius and solidity, and "longitudinal dihedral." Effects of these parameters can be studied either together or separately.

This analysis of tandem-helicopter speed stability is of particular value in studies, such as the study of the relative effects of changes in the various parameters, wherein it is not necessary to know accurately the value of downwash or the fuselage contribution. In order to predict the absolute value of speed stability, the downwash must be estimated for the configuration and flight condition under consideration, and the variation of the fuselage moments must be known. The results of flow-field measurements

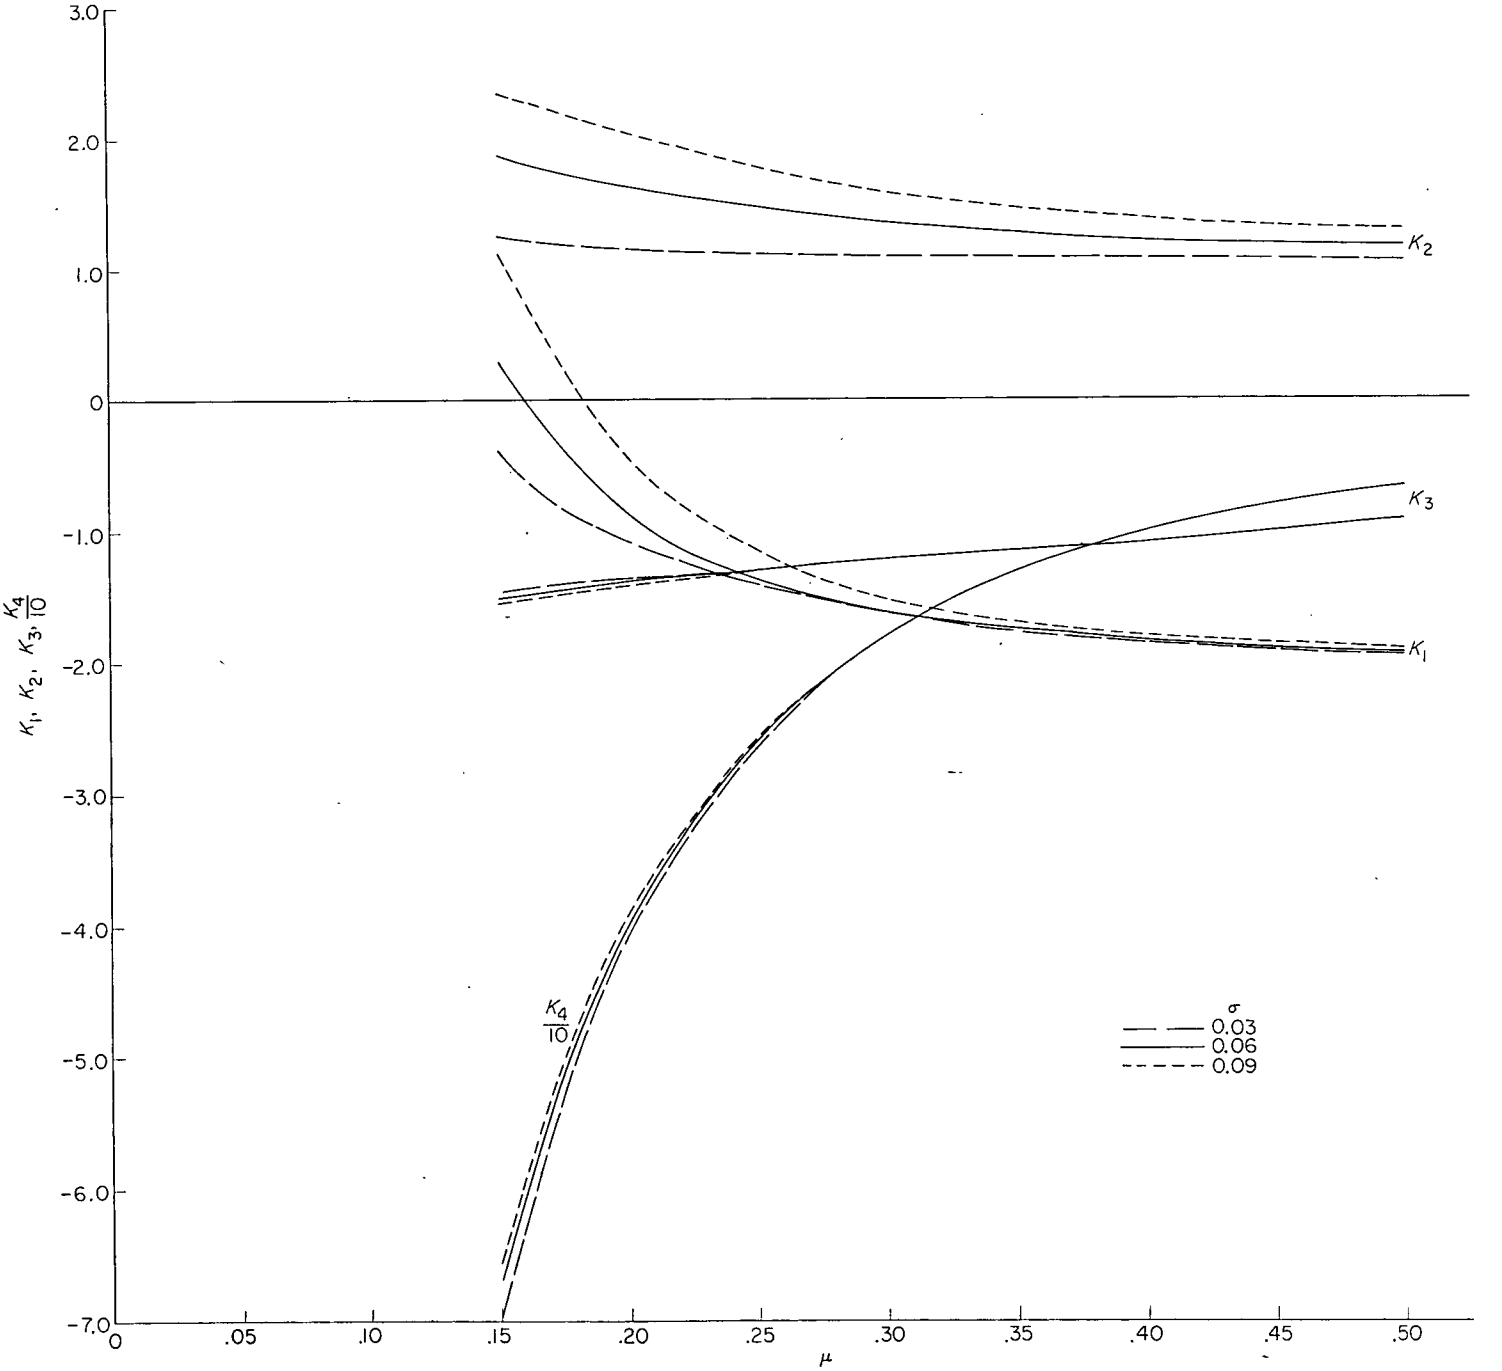

FIGURE 5.—Equation for speed stability of tandem-rotor helicopters.

$$\frac{d(\Delta\theta)}{d\mu}=K_1\left(\frac{C_T}{\sigma}\right)_{AV}\left(\frac{\Delta T}{W}-\frac{\Delta R}{R_{AV}}\right)+K_2\left(\frac{C_T}{\sigma}\right)_{AV}\left[\frac{\Delta\sigma}{\sigma_{AV}}+2\,\frac{\Delta(\Omega R)}{(\Omega R)_{AV}}\right]+K_3\Delta\alpha_d+K_4C_T$$

presented in references 15 to 18 should be useful in estimating the magnitude of the downwash applicable to a specific condition.

Lateral-directional characteristics.—The next important item in helicopter stability is the lateral-directional characteristics. If roll, yaw, and sideslip are considered as degrees of freedom, the equations of motion are as follows:

$$I_{x'}\ddot{\phi}+\frac{\partial L}{\partial p}\dot{\phi}+\frac{\partial L}{\partial v}v-\frac{\partial L}{\partial \delta}\delta=0$$

$$I_{z'}\ddot{\psi}+\frac{\partial N}{\partial r}\dot{\psi}+\frac{\partial N}{\partial v}v-\frac{\partial N}{\partial \delta}\delta=0$$

$$\left(mV-\frac{\partial Y}{\partial r}\right)\dot{\psi}-\left(mV\sin\eta+\frac{\partial Y}{\partial p}\right)\dot{\phi}-T\phi-T\psi\tan\gamma+m\dot{v}-\frac{\partial Y}{\partial v}v-\frac{\partial Y}{\partial \delta}\delta=0$$

For convenience in determining the derivatives, these equations are based on principal axes of inertia (primed symbols) rather than on the relative wind. In general, the rotor contribution to the derivatives needed in these equations can also be determined from rotor theory. Fuselage contributions can be predicted from wind-tunnel data and previous experience or from flight data where available.

These equations have been found useful particularly in estimating the effects on helicopter characteristics of changes in the individual stability derivatives. As an example, figure 6 shows the theoretically predicted time histories of rolling velocity and sideslip angle of a tandem-rotor helicopter. The curves on the left-hand side of figure 6 represent the predicted time histories for the original helicopter. On the right-hand side of figure 6 are time histories of the same quantities when the effective-dihedral derivative is reduced 50 percent. This figure indicates that a 50-percent reduction in the effective dihedral would substantially improve the oscillatory characteristics of the helicopter. In an attempt to improve the characteristics, this means was tried experimentally. The results are shown in figure 7, wherein the experimentally measured time histories of rolling velocity and sideslip angle before and after the derivative change are compared. The comparison shows that, as predicted by the theory, a reduction in the effective dihedral improved the

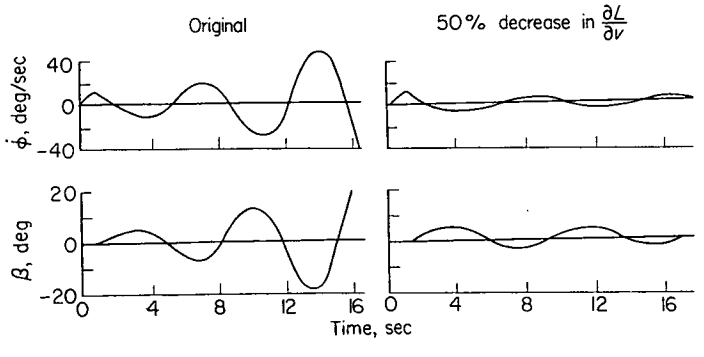

FIGURE 6.—Predicted effect of reduction in effective dihedral on lateral oscillation.

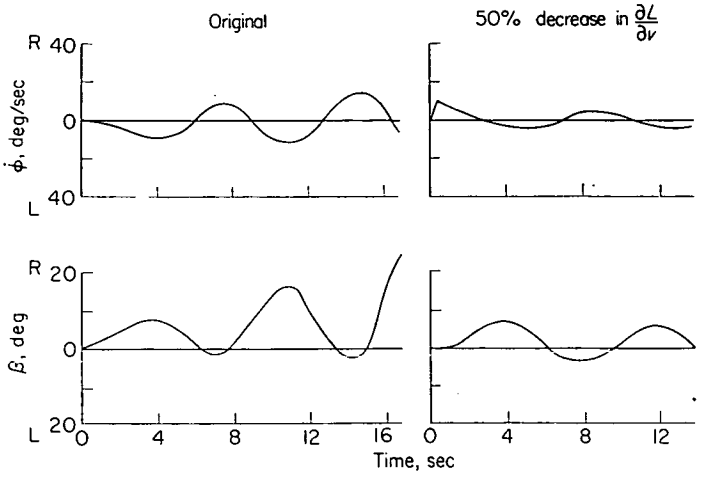

FIGURE 7.—Measured effect of reduction in effective dihedral on lateral oscillation.

oscillation. Thus, in this case, the theory was employed successfully to indicate the course to be followed in making an improvement.

CONCLUDING REMARKS FOR PART II

It will frequently not be feasible to predict accurately absolute magnitudes for the stability of the complete helicopter, particularly because of the difficulty of predetermining final, full-scale fuselage characteristics. However, on the basis of the studies discussed herein, a first approximation can be made, and by making some comparatively straightforward flight measurements of stability derivatives and reemploying the theory to show what modifications are needed, it appears feasible to handle at least those problems with which direct experience has been had. It appears likely that, in most cases, changes in several derivatives simultaneously would be necessary to achieve most efficiently the desirable stability characteristics, and the equations discussed herein should prove very useful in this type of study.

REPORT 1351

FOREWORD

During the early part of World War II, some of the helicopters designed for military use were observed during ground tests to exhibit a violent oscillatory rotor instability which endangered the safety of the aircraft. This instability was at first attributed to rotor-blade flutter, but a careful analysis indicated it to be caused by a hitherto unknown phenomenon in which the rotational energy of the rotor was converted into oscillatory energy of the blades. This phenomenon was usually critical when the helicopter was operating on or near the ground and, hence, was called ground resonance. An oscillatory instability of such magnitude as resulted from this phenomenon would generate forces that could quickly destroy a helicopter. The research efforts of the National Advisory Committee for Aeronautics were therefore enlisted to investigate the difficulties introduced by this phenomenon. During the interval between 1942 and 1947, a theory of the self-excited instability of hinged rotor blades was worked out by Robert P. Coleman and Arnold M. Feingold at the Langley Aeronautical Laboratory. This theory defined the important parameters and provided design information which made it possible to eliminate this type of instability. These results were originally released by the NACA in three separate papers, as follows:

(1) NACA Advance Restricted Report 3G29, 1943 (Wartime Report L–308) entitled "Theory of Self-Excited Mechanical Oscillations of Hinged Rotor Blades," by Robert P. Coleman.

(2) NACA Advance Restricted Report 3I13, 1943 (Wartime Report L–312) entitled "Theory of Mechanical Oscillations of Rotors With Two Hinged Blades," by Arnold M. Feingold.

(3) NACA Technical Note 1184, 1947, entitled "Theory of Ground Vibrations of a Two-Blade Helicopter Rotor on Anisotropic Flexible Supports," by Robert P. Coleman and Arnold M. Feingold.

These three reports have been recognized to contain the fundamental reference material on the subject of rotor mechanical instability but were for some time out of print. As a result of demands for this type of information, they were combined into a single volume and reissued with appropriate corrections as NACA Technical Note 3844. The combined volume (reissued here as an NACA Report) consists of three chapters representing the three aforementioned papers in consecutive order.

Inasmuch as the authors of these papers are no longer with the NACA, the task of checking these papers and incorporating such corrections as seemed proper was undertaken by George W. Brooks, Vibration and Flutter Branch, Dynamic Loads Division, of the Langley Aeronautical Laboratory. Mr. Brooks also prepared an appendix to chapter III, which deals with the general equations of motion for a two-blade rotor and includes the effects of damping.

THEORY OF SELF-EXCITED MECHANICAL OSCILLATIONS OF HELICOPTER ROTORS WITH HINGED BLADES [1]

By Robert P. Coleman and Arnold M. Feingold

CHAPTER I

THEORY OF SELF-EXCITED MECHANICAL OSCILLATIONS OF HINGED ROTOR BLADES

By Robert P. Coleman

SUMMARY

Vibrations of rotary-wing aircraft may derive their energy from the rotation of the rotor rather than from the air forces. A theoretical analysis of these vibrations is described and methods for its application are explained herein.

The theory includes the effects of unequal stiffness of the pylon for deflections in different directions and the effect of damping in the hinges and in the pylon. Both the derivation of the characteristics equation and the methods of application of the theory are given. In particular, the theory predicts the so-called "odd frequency" self-excited speed range as well as the shaft critical speed. Charts are presented from which the shaft critical and the self-excited instabilities can be predicted for a great variety of cases. The influence of each physical parameter upon the instabilities has been obtained. The comprehensive treatment applies to a rotor that has any number of blades greater than two. Only a brief discussion and the formula for shaft critical speed are given for the one- or two-blade rotor.

The use of complex variables in conjunction with Lagrange's equations has been found very convenient for the treatment of vibrations of rotating systems.

INTRODUCTION

A rotary-wing aircraft that has hinged blades will, under certain conditions, be subject to vibrations which derive their energy from the rotation of the rotor instead of from the air forces. The term "ground resonance" usually refers to vibrations of this type. Although such vibrations have apparently caused accidents in some rotary-wing aircraft and have impaired the flying qualities of others, very little attention has been given this problem in the literature. A theoretical analysis has therefore been undertaken, and the purpose of the present chapter is to present the theory and to describe the application of the theory to rotary-wing aircraft.

General vibration theory and its application to allied problems as well as to the particular problem of rotor vibration are discussed in references 1 to 4. A good general background for the present problem is provided in the chapters on rotating machinery and on self-excited vibrations in reference 1. References 2 and 3 treat in more abstract fashion the topics of rotation and damping. A discussion of the variety of modes of vibration that exist in rotors and a number of frequency formulas obtained by considering separately each degree of freedom are given in reference 4. This discussion does not, however, lead to a prediction of self-excited modes of vibration.

Experience has shown that two types of mechanical vibration may occur in rotors. The vibration frequency of the pylon is equal to the rotational speed in one type and is unequal in the other. The first type is sometimes called the even-frequency vibration or the one-to-one frequency, and the second type, the odd frequency. The one-to-one frequency vibration resembles the phenomenon occurring at a critical speed of the shaft of rotating machinery and will consequently be referred to in this chapter as a shaft critical vibration. The odd-frequency vibration is properly called a self-excited vibration.

A derivation of the characteristic equation for the whirling speeds of a three-blade rotor has been given by Wagner of the Kellett Autogiro Corporation. By considering only the case of a pylon having equal stiffness in all directions of deflection, Wagner has shortened the analysis by considering directly the equilibrium of forces and moments under conditions of steady circular whirling. Some examples of the dependence of whirling speed upon rotational speed are given, and the formula for the shaft critical speed is obtained.

In the present chapter, the theory also includes the effects of damping in the hinges and in the hub and the effects of different stiffnesses of pylon deflection in different directions. The method of analysis, particularly the use of complex

[1] Supersedes NACA Technical Note 3844 by Robert P. Coleman and Arnold M. Feingold, 1957.

variables in the equations of motion, is explained in some detail and all the previous results are shown to be a special case of the more general problem treated here.

SYMBOLS

a	radial position of vertical hinge
A_{11}, $\overline{A}_{11}$, $\Delta A_{11}=\Delta\overline{A}_{11}$, $A_{12}=\overline{A}_{12}$, $A_{21}=\overline{A}_{21}$, A_{22}, $\overline{A}_{22}$	elements of the characteristic determinant (see eq. (31))
b	distance from vertical hinge to center of mass of blade
B	damping force per unit velocity of pylon displacement $\left(B_f=\frac{B_x+B_y}{2}\right)$
$\Delta B_f=\frac{B_x-B_y}{2}$	
B_I	coefficient defined in equation (35)
B_R	coefficient defined in equation (34)
$c, C_1, \ldots C_4$	arbitrary constants
C_I	coefficient defined in equation (35)
C_R	coefficient defined in equation (34)
D	time-derivative operator, d/dt
F	dissipation function
I	moment of inertia of blade about hinge, $m_b b^2\left(1+\frac{r^2}{b^2}\right)$
$I_1, \ldots I_5$	coefficients defined in expressions (37)
j, k	indices and subscripts used with hinge coordinates (eq. (14))
K	spring constant $\left(K_f=\frac{K_x+K_y}{2}\right)$
$\Delta K_f=\frac{K_x-K_y}{2}$	
m	effective mass of pylon $\left(m_f=\frac{m_x+m_y}{2}\right)$
m_b	blade mass
$\Delta m_f=\frac{m_x-m_y}{2}$	
M	total effective mass of blades and pylon, m_f+nm_b
ΔM	mass added at hub for vibration test
n	total number of blades
r	radius of gyration of blade about its center of mass
$R_1, \ldots R_5$	coefficients defined in expressions (37)
s	stiffness ratio, K_y/K_x
t	time
T	kinetic energy
T_r	kinetic energy of rotation of blade about its center of mass
T_k	kinetic energy of translational motion of kth blade
T_s	kinetic energy of pylon
V	potential energy
x, y	displacements
x_o, y_o	values of x and y when $t=0$
z	complex displacement, $x+iy$
$\bar{z}$	complex conjugate of z, $x-iy$
α	angle between blades, $2\pi/n$
$\beta_0, \beta_1, \ldots \beta_k$	angular displacements of blades
β_{k_o}	value of β_k when $t=0$
$\zeta_0, \zeta_1, \ldots \zeta_k$	variables representing hinge deflections when equations are expressed in fixed coordinate system
$\theta_0, \theta_1, \ldots \theta_k$	variables representing hinge deflections when equations are expressed in rotating coordinate system
$\lambda_x=\frac{B_x}{M_x}\left(\frac{B_x}{M_x\omega_r}\text{ in applications}\right)$	
$\lambda_y=\frac{B_y}{M_y}\left(\frac{B_y}{M_y\omega_r}\text{ in applications}\right)$	
$\lambda_\beta=\frac{B_\beta}{I}\left(\frac{B_\beta}{I\omega_r}\text{ in applications}\right)$	
$\lambda_f=\frac{B_f}{M}$	
$\lambda_a=\frac{B_a}{M}$	
$\Delta\lambda_f=\frac{\Delta B_f}{M}$	
$\Lambda_1=\frac{a}{b\left(1+\frac{r^2}{b^2}\right)}$	
$\Lambda_2=\frac{K_\beta}{I}\left(\frac{K_\beta}{I\omega_r^2}\text{ in applications}\right)$	
$\Lambda_3=\frac{\mu}{2\left(1+\frac{r^2}{b^2}\right)}$	
μ	mass ratio, $\frac{nm_b}{m_f+nm_b}$
ν_1, ν_2	expressions defined in equation (3)
ω	angular velocity of rotor (the dimensionless ratio ω/ω_r is called ω in applications)
ω_a	angular whirling velocity measured in rotating coordinate system (used in nondimensional form in applications)
ω_f	angular whirling velocity measured in fixed coordinate system (used in nondimensional form in applications)
ω_r	reference frequency, $\sqrt{K_x/M_x}$
Subscripts:	
f	fixed coordinate system
a	rotating coordinate system
β	hinge deflection
x, y	component directions in fixed coordinate system

APPROACH TO THE VIBRATION PROBLEM

STABILITY AND INSTABILITY

If a vibrator were attached to a rotorcraft, several modes of vibration could be excited at any rotor speed. Only the modes that are likely to be excited during operation of the aircraft, however, are important.

In the present discussion, it is convenient to classify the modes of vibration according to the circumstances required for their excitation. The different types of vibration are identified analytically by the nature of the roots of the characteristic equation. A hinged rotor may encounter three types of vibration which, for convenience, are herein designated ordinary, self excited, and shaft critical. At zero or slow rotational speeds, an external force is required to excite vibration. The friction always present in such systems causes the vibration to be damped out when the force is removed. Modes of vibration requiring an external applied force to maintain them will be called ordinary vibrations. The mathematically idealized case of zero damping will also be considered an ordinary vibration when it is understood to be an approximation to a system actually damped. Self-excited modes of vibration are those with negative damping and are recognized analytically by the fact that a root of the characteristic equation is a complex number which has a negative imaginary part. A slight disturbance will tend to increase with time instead of damping out.

When a rotating system is not perfectly balanced, the centrifugal force of the unbalanced mass may excite vibrations that have peak amplitudes at certain rotational speeds. Vibration excited by unbalance and in resonance with the rotation will be called shaft critical vibration. This type occurs at the rotational speed at which the spring stiffness of the pylon is neutralized by the centrifugal force. In the analysis, the shaft critical vibration is recognized in rotating coordinates as a zero frequency and in fixed coordinates as a frequency equal to the rotational speed. The critical speeds of a rotating shaft are a common example of this class.

The purpose of a theory of rotor vibration is mainly to predict the occurrence of and, if possible, to show how to avoid self-excited and shaft critical vibrations.

CHOICE OF DEGREES OF FREEDOM

Of the large number of degrees of freedom of a hinged rotor, the important ones for the present problem have been found to be hinge deflection of the blades in the plane of rotation and horizontal deflections of the pylon. Other degrees of freedom, such as the flapping hinge motion of the blades, the bending or torsion of the blades, and the torsion of the drive shaft, are considered unimportant in the problem of self-excited oscillations. Some motions, such as landing-gear deflection, that produce lateral deflection at the top of the pylon may, however, be important.

PHYSICAL PARAMETERS

The theoretical results given later provide a means of predicting the natural frequencies and, in particular, the critical speeds and unstable speed ranges in terms of certain physical parameters, such as mass, stiffness, and length. The successful application of the theory depends upon the determination of the proper values of these physical parameters for the aircraft or model being studied.

The important parameters to be determined are:

a radial position of vertical hinge

b distance from vertical hinge to center of mass of blade

m_b mass of blade (Flexibility of the blade structure may have to be taken into account by the use of an effective value of m_b different from the actual blade mass. The effective blade mass can be taken as the value required to make the theory predict the correct pylon natural frequency when the rotor has a zero or very slow rotational speed.)

I moment of inertia of blade about hinge,

$$m_b b^2 \left(1+\frac{r^2}{b^2}\right)$$

K_β spring constant of self-centering springs, which can be determined by a force test or from the hinge frequency with the hub rigidly supported

m_x, m_y effective mass of pylon for deflections in x- and y-directions

K_x, K_y effective stiffness of pylon

The effective mass of the pylon is the value of a concentrated mass that would have the same kinetic energy expressed in terms of the deflections at the hub as the actual pylon and hub if it were placed at the rotor hub in the plane of rotation. The effective stiffness of the pylon is the stiffness of a spring that, if placed at the hub in the plane of rotation, would have the same potential energy in terms of deflections at the hub as the actual pylon. Equivalent definitions are that, if a simple spring and mass were imagined to be substituted at the hub in the plane of rotation for the pylon and hub, the natural frequency and the change of natural frequency with added mass would be the same as for the actual pylon.

An experimental method of measuring the effective mass m_x and stiffness K_x of the pylon is to replace the rotor by an approximately equal, rigid, concentrated mass ΔM at the hub and to measure the natural frequency for two or more values of this added mass. The quantities are then related by the equation

$$\omega_x=\sqrt{\frac{K_x}{m_x+\Delta M}}$$

or

$$\frac{1}{\omega_x^2}=\frac{1}{K_x}(m_x+\Delta M)$$

If measured values of $1/\omega_x^2$ are plotted against added mass ΔM and a straight line is drawn through the points, the intercept and the slope of the line will determine the effective values of K_x and m_x.

For the parameters a and b, the actual geometric lengths should be used unless the flexibility of the hinge offset arm a is comparable in magnitude with the hinge spring stiffness. In this case, it is recommended that an effective value of a be guessed and that b be determined by subtraction from the

correct geometric value of $a+b$.

The damping parameters may be defined by the form of a dissipation function F. The function

$$2F=B_x\dot{x}_f^2+B_y\dot{y}_f^2+\sum_{k=0}^{n-1}B_\beta\dot{\beta}_k^2$$

is equal to the rate of dissipation of energy by damping. The parameters B_x and B_y thus measure the damping force per unit velocity referred to linear displacements of the top of the pylon and B_β is the damping torque per unit angular velocity at a blade hinge. If the damping force per unit velocity is not a constant, effective values should be used that will represent the same dissipation of energy per cycle as actually occurs with a reasonable amplitude of vibration. The amplitude of free vibration in a single degree of freedom is given in terms of B_x, B_y, and B_β by

$$x_f=x_oe^{-\frac{B_x}{2M}}$$

$$y_f=y_oe^{-\frac{B_y}{2M}}$$

$$\beta_k=\beta_{k_o}e^{-\frac{B_\beta}{2I}t}$$

The damping parameters are probably the most difficult ones to measure accurately. In practice, it is advisable to make calculations for a given case, first on the basis of no damping and then with the use of the estimated values of the damping parameters.

MATHEMATICAL DEVELOPMENTS

METHOD OF ANALYSIS

The derivation of the characteristic equation that is used as the basis for predicting the unstable oscillations of a rotor is presented in this section. Readers interested solely in applications can omit this section and proceed immediately to the section entitled "Method of Applying Theory."

The method of analysis treats the equations of motion for small displacements from the equilibrium condition with steady rotation. A proper choice of coordinates leads to equations with constant coefficients. The solutions are exponential or trigonometric functions.

The mathematical manipulations involved in treating the motions of a mass in a plane of rotation are facilitated by the use of a complex variable. The typical disturbed motion obtained by solving the equations of motion is an elliptic whirling motion, which is represented in terms of a complex variable $z=x+iy$. At any instant, z represents the displacement of the pylon from its equilibrium position. An expression such as

$$z=ce^{i\omega_f t}$$

represents whirling of the pylon in a circle of radius c with angular velocity ω_f. The sign of ω_f determines the sense of the rotation. Two rotations in opposite sense with the same radius are equivalent to a vibratory motion in a straight line and are given as follows:

$$z=c(e^{i\omega_f t}+e^{-i\omega_f t})$$

$$=2c\cos\omega_f t$$

Two opposite rotations of different radii are equivalent to whirling in an ellipse. A complex value of ω_f represents whirling in a spiral, which may be either a damped or a self-excited motion depending upon the sign of the imaginary part. A self-excited motion exists when the imaginary part of ω_f is negative, and the magnitude of z increases with time.

The displacements may be referred to a fixed or to a rotating coordinate system. If z_f and z_a are the displacements with respect to a fixed and to a rotating reference system, respectively,

$$z_f=z_ae^{i\omega t}$$

$$z_a=ce^{i\omega_a t}$$

then

$$z_f=ce^{i(\omega_a+\omega)t}$$

A whirling speed ω_a with respect to the rotating coordinates thus corresponds to a whirling speed $\omega_f=\omega_a+\omega$ with respect to the fixed coordinates. A shaft critical vibration corresponds to $\omega_a=0$ in the rotating coordinate system or to $\omega_f=\omega$ in the fixed coordinate system.

EXAMPLE OF ROTOR WITH LOCKED HINGES

An example that involves a partial use of complex variables is given on page 253 of reference 2. The problem given there of a mass particle moving on the inner surface of a rotating spherical bowl is mathematically equivalent to the disturbed motion of a flywheel and shaft or of a rotor with locked hinges. The equations of motion obtained in real form in rotating coordinates

$$\left.\begin{aligned}\ddot{x}_a-2\omega\dot{y}_a-\omega^2x_a&=-\frac{B_a\dot{x}_a}{M}-\frac{K}{M}x_a\\ \ddot{y}_a+2\omega\dot{x}_a-\omega^2y_a&=-\frac{B_a\dot{y}_a}{M}-\frac{K}{M}y_a\end{aligned}\right\}\quad(1)$$

are combined in the single equation

$$\ddot{z}_a+\left(2i\omega+\frac{B_a}{M}\right)\dot{z}_a+\left(\frac{K}{M}-\omega^2\right)z_a=0\quad(2)$$

where

$$z_a=x_a+iy_a$$

is the complex position vector in the rotating coordinate system. The complete solution, if small damping is assumed, is

$$z_ae^{i\omega t}=C_1e^{-\nu_1 t+i\omega_r t}+C_2e^{-\nu_2 t-i\omega_r t}\quad(3)$$

where

$$\nu_1=\frac{1}{2}\frac{B_a}{M}\left(1-\frac{\omega}{\omega_r}\right)$$

$$\nu_2=\frac{1}{2}\frac{B_a}{M}\left(1+\frac{\omega}{\omega_r}\right)$$

The path of the motion is represented by rotations of a complex vector in a plane.

The use of a complex variable has thus cut in half the number of equations to be handled and has yielded a solution from which the geometric path of the motion may easily be reconstructed. The advantage of the z-notation is not fully

realized, however, unless it is used from the very beginning of the problem. The close similarity of this problem to the rotor-vibration problem makes it worthwhile to show the full application of the z-notation to the preceding example. The complex variable z_a at any instant determines the position of the mass particle relative to the rotating coordinate system. If the position in a fixed coordinate system is denoted by z_f,

$$z_f=z_a e^{i\omega t} \tag{4}$$

and z_a can be treated as a generalized coordinate in the Lagrangian equations of motion. The kinetic- and potential-energy expressions can be immediately written as

$$T=\frac{1}{2}M\dot{z}_f\dot{\bar{z}}_f$$

$$=\frac{1}{2}M(\dot{z}_a+i\omega z_a)(\dot{\bar{z}}_a-i\omega\bar{z}_a)$$

$$V=\frac{1}{2}Kz_a\bar{z}_a$$

A dissipation function for damping that depends upon motion relative to the rotating system can be written

$$F=\frac{1}{2}B_a\dot{z}_a\dot{\bar{z}}_a$$

The equations of motion are now obtained by considering z_a and $\bar{z}_a$ as generalized coordinates in the Lagrangian equations. Substitution in the equation

$$\frac{d}{dt}\left(\frac{\partial T}{\partial\dot{\bar{z}}_a}\right)-\frac{\partial T}{\partial\bar{z}_a}+\frac{\partial F}{\partial\dot{\bar{z}}_a}+\frac{\partial V}{\partial\bar{z}_a}=0$$

thus yields the equation previously given

$$\ddot{z}_a+\left(2i\omega+\frac{B_a}{M}\right)\dot{z}_a+\left(\frac{K}{M}-\omega^2\right)z_a=0$$

The same method can be used to obtain the equations of motion in the fixed coordinate system. In this case,

$$\left.\begin{aligned}T&=\frac{1}{2}M\dot{z}_f\dot{\bar{z}}_f\\ V&=\frac{1}{2}Kz_f\bar{z}_f\\ F&=\frac{1}{2}B_a\,(\dot{z}_f-i\omega z_f)\,(\dot{\bar{z}}_f+i\omega\bar{z}_f)\end{aligned}\right\} \tag{5}$$

The equation of motion in terms of z_f becomes

$$\ddot{z}_f+\frac{B_a}{M}\,(\dot{z}_f-i\omega z_f)+\frac{K}{M}\,z_f=0 \tag{6}$$

and the solution for small values of damping is

$$z_f=C_1e^{-\frac{B_a}{2M}\left(1-\frac{\omega}{\sqrt{K/M}}\right)t+i\sqrt{K/M}t}+C_2e^{-\frac{B_a}{2M}\left(1+\frac{\omega}{\sqrt{K/M}}\right)t-i\sqrt{K/M}t} \tag{7}$$

This solution shows that the motion consists of two circular vibrations in opposite directions and, moreover, that for $\omega>\sqrt{K/M}$ the first term represents unstable motion; that is, the vibration has negative damping.

This example illustrates a shaft critical speed for $\omega=\sqrt{K/M}$ and a self-excited instability for $\omega>\sqrt{K/M}$. A discussion of the physical picture of this instability due to damping is given on page 293 of reference 1.

The effect of damping in a nonrotating part of the system can be included in the analysis merely by adding to the previous dissipation function the term

$$\frac{1}{2}B_f\dot{z}_f\dot{\bar{z}}_f$$

The equation of motion then becomes

$$M\ddot{z}_f+B_f\dot{z}_f+B_a(\dot{z}_f-i\omega z_f)+Kz_f=0 \tag{8}$$

The solution for small values of damping becomes

$$Z_f=C_1e^{\left[-\frac{B_f}{2M}-\frac{B_a}{2M}\left(1-\frac{\omega}{\sqrt{K/M}}\right)+i\sqrt{K/M}\right]t}+$$

$$C_2e^{\left[-\frac{B_f}{2M}-\frac{B_a}{2M}\left(1+\frac{\omega}{\sqrt{K/M}}\right)-i\sqrt{K/M}\right]t} \tag{9}$$

The motion is now unstable above the speed

$$\omega=\sqrt{\frac{K}{M}}\left(1+\frac{B_f}{B_a}\right) \tag{10}$$

HINGED ROTOR

Inclusion of the effect of hinge motion in the plane of rotation increases the number of degrees of freedom and the number of equations of motion. For example, three hinged blades and two directions of pylon deflection give five degrees of freedom to be considered. If special linear combinations of the hinge deflections β_k are used as generalized coordinates, no more than four degrees of freedom need be considered simultaneously. The use of complex variables reduces these four equations to two equations.

Appropriate variables in the rotating system for a three-blade rotor are

$$\left.\begin{aligned}\theta_0&=\frac{bi}{3}\,(\beta_0+\beta_1+\beta_2)\\ \theta_1&=\frac{bi}{3}\left(\beta_0+\beta_1e^{\frac{2\pi i}{3}}+\beta_2e^{\frac{4\pi i}{3}}\right)\\ \theta_2&=\frac{bi}{3}\left(\beta_0+\beta_1e^{\frac{4\pi i}{3}}+\beta_2e^{\frac{8\pi i}{3}}\right)\end{aligned}\right\} \tag{11}$$

These variables and their complex conjugates satisfy the relations

$$\bar{\theta}_1=-\theta_2$$

$$\bar{\theta}_2=-\theta_1$$

and also

$$\theta_0\bar{\theta}_0+\theta_1\bar{\theta}_1+\theta_2\bar{\theta}_2=-\theta_0^2+2\theta_1\bar{\theta}_1$$

$$=\frac{b^2}{3}\left(\beta_0^2+\beta_1^2+\beta_2^2\right)$$

The variables β_k, by virtue of their meaning, are referred to a rotating coordinate system. The special linear combinations of the β_k denoted by θ_k are also referred to a rotating

coordinate system. The appropriate variables to represent the hinge deflections when fixed coordinates are used are defined by

$$\zeta_k=\theta_k e^{i\omega t} \tag{12}$$

and $\bar{\zeta}_k$ is the complex conjugate of ζ_k.

Geometrically, θ_1 or ζ_1 is the complex vector representing the displacement due to hinge deflection of the center of mass of all the blades, just as z represents the position of the shaft due to pylon deflection. It will be shown later that in equations of motion, θ_1 is coupled with z and θ_0 is an independent principal coordinate. Equations (11) when solved for β_0, β_1, and β_2 become

$$\theta_0+\theta_1+\theta_2=bi\beta_0$$

$$\theta_0+\theta_1 e^{-i\alpha}+\theta_2 e^{i\alpha}=bi\beta_1$$

$$\theta_0+\theta_1 e^{i\alpha}+\theta_2 e^{-i\alpha}=bi\beta_2$$

Then, in a mode involving θ_1,

$$\left.\begin{aligned}\theta_0&=0\\ \theta_1&=\frac{b}{2}e^{i\omega_a t}\\ \theta_2&=-\bar{\theta}_1\\ \beta_0&=\sin\omega_a t\\ \beta_1&=\sin(\omega_a t-\alpha)\\ \beta_2&=\sin(\omega_a t+\alpha)\end{aligned}\right\} \tag{13}$$

Equations (13) show that in the θ_1-mode, the blades are undergoing sinusoidal vibrations 120° out of phase with one another in a manner analogous to three-phase electrical currents.

General formulas for any number of blades are

$$\left.\begin{aligned}\theta_j&=\frac{bi}{n}\sum_{k=0}^{n-1}\beta_k e^{ijak}\\ \alpha&=\frac{2\pi}{n}\\ \bar{\theta}_j&=-\theta_{n-j}\\ \theta_n&=\theta_0\\ \sum_{k=0}^{n-1}\theta_k\bar{\theta}_k&=\frac{b^2}{n}=\sum_{k=0}^{n-1}\beta_k{}^2\end{aligned}\right\} \tag{14}$$

DERIVATION OF EQUATIONS OF MOTION

The equations of motion and the characteristic equation of whirling speeds are herein derived for the general case of three or more equal blades on a pylon that may have different stiffness properties in different directions of deflection. The effects of damping in the blade hinges and in the pylon are included. The equations are first formulated in a nonrotating reference system. The required modifications are then given for the case of isotropic support stiffness. The corresponding equations referred to the rotating coordinates are then obtained.

Let the position of the center of mass of the kth blade be represented by the complex quantity z_k in the plane of rotation. (See fig. I–1.) Let the bending deflection of the pylon be represented by z_f in a nonrotating coordinate system and let β_k be the hinge deflection of the kth blade. Then

$$z_k=z_f+(a+be^{i\beta_k})e^{i(\alpha k+\omega t)} \tag{15}$$

The complex velocity is

$$\dot{z}_k=\dot{z}_f+[bi\dot{\beta}_k e^{i\beta_k}+i\omega(a+be^{i\beta_k})]e^{i(\alpha k+\omega t)} \tag{16}$$

Because only small displacements are being considered, the exponential factors containing β_k can be expanded and only the terms that lead to quadratic terms for the kinetic-energy expression need be considered.

Some terms can be ignored either because they cancel after summation for all the blades or because the corresponding derivative expressions in the Lagrangian equations vanish. The substitution

$$e^{i\beta_k}=1+i\beta_k-\frac{\beta_k{}^2}{2}$$

leads to the following expression for the kinetic energy of translational motion of the kth blade:

$$T_k=\frac{1}{2}m_b\dot{z}_k\dot{\bar{z}}_k \tag{17}$$

where

$$\dot{z}_k\dot{\bar{z}}_k=\dot{z}_f\dot{\bar{z}}_f+\dot{\bar{z}}_f bi(\dot{\beta}_k+i\omega\beta_k)e^{i(\alpha k+\omega t)}+$$
$$\dot{z}_f(-bi)(\dot{\beta}_k-i\omega\beta_k)e^{-i(\alpha k+\omega t)}+b^2\dot{\beta}_k{}^2-\omega^2 ab\beta_k{}^2$$

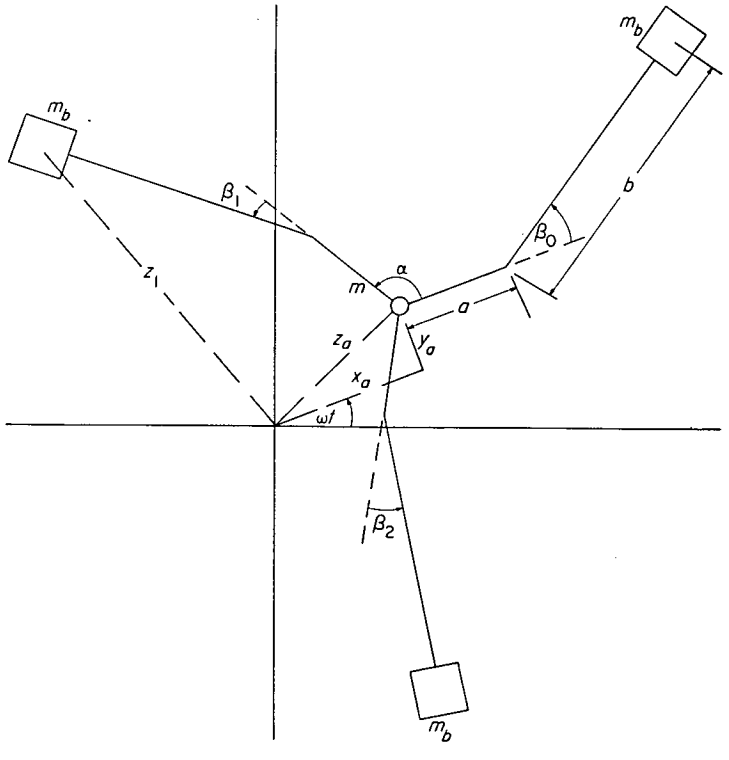

FIGURE I–1.—Simplified mechanical system representing rotor.

The kinetic energy of rotation about the center of mass of the blade is

$$T_r=\frac{1}{2}m_b r^2\dot{\beta}_k^2 \tag{18}$$

The effective mass of the pylon may be different in the x_f- and in the y_f-directions. Allowance for this possibility is made by writing the kinetic energy of the pylon as

$$T_s=\frac{1}{2}(m_x\dot{x}_f^2+m_y\dot{y}_f^2)$$

$$=\frac{1}{2}\left[m_f\dot{z}_f\dot{\bar{z}}_f+\Delta m_f\left(\frac{\dot{z}_f^2+\dot{\bar{z}}_f^2}{2}\right)\right] \tag{19}$$

where

$$m_f=\frac{m_x+m_y}{2}$$

$$\Delta m_f=\frac{m_x-m_y}{2}$$

The total kinetic energy is the sum of the expressions for the separate kinetic energies.

The pylon spring constant may differ in the x_f- and in the y_f-directions and, consequently, the potential energy can be expressed as

$$V=\frac{1}{2}\left(K_f z_f\bar{z}_f+\Delta K_f\frac{z_f^2+\bar{z}_f^2}{2}+\sum_{k=0}^{n-1}K_\beta\beta_k^2\right. \tag{20}$$

The effect of damping will be expressed with the aid of a dissipation function. If damping exists in the pylon, in the rotating shaft, and in the hinges, this function becomes

$$F=\frac{1}{2}\left(B_f\dot{z}_f\dot{\bar{z}}_f+\Delta B_f\frac{\dot{z}_f^2+\dot{\bar{z}}_f^2}{2}+B_a\dot{z}_a\dot{\bar{z}}_a+\sum_{k=0}^{n-1}B_\beta\dot{\beta}_k^2\right) \tag{21}$$

The sum of the various energy expressions for all the blades, expressed in terms of the variables z_f and ζ_k in the nonrotating coordinates, becomes

$$\left.\begin{aligned}
T=&\frac{1}{2}\left\{\Delta m_f\frac{\dot{z}_f^2+\dot{\bar{z}}_f^2}{2}+(m_f+nm_b)\,\dot{z}_f\dot{\bar{z}}_f+nm_b\left[(\dot{\bar{z}}_f\dot{\zeta}_1+\right.\right.\\
&\dot{z}_f\dot{\bar{\zeta}}_1)+\left(1+\frac{r^2}{b^2}\right)\sum_{k=0}^{n-1}(\dot{\zeta}_k-i\omega\zeta_k)(\dot{\bar{\zeta}}_k+i\omega\bar{\zeta}_k)-\\
&\left.\left.\omega^2\frac{a}{b}\sum_{k=0}^{n-1}\zeta_k\bar{\zeta}_k\right]\right\}\\
V=&\frac{1}{2}\left(\Delta K_f\frac{z_f^2+\bar{z}_f^2}{2}+K_f z_f\bar{z}_f+\frac{nK_\beta}{b^2}\sum_{k=0}^{n-1}\zeta_k\bar{\zeta}_k\right)\\
F=&\frac{1}{2}\left[\Delta B_f\frac{\dot{z}_f^2+\dot{\bar{z}}_f^2}{2}+B_f\dot{z}_f\dot{\bar{z}}_f+B_a(\dot{z}_f-i\omega z_f)\,(\dot{\bar{z}}_f+i\omega\bar{z}_f)+\right.\\
&\left.\frac{nB_\beta}{b^2}\sum_{k=0}^{n-1}(\zeta_k-i\omega\zeta_k)(\dot{\bar{\zeta}}_k+i\omega\bar{\zeta}_k)\right]
\end{aligned}\right\} \tag{22}$$

The Lagrangian equations of motion are

$$\left.\begin{aligned}
&\frac{d}{dt}\left(\frac{\partial T}{\partial\dot{\bar{z}}_f}\right)-\frac{\partial T}{\partial\bar{z}_f}+\frac{\partial F}{\partial\dot{\bar{z}}_f}+\frac{\partial V}{\partial\bar{z}_f}=0\\
&\frac{d}{dt}\left(\frac{\partial T}{\partial\dot{\bar{\zeta}}_1}\right)-\frac{\partial T}{\partial\bar{\zeta}_1}+\frac{\partial F}{\partial\dot{\bar{\zeta}}_1}+\frac{\partial V}{\partial\bar{\zeta}_1}=0
\end{aligned}\right\} \tag{23}$$

and similar expressions for the other variables. The equations of motion in fixed coordinates then become

$$\left.\begin{aligned}
&(n+nm_b)\ddot{z}_f+B\dot{z}_f+B_a(\dot{z}_f-i\omega z_f)+Kz_f+\Delta m\ddot{\bar{z}}_f+\Delta B\dot{\bar{z}}_f+\\
&\Delta K\bar{z}_f+nm_b\ddot{\zeta}_1=0\\
&nm_b\ddot{z}_f+2nm_b\left[\left(1+\frac{r^2}{b^2}\right)(\ddot{\zeta}_1-2i\omega\dot{\zeta}_1-\omega^2\zeta_1)+\right.\\
&\left.\frac{B_\beta}{m_b b^2}(\dot{\zeta}_1-i\omega\zeta_1)+\omega^2\frac{a}{b}\zeta_1+\frac{K_\beta}{m_b b^2}\zeta_1\right]=0\\
&nm_b\left[\left(1+\frac{r^2}{b^2}\right)(\ddot{\zeta}_k-2i\omega\dot{\zeta}_k-\omega^2\zeta_k)+\frac{B_\beta}{m_b b^2}(\dot{\zeta}_k-i\omega\zeta_k)+\right.\\
&\left.\omega^2\frac{a}{b}\zeta_k+\frac{K_\beta}{m_b b^2}\zeta_k\right]=0
\end{aligned}\right\} \tag{24}$$

where ζ_k refers to the ζ-variables other than ζ_1 and ζ_{n-1}. The complex conjugates of these equations are also obtained but give no additional information. Each complex equation is, of course, equivalent to two real equations. It is noticed that the first two equations contain only the variables z_f, $\bar{z}_f$, and ζ_1 and that the third equation represents n–2 equations, each containing one independent principal coordinate ζ_k. The physical meaning of this partial separation of variables is that a blade motion represented by ζ_1 involves a motion of the common center of mass of the blades and, thus, a coupling effect with the pylon. Blade motions in which the common center of mass does not move are represented by $\zeta_0, \ldots \zeta_n$. For three blades, the only such mode is the one corresponding to ζ_0. In this mode, all the blades move in phase; the motion is always damped and does not lead to instability.

The equations of motion of a one- or two-blade rotor are somewhat different from equations (24). The difference is connected with the circumstance that a rotor of three or more equal blades has no preferred direction in its plane; whereas, a one- or two-blade rotor has different dynamic properties in directions along and normal to the blades. Only a brief statement and the final equation for shaft critical speed will be given for the one- or two-blade rotor.

The equations of motion involving z_f and ζ_1 can be written more compactly by use of the notation

$$D=\frac{d}{dt}\qquad D^2=\frac{d^2}{dt^2}$$

and the substitutions

$$\frac{B_f}{M}=\lambda_f\qquad\frac{B_\beta}{m_b b^2\left(1+\frac{r^2}{b^2}\right)}=\lambda_\beta$$

$$\frac{B_a}{M}=\lambda_a \qquad \frac{a}{b\left(1+\frac{r^2}{b^2}\right)}=\Lambda_1$$

$$\frac{\Delta B_f}{M}=\Delta\lambda_f \qquad \frac{K_\beta}{m_b b^2\left(1+\frac{r^2}{b^2}\right)}=\Lambda_2$$

$$\frac{nm_b}{m_f+nm_b}=\mu$$

Then

$$\left.\begin{aligned}\left[D^2+\lambda_f D+\lambda_a(D-i\omega)+\frac{K_f}{M}\right]z_f+\left(\frac{\Delta m_f}{M}D^2+\Delta\lambda_f D+\frac{\Delta K_f}{M}\right)\bar{z}_f+\mu D^2\zeta_1=0\\ \frac{1}{2\left(1+\frac{r^2}{b^2}\right)}D^2 z_f+[(D-i\omega)^2+\lambda_\beta(D-i\omega)+\omega^2\Lambda_1+\Lambda_2]\zeta_1=0\end{aligned}\right\} \tag{25}$$

or, briefly,

$$\left.\begin{aligned}A_{11}(D)z_f+\Delta A_{11}(D)\bar{z}_f+A_{12}(D)\zeta_1=0\\ A_{21}(D)z_f\qquad\qquad\quad+A_{22}(D)\zeta_1=0\end{aligned}\right\} \tag{26}$$

THE CHARACTERISTIC EQUATION

The general form of solution of equations (26) is an elliptic whirling motion that can be represented by

$$\left.\begin{aligned}z_f&=C_1e^{i\omega_f t}+C_2e^{-i\bar{\omega}_f t}\\ \bar{z}_f&=\bar{C}_1e^{-i\bar{\omega}_f t}+\bar{C}_2e^{i\omega_f t}\\ \zeta_1&=C_3e^{i\omega_f t}+C_4e^{-i\bar{\omega}_f t}\end{aligned}\right\} \tag{27}$$

Special cases of this motion include whirling in a circle ($C_2=C_4=0$) and linear vibration ($C_1=C_2$, $C_3=C_4$). Substitution of equations (27) in equation (26) gives

$$\left.\begin{aligned}&[A_{11}(i\omega_f)C_1+\Delta A_{11}(i\omega_f)\bar{C}_2+A_{12}(i\omega_f)C_3]e^{i\omega_f t}+[A_{11}(-i\bar{\omega}_f)C_2+\Delta A_{11}(-i\bar{\omega}_f)\bar{C}_1+A_{12}(-i\bar{\omega}_f)C_4]e^{-i\bar{\omega}_f t}=0\\ &[A_{21}(i\omega_f)C_1+A_{22}(i\omega_f)C_3]e^{i\omega_f t}+[A_{21}(-i\bar{\omega}_f)C_2+A_{22}(-i\bar{\omega}_f)C_4]e^{-i\bar{\omega}_f t}=0\end{aligned}\right\} \tag{28}$$

In order for equations (27) to be a solution of equations (26), equations (28) must be satisfied for each value of t. The coefficient of each time factor $e^{i\omega_f t}$ or $e^{-i\bar{\omega}_f t}$ must therefore separately vanish. Because each bracketed expression represents a complex quantity that vanishes, its complex conjugate also must vanish. The condition for a solution can therefore be expressed by the vanishing of the first bracketed terms and the complex conjugates of the second bracketed terms. Hence,

$$\left.\begin{aligned}A_{11}(i\omega_f)C_1+\Delta A_{11}(i\omega_f)\bar{C}_2+A_{12}(i\omega_f)C_3&=0\\ A_{21}(i\omega_f)C_1+A_{22}(i\omega_f)C_3&=0\\ \Delta\bar{A}_{11}(i\omega_f)C_1+\bar{A}_{11}(i\omega_f)\bar{C}_2+\bar{A}_{12}(i\omega_f)\bar{C}_4&=0\\ \bar{A}_{21}(i\omega_f)\bar{C}_2+\bar{A}_{22}(i\omega_f)\bar{C}_4&=0\end{aligned}\right\} \tag{29}$$

where $\bar{A}_{11}(i\omega_f)$ is the complex conjugate of $A_{11}(-i\bar{\omega}_f)$ and is obtained from $A_{11}(i\omega_f)$ by changing $i\omega$ to $-i\omega$ without changing $i\omega_f$. The characteristic equation giving the rotational speeds is the determinant of the coefficients of C_1, $\bar{C}_2$, C_3, and $\bar{C}_4$ equated to zero. With the second and third columns interchanged for symmetry, the determinant becomes

$$\begin{vmatrix}A_{11} & A_{12} & \Delta A_{11} & 0\\ A_{21} & A_{22} & 0 & 0\\ \Delta\bar{A}_{11} & 0 & \bar{A}_{11} & \bar{A}_{12}\\ 0 & 0 & \bar{A}_{21} & \bar{A}_{22}\end{vmatrix}=0 \tag{30}$$

The expanded form of this determinant is

$$(A_{11}A_{22}-A_{12}A_{21})(\bar{A}_{11}\bar{A}_{22}-\bar{A}_{12}\bar{A}_{21})-\Delta A_{11}\Delta\bar{A}_{11}A_{22}\bar{A}_{22}=0 \tag{31}$$

where

$$A_{11}=-\omega_f^2+i\omega_f\lambda_f+i\lambda_a(\omega_f-\omega)+\frac{K_f}{M}$$

$$\bar{A}_{11}=-\omega_f^2+i\omega_f\lambda_f+i\lambda_a(\omega_f+\omega)+\frac{K_f}{M}$$

$$\Delta A_{11}=\Delta\bar{A}_{11}=-\frac{\Delta m_f}{M}\omega_f^2+i\omega_f\Delta\lambda_f+\frac{\Delta K_f}{M}$$

$$A_{12}A_{21}=\overline{A}_{12}\overline{A}_{21}=\frac{\mu}{2\left(1+\frac{r^2}{b^2}\right)}\omega_f{}^4=\Lambda_3\omega_f{}^4$$

$$A_{22}=-(\omega_f-\omega)^2+i\lambda_\beta(\omega_f-\omega)+\omega^2\Lambda_1+\Lambda_2$$

$$\overline{A}_{22}=-(\omega_f+\omega)^2+i\lambda_\beta(\omega_f+\omega)+\omega^2\Lambda_1+\Lambda_2$$

The roots ω_f of this equation are the characteristic whirling speeds of the rotor.

For the case of isotropic supports,

$$\Delta A_{11}=0$$

and the equations of motion are satisfied by equations (27) with $C_2=C_4=0$.

The characteristic equation is then simply

$$A_{11}A_{22}-A_{12}A_{21}=0 \tag{32}$$

In a rotating coordinate system, the complex coordinates are z_a and θ_1, where

$$z_f=z_ae^{i\omega t}$$

$$\zeta_1=\theta_1e^{i\omega t}$$

Then

$$Dz_f=(Dz_a+i\omega z_a)e^{i\omega t}$$

$$D\zeta_1=(D\theta_1+i\omega\theta_1)e^{i\omega t}$$

If the whirling speed in rotating coordinates is represented by ω_a,

$$z_a=C_1e^{i\omega_a t}$$

$$\theta_1=C_2e^{i\omega_a t}$$

The characteristic equation is then obtained by substituting $\omega_a+\omega$ for ω_f:

$$A_{11}(\omega_a+\omega)A_{22}(\omega_a+\omega)-A_{12}(\omega_a+\omega)A_{21}(\omega_a+\omega)=0 \tag{33}$$

The characteristic equation can thus be stated in terms of a whirling speed in either the fixed or the rotating coordinate system.

METHOD OF APPLYING THEORY

APPLICATION NEGLECTING DAMPING

In plotting curves for use in applications of the theory, it is convenient to consider one of the pylon bending frequencies $\omega_r=\sqrt{K_x/M_x}$ as a reference frequency and to refer all other frequencies as well as the rotational speed ω to the reference frequency as unit. The number of independent parameters is thus reduced by 1. All quantities in equations (31) to (33) are then expressed nondimensionally.

The natural whirling speeds and the three types of vibration—ordinary, self excited, and shaft critical—can now be predicted from a study of the roots of equation (31) in which ω_f is considered a function of ω for fixed values of the other parameters.

The case of no damping will be considered first. Because equation (31) with damping terms omitted is of the fourth degree in $\omega_f{}^2$ and of only the second degree in ω^2, it may be solved conveniently by first choosing values of ω_f and then solving the equation for ω^2. Similar indirect methods can be used with equations (32) and (33). Special methods to be used when damping is included will be discussed later.

The meaning of equations (31) to (33) will be illustrated by examples. The real part of ω_f will be plotted against ω for selected values of the parameters Λ_1, Λ_2, Λ_3, and s. The simplest case is that in which the mass of the blades is so small that any force on the pylon due to blade motions is negligible. The pylon motions are then independent of the blade motions. This case is obtained by putting $\Lambda_3=0$. The characteristic equation (31), (32), or (33) then factors into expressions yielding straight lines and hyperbolas.

An example of a rotor with particular values of the parameters is plotted as long-dash lines in figure I–2. The horizontal straight lines correspond to pylon bending and the slanting hyperbolas correspond to hinge deflection. Each curve represents the trend of one of the real roots ω_f. As Λ_3 increases slightly from zero, the greatest changes in the curves occur in the vicinity of the intersections of the straight lines with the hyperbolas. Here each branch breaks away from the intersection and rejoins the other branch. At a gap, such as C in figure I–2, the number of real roots of the frequency equation is reduced by I–2. The missing roots are complex conjugate numbers, and one of them must have a negative imaginary part, which implies a self-excited vibration.

Consider the interpretation of figure I–2 as ω is gradually increased from zero. At zero rotational speed, the values of ω_f are the natural frequencies that could be excited as ordinary vibration by applied vibrating force. Positive and negative values occur in pairs of equal magnitude and correspond to linear vibration modes represented in complex notation as

$$z_f=c(e^{i\omega_f t}+e^{-i\omega_f t})$$

As ω increases from zero, the positive and negative values of ω_f no longer are equal in magnitude. The normal modes are therefore whirling motions with angular velocities equal to the plotted values of ω_f.

The shaft critical speed is the rotational speed at which $\omega_f=\omega$ and hence is given by the point A where a 45° line

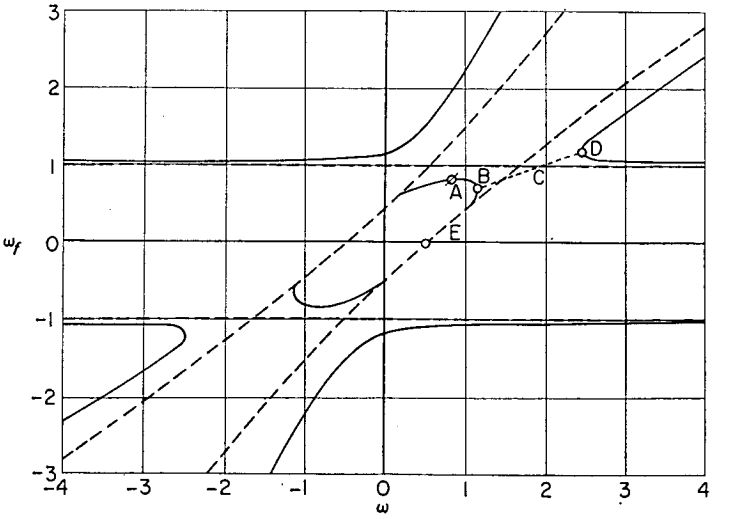

FIGURE I–2.—The effect of coupling between pylon and hinge motions.

through the origin intersects the ω_f-curve. This speed corresponds to the peak for vibrations excited by unbalance in the rotating system. As ω increases above the shaft critical speed, the modes of whirling are stable until, for the case of no damping, the value of ω_f becomes complex at the value of ω at which a vertical line is tangent to the plotted curve. This point B is the beginning of the self-excited range. At the point D, the motion again becomes stable. The real part of ω_f is plotted in the region C as a short-dash line. The complex roots in the region C have been calculated and plotted in figure I–3.

The point E, at which $\omega_f=0$, is of some interest. At this speed, a vibration of the blades could be excited by a steady force ($\omega_f=0$, $\omega_a=-\omega$), such as the force of gravity if the plane of the rotor is not horizontal.

Because the most important information to be obtained from the frequency equation is the critical value of ω for the shaft critical and self-excited vibrations, a set of charts that gives this information for a large variety of values of the physical parameters has been prepared. These charts are given in figures I–4 to I–6, which correspond to values of stiffness ratio $K_y/K_x=s$ of 1, ∞, and 0, respectively. The use of the charts is illustrated by a numerical example. Suppose the values of the parameters for a certain rotor are $\Lambda_1=0.07$, $\Lambda_2=0.22$, $\Lambda_3=0.1$, $s=1$, and $\omega_r=155$ cycles per minute. A straight line, such as AB in figure I–4, is first drawn to represent the function $\omega^2\Lambda_1+\Lambda_2$. This line intersects contours $\Lambda_3=0.1$ at $\omega^2=0.77$ for the shaft critical point and $\omega^2=1.6$ and 4.85 for the beginning and for the end of the self-excited range, respectively. With a reference frequency of 155 cycles per minute, these values correspond to actual rotational speeds of 136, 196, and 342 rpm.

All possible values of Λ_1, Λ_2, and Λ_3 are thus covered by suitably changing the straight line AB. The general effect of the stiffness ratio s is not large; any case can therefore be estimated with a fair degree of accuracy by use of figures I–4 to I–6.

POSSIBILITY OF AVOIDING OCCURRENCE OF VIBRATION

Figures I–4 to I–6 can also be used for the inverse problem of finding the values of the parameters that are required to obtain given values of critical rotational speed. These figures show that to eliminate entirely the self-excited instability requires that Λ_1 be equal to or greater than 1.

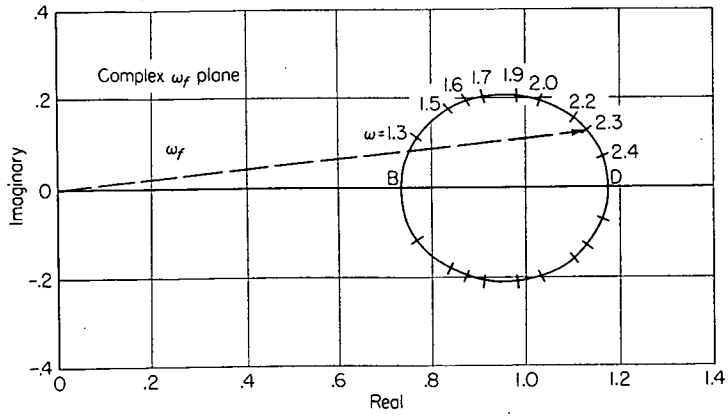

FIGURE I–3.—The complex frequency in the unstable range for $\Lambda_1=0.07$, $\Lambda_2=0.22$, $\Lambda_3=0.1$, and $s=1$.

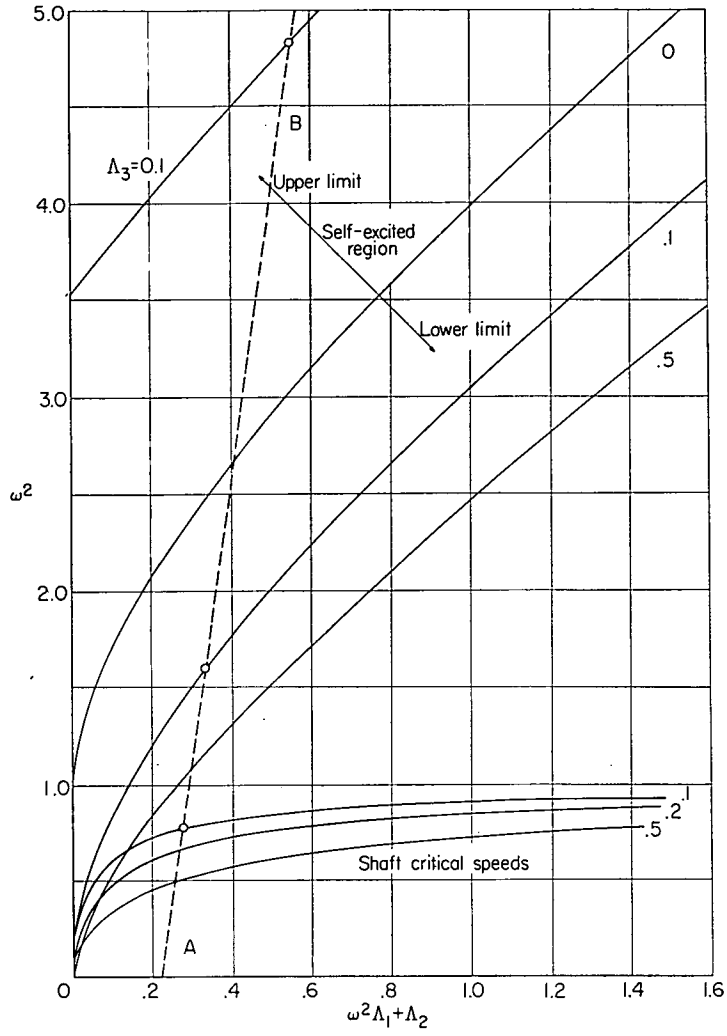

FIGURE I–4.—Stability chart for $s=1$.

The shaft critical instability can be entirely eliminated only with a value of Λ_1 in a small range near 4 and with $s=\infty$ or $s=0$. These values of Λ_1 differ radically from present designs in which a typical value is 0.07.

The satisfactory requirement of keeping the instabilities outside the operating range of rotational speed is found by first picking a reasonable value of the pylon frequency $\sqrt{K_x/M_x}$ to fix the scale unit for ω and by then observing the combinations of Λ_1 and Λ_2 that can be used to avoid the critical Λ_3-contours.

EFFECT OF DAMPING

The effect of damping has been included in equation (31) through the parameters λ_f, $\Delta\lambda_f$, λ_a, and λ_β. A method of computation similar to that used in flutter theory appears preferable to attempting to solve the equation directly for ω_f. The beginning and the end of an unstable range can be found by the following method: At a limit point between a stable and an unstable speed range, the value of ω_f is real. Equation (31) is first separated into real and imaginary parts with ω_f considered real. Each part is considered a functional relation between ω_f and ω and is plotted for a given set of values of the parameters. The intersections of the real and the imaginary equations give the rotor speeds and frequencies corresponding to the beginning and the end of the unstable

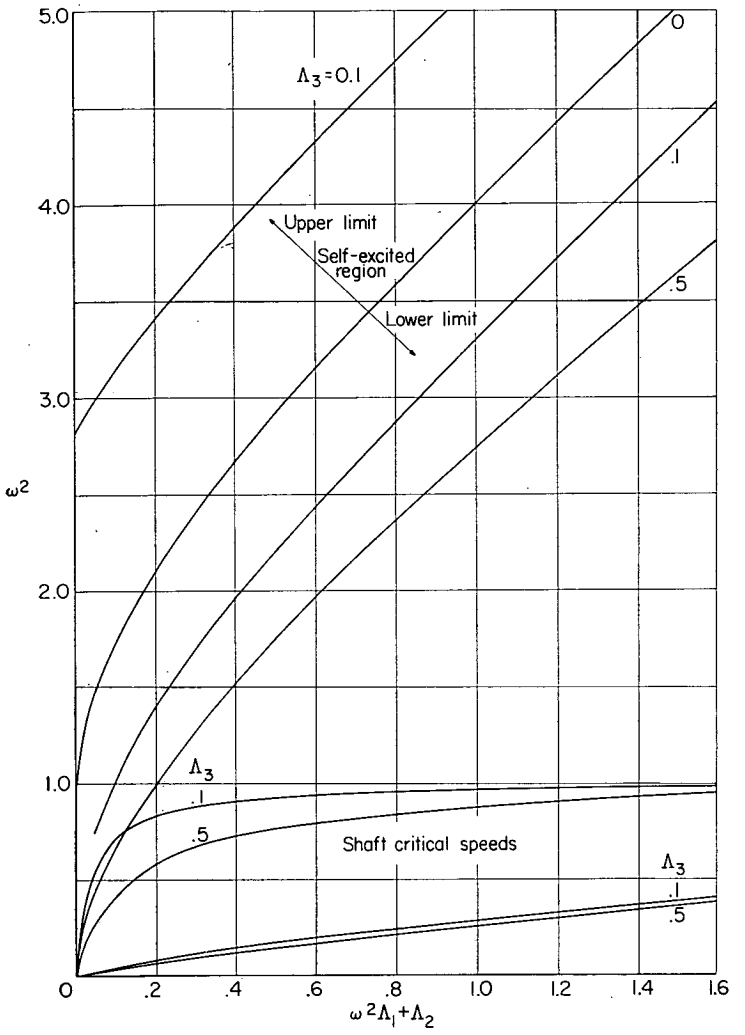

FIGURE I–5.—Stability chart for $s=\infty$.

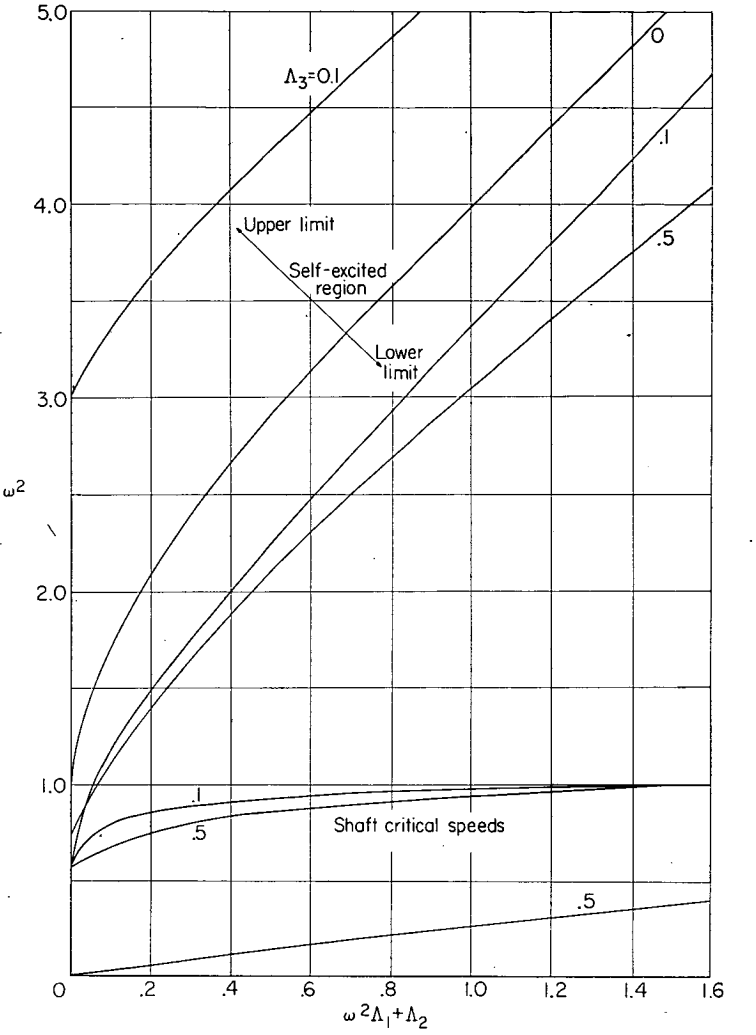

FIGURE I–6.—Stability chart for $s=0$.

ranges. In the computations, it is preferable to choose values of ω_f and to solve the equations for the corresponding values of ω.

The explicit form for computation in the simplest case of isotropic supports, with damping in the pylon and in the hinges but not in the rotating shaft ($\lambda_a=0$), is obtained from equation (32) rearranged as follows:

For the real equation

$$\omega^2-2B_R\omega+C_R=0 \qquad (34)$$

$$\omega=B_R\pm\sqrt{B_R^2-C_R}$$

where

$$B_R=\frac{\omega_f}{1-\Lambda_1}\left[1+\frac{\lambda_f\lambda_\beta}{2\left(-\omega_f^2+\frac{K_f}{M}\right)}\right]$$

and

$$C_R=-\frac{\omega_f^2}{1-\Lambda_1}\left(-1+\frac{\Lambda_2}{\omega_f^2}-\frac{\Lambda_3\omega_f^2+\lambda_f\lambda_\beta}{-\omega_f^2+\frac{K_f}{M}}\right)$$

For the imaginary equation

$$\omega^2-2B_I\omega+C_I=0 \qquad (35)$$

where

$$B_I=\frac{1}{1-\Lambda_1}\left[\omega_f-\frac{\lambda_\beta}{2\lambda_f\omega_f}\left(-\omega_f^2+\frac{K_f}{M}\right)\right]$$

and

$$C_I=-\frac{1}{1-\Lambda_1}\left[\frac{\lambda_\beta}{\lambda_f}\left(-\omega_f^2+\frac{K_f}{M}\right)+(-\omega_f^2+\Lambda_2)\right]$$

The real and imaginary equations for the most general case of equation (31) can be written, respectively, as follows:

$$\lambda_a^2(1-\Lambda_1)^2\omega^6+[R_1(1-\Lambda_1)^2+\lambda_a^2R_3]\omega^4+(R_1R_3-I_1I_3+\lambda_a^2R_2-R_5)\omega^2+R_1R_2-I_1I_2-R_4+\Lambda_3^2\omega_f^8=0 \qquad (36)$$

$$[I_1(1-\Lambda_1)^2+\lambda_a^2I_3]\omega^4+(R_1I_3+R_3I_1+\lambda_a^2I_2-I_5)\omega^2+R_1I_2+R_2I_1-I_4=0 \qquad (37)$$

where

$$R_1=\frac{M_xM_y}{M^2}\left(-\omega_f^2+\frac{K_x}{M_x}\right)\left(-\omega_f^2+\frac{K_y}{M_y}\right)-\omega_f^2\left(\lambda_x\frac{M_x}{M}+\lambda_a\right)\left(\lambda_y\frac{M_y}{M}+\lambda_a\right)$$

$$I_1=\frac{M_x}{M}\left(-\omega_f^2+\frac{K_x}{M_x}\right)\omega_f\left(\lambda_y\frac{M_y}{M}+\lambda_a\right)+\frac{M_y}{M}\left(-\omega_f^2+\frac{K_y}{M_y}\right)\omega_f\left(\lambda_x\frac{M_x}{M}+\lambda_a\right)$$

$$R_2=(-\omega_f^2+\Lambda_2)^2-\omega_f^2\lambda_\beta^2$$

$$I_2=2(-\omega_f^2+\Lambda_2)\omega_f\lambda_\beta$$

$$R_3=-2(1-\Lambda_1)(-\omega_f^2+\Lambda_2)-4\omega_f^2+\lambda_\beta^2$$

$$I_3=-2(1-\Lambda_1)\omega_f\lambda_\beta+4\omega_f\lambda_\beta$$

$$R_4=2\omega_f^4\Lambda_3\left[\left(-\omega_f^2+\frac{K_f}{M}\right)(-\omega_f^2+\Lambda_2)-\omega_f^2(\lambda_f+\lambda_a)\lambda_\beta\right]$$

$$I_4=2\omega_f^4\Lambda_3\left[\left(-\omega_f^2+\frac{K_f}{M}\right)\omega_f\lambda_\beta+\omega_f(\lambda_f+\lambda_a)(-\omega_f^2+\Lambda_2)\right]$$

$$R_5=2\omega_f^4\Lambda_3\left[-(1-\Lambda_1)\left(-\omega_f^2+\frac{K_f}{M}\right)-\lambda_a\lambda_\beta\right]$$

$$I_5=2\omega_f^4\Lambda_3[-(1-\Lambda_1)\omega_f(\lambda_f+\lambda_a)-2\lambda_a\omega_f]$$

Examples of calculated cases with damping are shown in figures I–7 to I–9. The presence of small amounts of damping in both the pylon and the hinge degrees of freedom does not greatly change the predictions that would be made from the equations with no damping. The plot of the real equation is practically the same as the plot obtained when damping is neglected. The intersections of the curves of the imaginary and the real equations with any reasonable value of λ_f/λ_β are near the points that would be considered the limits of the unstable range if damping were neglected. Increasing the amount of damping decreases the gap between the limits of stability until the unstable range is finally eliminated. An approximate solution for the amount of damping required to eliminate the self-excited instability is obtained by requiring that the damping be at least large enough to make the curve of the real equation pass through the point where $\omega_f=1$ and ω is the value given by the equation

$$1=\omega-\sqrt{\omega^2\Lambda_1+\Lambda_2}$$

The values required in the case of $s=\infty$ have been computed and plotted in figure I–10. The elimination of self-excited vibration by damping thus looks promising and merits further study with reference to specific application.

LIMITATIONS AND FURTHER DEVELOPMENTS OF THE THEORY

POLAR SYMMETRY

An important idea in the rotor vibration theory is the concept of polar symmetry. This concept implies the absence of a preferred direction in the plane of the rotor. A rotor of three or more equal blades has polar symmetry. A rotor of two blades or one with unequal centering springs does not have polar symmetry. A pylon for which $K_x=K_y$, $B_x=B_y$, and $m_x=m_y$ has polar symmetry. The possibility of solving the rotor vibration problem in terms of exponential or trigonometric functions depends upon the existence of polar symmetry in the rotating parts or in the nonrotating parts or in both. The general case of no polar symmetry would lead to Mathieu functions or something similar.

TWO BLADES

A brief comparison between the two-blade and the general case is presented herein. Polar symmetry of the pylon is assumed. The shaft critical speed is obtained by substituting $\omega_a=0$ in the characteristic equation as expressed in a rotating coordinate system. For one or two blades, the equation obtained is

$$\left[\left(-\omega^2+\frac{K_f}{M}\right)\left(\omega^2\frac{a}{b}+\frac{K_\beta}{m_b b^2}\right)-\mu\omega^4\right]\left(-\omega^2+\frac{K_f}{M}\right)=0 \qquad (38)$$

The first bracketed factor gives the beginning of a self-excited range and the second factor gives the end of the range.

Equation (38) can be compared with the following equation for the shaft critical speed of a rotor with three or more equal blades and polar symmetry:

$$\left(-\omega^2+\frac{K_f}{M}\right)\left(\omega^2\frac{a}{b}+\frac{K_\beta}{m_b b^2}\right)-\frac{\mu}{2}\omega^4=0 \qquad (39)$$

A useful chart based on equation (39) is given in figure I–11; some experimental results of tests of a simple model are given in figure I–12. These tests demonstrate the essential difference between the two-blade and the general case.

CHAPTER II

THEORY OF MECHANICAL OSCILLATIONS OF ROTORS WITH TWO HINGED BLADES

By ARNOLD M. FEINGOLD

SUMMARY

The mechanical stability of a rotor having two vertically hinged blades mounted upon symmetrical supports, that is, of equal stiffness and mass in all horizontal directions, is investigated and reported herein. The frequency equation is derived and shows the existence, in general, of two ranges of rotational speeds at which instability occurs. The lower region of instability is bounded by two shaft critical speeds. At rotor speeds within this region, self-excited divergence of the rotor takes place analogous to the instability exhibited by a rotating shaft that is elliptical in cross section. Within the second instability range, the rotor system undergoes self-excited oscillations. Charts are presented giving the boundary points of both instability regions for a large variety of values of the physical parameters. The effect of damping is also included in the analysis.

INTRODUCTION

In chapter I, Coleman gives an analytical study of the mechanical stability of a rotor having three or more vertically hinged blades, mounted on flexible supports. It was shown that, in addition to the usual shaft critical speeds, self-excited vibrations occurred over a range of rotational speeds. Experiments with rotary-wing aircraft have confirmed the soundness of the analysis.

The present chapter is an investigation of the stability of the two-blade rotor mounted on symmetrical supports. As will be shown later, the results differ from those for a three-blade rotor. The reason for the different behavior lies in the inherent asymmetry of a rotor with only two blades. Motion of the center of mass of the blades of a two-blade rotor with respect to the rotor hub, due to small hinge deflections of the blades, must be normal to the line of the blades. This restraint, which does not appear in a rotor of three or more blades, results in the rotor system having different dynamic properties along and normal to the line of the blades. Therefore, with supports that have equal stiffness and mass in all directions attached to a two-blade rotor, two principal vibration axes of the rotor hub can still be distinguished. No preferred vibration axes can be distinguished for a three-blade rotor mounted on symmetrical supports. This distinction shows up physically in the shape of the vibration modes. Whereas a three-blade rotor whirls in a circle, a two blade rotor whirls in an ellipse, of which the principal axes are along and normal to the line of the rotor blades.

A two-blade rotor can be expected to show, in addition to some features of a three-blade rotor, some of the characteristics of a rotating shaft that is elliptical in cross section. Such a shaft, mounted on symmetrical bearings, is known to have two critical speeds, which correspond to each of the two principal stiffnesses. (See, for example, ref. 1.) For all rotational speeds between the critical speeds, the shaft is unstable and diverges. It will be shown that an exactly similar phenomenon exists for a two-blade rotor. The existence of this region of instability for a two-blade rotor is predicted in chapter I, in which the formula for the shaft critical speeds bounding this instability range is given. In addition to this region of instability, a second range of instability analogous to that exhibited by a three-blade rotor is also present.

Only the case of symmetrical supports is analyzed in the present report. In the case of asymmetric supports, the equations of motion are linear differential equations that are difficult to solve because the coefficients vary periodically with the time (Mathieu type). Similar equations are obtained in the problem of a rotating elliptical shaft mounted on asymmetric bearings. (See ref. 1.)

SYMBOLS

a	radial position of vertical hinge
b	distance from vertical hinge to center of mass of blade
B	damping force per unit velocity of rotor-hub displacement
B_β	damping force per unit angular velocity of blade displacement about hinge
D	time-derivative operator, d/dt
F	dissipation function
I	moment of inertia of blade about hinge, $m_b b^2\left(1+\frac{r^2}{b^2}\right)$
K	spring constant of rotor-hub displacement
K_β	spring constant of blade self-centering spring
m	effective mass of pylon
m_b	effective mass of rotor blade
M	total effective mass of blades and pylon, $m+2m_b$
r	radius of gyration of blade about its center of mass
s	arbitrary parameter
t	time
T	kinetic energy
T_1, T_2	kinetic energies of rotor blades
T_s	kinetic energy of rotor hub
V	potential energy
x, y	displacements of rotor hub in rotating coordinate system

X_a, Y_a rotating coordinate axes
X_f, Y_f fixed coordinate axes
x_o, y_o values of x and y when $t=0$
x_1, y_1 displacement of first rotor blade in fixed coordinate system
x_2, y_2 displacement of second rotor blade in fixed coordinate system
β_1, β_2 angular displacements of blades about their hinges

$$\theta_0=\frac{b(\beta_1+\beta_2)}{2}$$

$$\theta_1=\frac{b(\beta_1-\beta_2)}{2}$$

θ_{1_o} value of θ_1 when $t=0$

$$\lambda=\frac{B}{M\omega_r}$$

$$\lambda_\beta=\frac{B_\beta}{I\omega_r}$$

$$\Lambda_1=\frac{a}{b\left(1+\frac{r^2}{b^2}\right)}$$

$$\Lambda_2=\frac{K_\beta}{I\omega_r{}^2}$$

$$\Lambda_3=\frac{m_b}{M\left(1+\frac{r^2}{b^2}\right)}$$

ω angular velocity of rotor (the dimensionless ratio ω/ω_r is called ω in applications)
ω_a natural frequency of rotor system observed in rotating coordinate system (used in nondimensional form in applications)
ω_f natural frequency of rotor system in fixed coordinate system (nondimensional in applications)
ω_r reference frequency, $\sqrt{K/M}$

MATHEMATICAL ANALYSIS

Four degrees of freedom of the system are considered—horizontal deflection of the rotor hub in the x- and y-directions, and hinge deflections β_1 and β_2 of the blades in the horizontal plane of the rotor hub. The rotor is assumed to rotate at a constant velocity ω.

Deflection of the rotor hub may be due either to the bending of a flexible pylon or to a rocking of the rotor craft upon its landing gear. Ground-resonance vibrations usually involve landing-gear flexibility. The mathematical treatment is the same in both cases, but the values of several of the physical parameters will depend upon which mode is being investigated. In this chapter, the terms "rotor supports" and "pylon" will be used interchangeably to denote the nonrotating structure coupled with the rotor blades.

The mathematical treatment herein differs from that in chapter I, in which are used the complex notation and the notion of "whirling speeds," that is, directional frequencies resulting from the use of complex numbers. Although the method of chapter I is valuable for systems, such as the three-blade rotor on symmetrical supports, which have circular modes of vibration, it offers little advantage for the present problem, in which the rotor performs elliptical motion. Rectangular coordinates accordingly are used in the present report and frequencies are used instead of whirling speeds. In comparing the results of the present report with those of chapter I, care should be taken to distinguish between frequencies and whirling speeds. Whirling speeds have directional significance; whereas frequencies are essentially positive quantities and do not give any immediate information concerning the direction of whirl of the vibration.

The equations of motion are set up in a coordinate system rotating at the velocity ω. Let the deflection of the rotor hub be represented by x and y in rotating coordinates. (See fig. II–1 in which the intersection of the coordinate axes represents the undisturbed position of the rotor hub.) The disturbed positions of the two blades in fixed coordinates are

$$x_1=(x+a+b\cos\beta_1)\cos\omega t-(y+b\sin\beta_1)\sin\omega t$$

$$y_1=(y+b\sin\beta_1)\cos\omega t+(x+a+b\cos\beta_1)\sin\omega t$$

and

$$x_2=(x-a-b\cos\beta_2)\cos\omega t-(y-b\sin\beta_2)\sin\omega t$$

$$y_2=(y-b\sin\beta_2)\cos\omega t+(x-a-b\cos\beta_2)\sin\omega t$$

The kinetic energies of the two rotor blades are

$$T_1=\frac{1}{2}m_b\left[\dot{x}_1{}^2+\dot{y}_1{}^2+r^2(\omega+\dot{\beta}_1)^2\right]$$

and

$$T_2=\frac{1}{2}m_b\left[\dot{x}_2{}^2+\dot{y}_2{}^2+r^2(\omega+\dot{\beta}_2)^2\right]$$

The kinetic energy of the pylon is

$$T_s=\frac{1}{2}m\left[\dot{x}^2+\dot{y}^2+\omega^2(x^2+y^2)-2\omega(\dot{x}y-x\dot{y})\right]$$

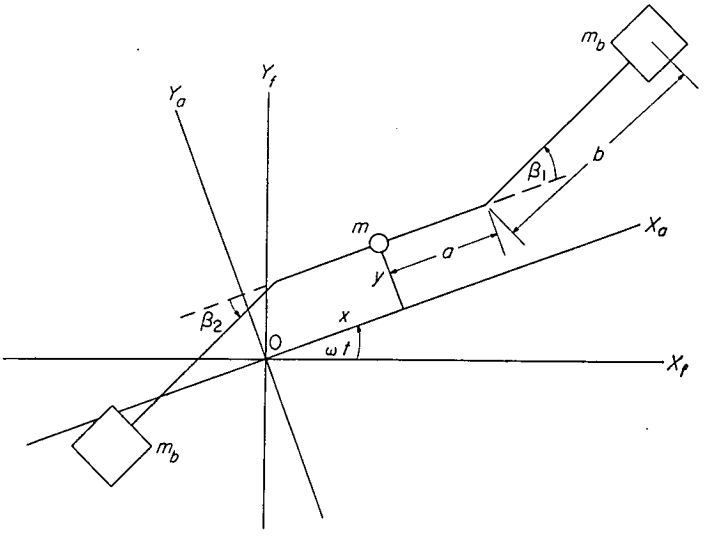

FIGURE II–1.—Simplified mechanical system representing rotor.

Because only small displacements from the equilibrium position are considered, the trigonometric expressions containing β_1 and β_2 may be expanded as power series and only the terms that lead to quadratic terms in the energy expressions need be retained. Thus

$$\sin \beta_1=\beta_1$$

$$\cos \beta_1=1-\frac{\beta_1^2}{2}$$

and

$$\sin \beta_2=\beta_2$$

$$\cos \beta_2=1-\frac{\beta_2^2}{2}$$

New variables introduced to replace β_1 and β_2 are

$$\theta_0=\frac{b}{2}(\beta_1+\beta_2)$$

$$\theta_1=\frac{b}{2}(\beta_1-\beta_2)$$

where θ_1 represents the shift, due to hinge motion, of the center of mass of the two blades with respect to the rotor hub. The introduction of θ_0 and θ_1 results in a partial decoupling of the equations of motion.

The total kinetic energy of the system is

$$T=T_1+T_2+T_s$$

Only the quadratic terms will be retained in the kinetic-energy expression, because the terms of lower degree vanish in the Lagrange equations of motion. Then

$$T=\frac{1}{2}M[\dot{x}^2+\dot{y}^2+\omega^2(x^2+y^2)-2\omega(\dot{x}y-x\dot{y})]+m_b\left[2\dot{y}\dot{\theta}_1+2\omega^2 y\theta_1+2\omega x\dot{\theta}_1-2\omega\dot{x}\theta_1+\left(1+\frac{r^2}{b^2}\right)(\dot{\theta}_0^2+\dot{\theta}_1^2)-\omega^2\frac{a}{b}(\theta_0^2+\theta_1^2)\right]$$

The potential energy of the system is

$$V=\frac{1}{2}K(x^2+y^2)+\frac{K_\beta}{2}(\beta_1^2+\beta_2^2)$$

$$=\frac{1}{2}K(x^2+y^2)+\frac{K_\beta}{b^2}(\theta_0^2+\theta_1^2)$$

Two types of damping of the rotor system are assumed to exist: (1) damping in the rotor supports, which is proportional to velocity displacements of the rotor hub in a fixed coordinate system, and (2) damping in the blade hinges. The dissipation function F then becomes

$$F=\frac{1}{2}B[\dot{x}^2+\dot{y}^2+\omega^2(x^2+y^2)-2\omega(\dot{x}y-x\dot{y})]+\frac{B_\beta}{b^2}(\dot{\theta}_0^2+\dot{\theta}_1^2)$$

where B is the damping force per unit velocity of rotor-hub displacement and B_β is the damping force per unit velocity of a rotor-blade displacement about the blade hinge.

The Lagrange equation of motion for the variable x is

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{x}}\right)-\frac{\partial T}{\partial x}+\frac{\partial V}{\partial x}+\frac{\partial F}{\partial \dot{x}}=0$$

The use of similar expressions for y, θ_0, and θ_1 lead to the following equations of motion:

$$\left(D^2-\omega^2+\frac{B}{M}D+\frac{K}{M}\right)x-\frac{4m_b}{M}\omega D\theta_1-\left(2\omega D+\frac{B}{M}\omega\right)y=0 \quad (1)$$

$$2\omega Dx+\left[\left(1+\frac{r^2}{b^2}\right)D^2+\frac{B_\beta}{m_b b^2}D+\frac{K_\beta}{m_b b^2}+\frac{a}{b}\omega^2\right]\theta_1+(D^2-\omega^2)y=0 \quad (2)$$

$$\left(2\omega D+\frac{B}{M}\omega\right)x+\frac{2m_b}{M}(D^2-\omega^2)\theta_1+\left(D^2-\omega^2+\frac{B}{M}D+\frac{K}{M}\right)y=0 \quad (3)$$

$$\left[\left(1+\frac{r^2}{b^2}\right)D^2+\frac{B_\beta}{m_b b^2}D+\omega^2\frac{a}{b}+\frac{K_\beta}{m_b b^2}\right]\theta_0=0 \quad (4)$$

where

$$D=\frac{d}{dt} \qquad D^2=\frac{d^2}{dt^2}$$

Equation (4) can be solved independently of the others because it is an equation in only one variable θ_0. Equation (4), which also was obtained in the study of the three-blade rotor (chapter I), represents blade motion with the blades moving in phase, uncoupled with pylon motion. Motion in this mode is damped and does not lead to instability.

Assuming solutions of the form

$$\left.\begin{aligned} x&=x_o e^{i\omega_a t}\\ y&=y_o e^{i\omega_a t}\\ \theta_1&=\theta_{1_o} e^{i\omega_a t}\end{aligned}\right\} \quad (5)$$

and substituting these solutions in equations (1) to (3) gives the characteristic or frequency equation

$$\begin{vmatrix} -\omega_a^2-\omega^2+i\lambda\omega_a+1 & 4\Lambda_3\omega\omega_a & 2\omega\omega_a-i\lambda\omega \\ 2\omega\omega_a & -\omega_a^2+i\lambda_\beta\omega_a+\Lambda_2+\Lambda_1\omega^2 & -\omega_a^2-\omega^2 \\ 2\omega\omega_a-i\lambda\omega & -2\Lambda_3(\omega_a^2+\omega^2) & -\omega_a^2-\omega^2+i\lambda\omega_a+1 \end{vmatrix}=0 \quad (6)$$

where the nondimensional parameters

$$\Lambda_1=\frac{a}{b\left(1+\frac{r^2}{b^2}\right)}$$

$$\Lambda_2=\frac{K_\beta}{I\omega_r^2}$$

$$\Lambda_3=\frac{m_b}{M\left(1+\frac{r^2}{b^2}\right)}$$

$$\lambda=\frac{B}{M\omega_r}$$

$$\lambda_\beta=\frac{B_\beta}{I\omega_r}$$

have been introduced, and the rotational velocity ω and the frequency ω_a have also been made nondimensional by using $\omega_r=\sqrt{K/M}$ as reference frequency.

The frequency ω_a generally is a complex number, of which the real part is the frequency of the vibration and the imaginary part determines the rate of damping of the vibration. If the imaginary part of ω_a is negative, the vibration increases in amplitude with time and the rotor is unstable.

DISCUSSION OF FREQUENCY EQUATION

CASE OF ZERO DAMPING

If the damping parameters λ and λ_β are neglected, the frequency equation (6) may be expanded to

$$2\Lambda_3(\omega^2+\omega_a{}^2-1)+[4\omega^2\omega_a{}^2-(\omega^2+\omega_a{}^2-1)^2][-2\Lambda_3(\omega^2+\omega_a{}^2+1)+\omega_a{}^2-\Lambda_2-\Lambda_1\omega^2]=0 \qquad (7)$$

where ω_a is the natural frequency of the rotor system in a coordinate system rotating with the rotor. (Although equation (7) is a cubic equation in both ω^2 and $\omega_a{}^2$, rectangular hyperbolas of the form $\omega_a{}^2=\omega^2+s$, where s is an arbitrary parameter, intersect equation (7) at only two values of ω^2. For purposes of computation, therefore, equation (7) can be reduced to a quadratic equation in ω^2 by replacing $\omega_a{}^2$ with ω^2+s.)

The solutions for zero damping (eq. (5)) represent motion of the pylon in an ellipse expressed relative to the rotating coordinate axes. In fixed coordinates, the pylon would move in an ellipse precessing at the velocity ω. This motion can be resolved into simultaneous circular motion at the two frequencies $|\omega+\omega_a|$ and $|\omega-\omega_a|$, in which the vertical lines indicate that the quantity inside is to be considered positive. If the pylon is subjected to a harmonic force in the fixed coordinate system of frequency ω_f, resonance will occur at each of the frequencies

$$\omega_f=|\omega\pm\omega_a|$$

The frequency ω_f will be referred to as the natural frequency of the rotor system in fixed coordinates.

The graph of the frequency equation (7) for a typical set of values of the parameters is given in figure II–2 in rotating coordinates and in figure II–3 in fixed coordinates. For zero coupling between the blades and rotor hub—that is, when Λ_3 equals zero—equation (7) factors into straight lines and a hyperbola, which are shown as long-dash lines in figures II–2 and II–3. The straight lines represent hub motion and the hyperbola represents blade motion. A small increase in Λ_3 results in a breaking away of the curves at their intersections to form two self-excited regions. It is interesting to compare figure II–3 with figure II–4, which is the graph of the natural frequencies of a three-blade rotor having the same values of Λ_1, Λ_2, and Λ_3.

The shaft critical speeds, or natural frequencies that would be in resonance with an unbalance in the rotor system, are found by putting $\omega_a=0$ in equation (7). Figure II–2 shows two such speeds, at points A and B (shown also in fig. II–3), that bound a region in which ω_a is a pure imaginary number. If ω_a is a complex root of the characteristic

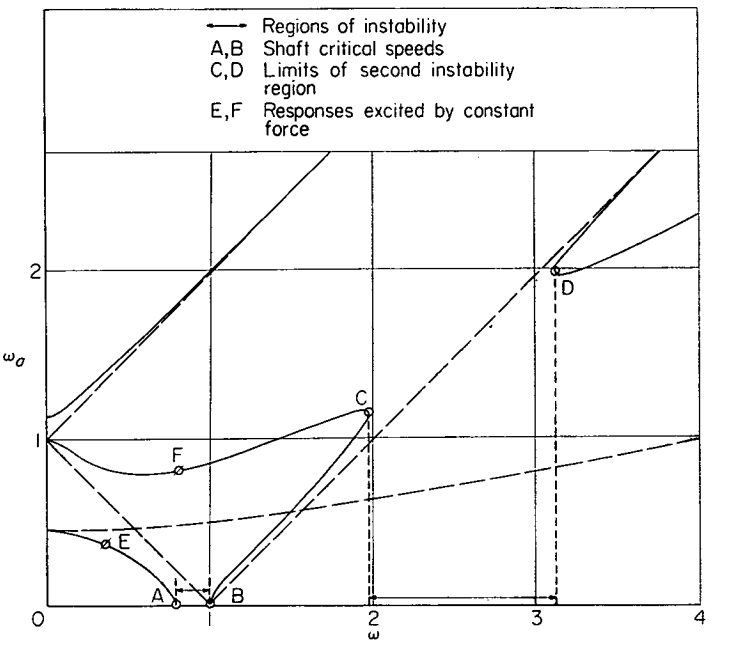

FIGURE II–2.—Natural frequencies of a two-blade rotor in rotating coordinates for case of $\Lambda_1=0.05$, $\Lambda_2=0.20$, and $\Lambda_3=0.10$.

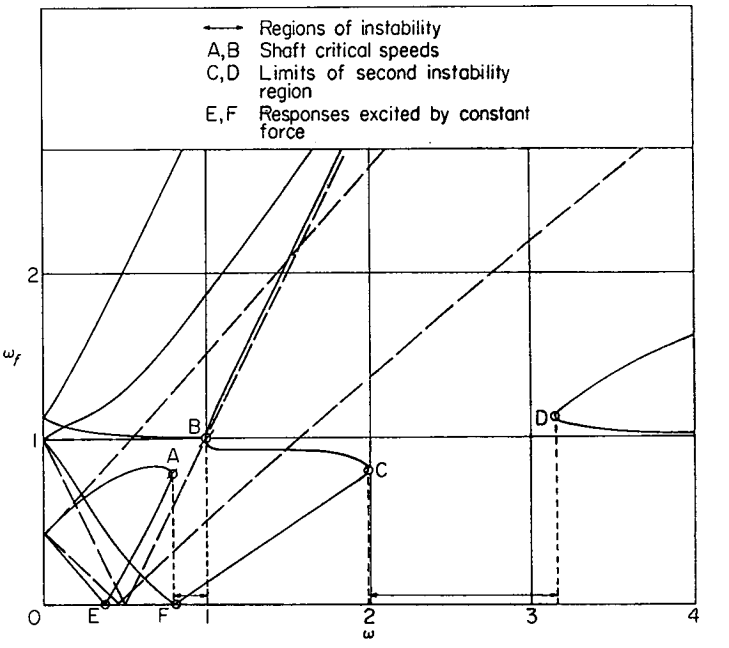

FIGURE II–3.—Natural frequencies of a two-blade rotor in fixed coordinates for case of $\Lambda_1=0.05$, $\Lambda_2=0.20$, and $\Lambda_3=0.10$.

equation, the complex conjugate of ω_a will also be a root and one of the two roots will have a negative imaginary part implying instability. The rotor system will thus be unstable for all rotational speeds between the two shaft critical speeds. Because ω_a is a pure imaginary number in this region, the frequency of the resultant self-excited vibration is zero in a rotating coordinate system—similar to the shaft critical speeds—and will appear as a self-excited divergence of the rotor.

The equation of the shaft critical speeds is

$$[(1-\omega^2)(\Lambda_2+\Lambda_1\omega^2)-2\Lambda_3\omega^4](1-\omega^2)=0 \qquad (8)$$

The first factor gives the lower shaft critical speed. The

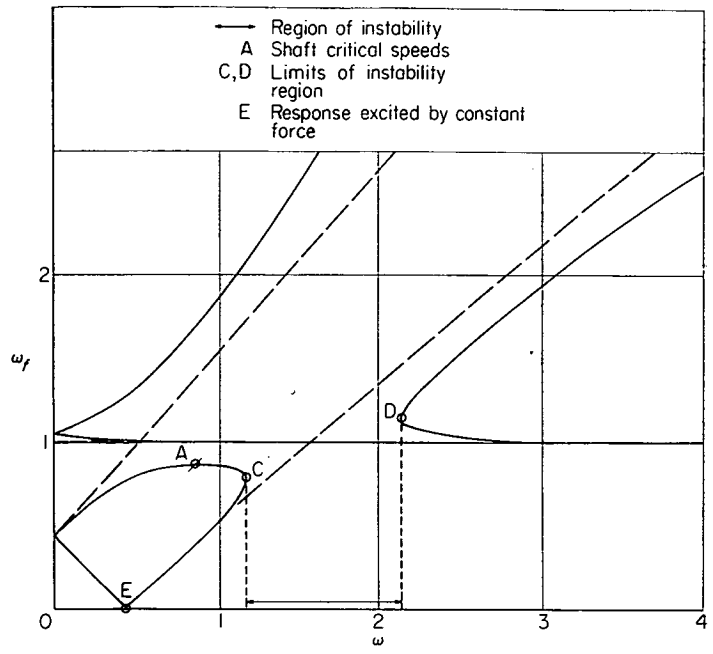

FIGURE II–4.—Natural frequencies of a three-blade rotor in fixed coordinates for case of $\Lambda_1=0.05$, $\Lambda_2=0.20$, and $\Lambda_3=0.10$.

second factor, which depends on only the reference frequency, marks the end of the range of instability and is the second shaft critical speed. Formula (8) and an experimental verification of it are given in chapter I. A convenient graph of equation (8) is given in figure II–5. It will be noticed that it is impossible to remove the two shaft critical speeds or the instability region between them by any possible change of the parameters Λ_1, Λ_2, or Λ_3; that is, without the introduction of damping, self-excited vibrations will always occur below the rotational speed ω_r.

Instability also occurs in a range of rotational speeds greater than ω_r. This range is shown in figures II–2 and II–3 as the region bounded by the points C and D and is similar in origin to the self-excited region exhibited by the three-blade rotor. In this region, the roots of the frequency equation are complex and self-excited vibrations will take place. Unlike the three-blade rotor, however, the rotor hub will be seen from a stationary position to be simultaneously executing self-excited vibrations at two different frequencies. Physically, of course, the rotor is moving in an ellipse at the frequency ω_a while precessing at the velocity ω.

A chart showing the lower and upper limits of this instability region for a wide choice of values for the parameters, Λ_1, Λ_2, and Λ_3 is given in figure II–6. The chart is used by drawing a straight line that represents the function $(1-4\Lambda_3)\omega^2$ plotted against $\Lambda_1\omega^2+\Lambda_2$. The intersections of this straight line with the proper Λ_3-curves give the desired values of ω. The short-dash line on the chart illustrates the method for the parameters of figure II–2.

The position of the instability region is very sensitive to the values of Λ_3. (See fig. II–7.) As Λ_3 increases, the region of instability occurs at greater rotational speeds and moves to infinity for $\Lambda_3=\frac{1}{4}(1-\Lambda_1)$. For values of Λ_3 greater than $\frac{1}{4}(1-\Lambda_1)$—that is, when the total effective mass of the rotor blades is greater than the effective mass of the rotor supports—the self-excited region does not appear.

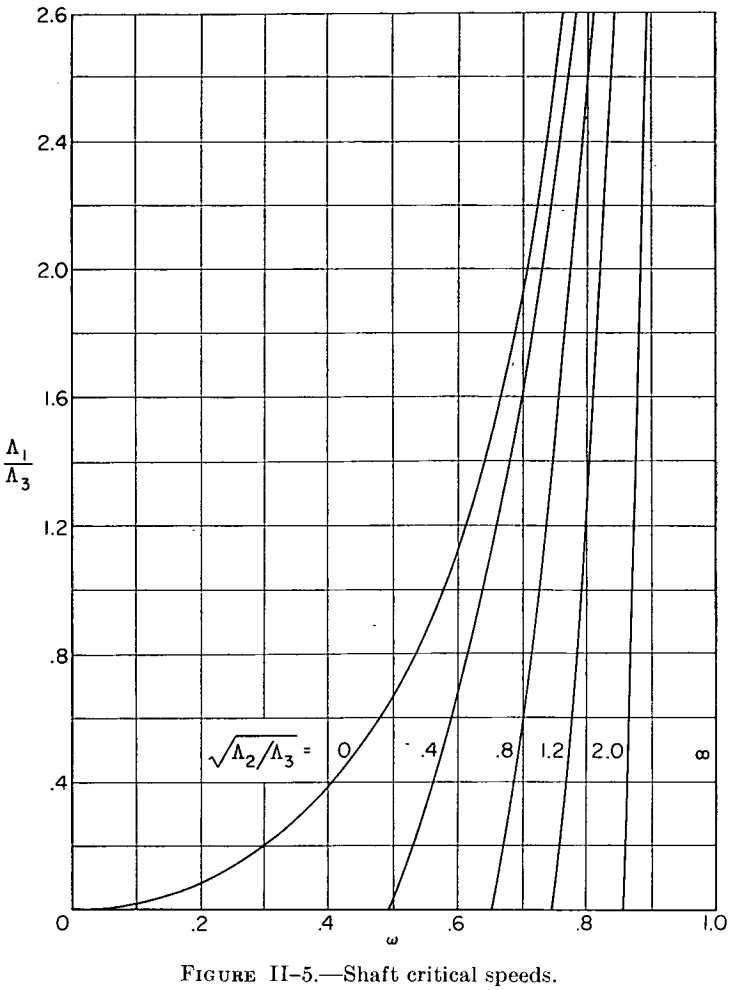

FIGURE II–5.—Shaft critical speeds.

At certain rotational speeds, $\omega_f=0$. At such speeds resonance may be excited by a steady force, constant in direction, acting on the pylon or blades—for example, gravity acting on a tilted rotor. The two-blade rotor has two such speeds, shown as points E and F in figures II–2 and II–3. The mathematical condition for such points is that $\omega_f=0$ or $\omega_a^2=\omega^2$ in equation (7). The equation giving the rotational speeds at which this condition may occur is

$$(\Lambda_1\omega^2+\Lambda_2)(4\omega^2-1)-\omega^2[\omega^2(4-16\Lambda_3)-1]=0 \qquad (9)$$

Equation (9) is plotted in figure II–8, which is used similarly to figure II–6. If $\Lambda_2=0$, then point E occurs at $\omega=0$. If $\Lambda_3\geqq\frac{1}{4}(1-\Lambda_1)$, as pointed out in reference 2, then point F occurs at $\omega=\infty$.

EFFECT OF DAMPING

The effect of damping will be determined in the same manner as for the three-blade rotor in chapter I. When the damping parameters λ and λ_β are retained, equation (6) in expanded form can be separated into powers of ω_a having real and imaginary coefficients. The terms of equation (6) with

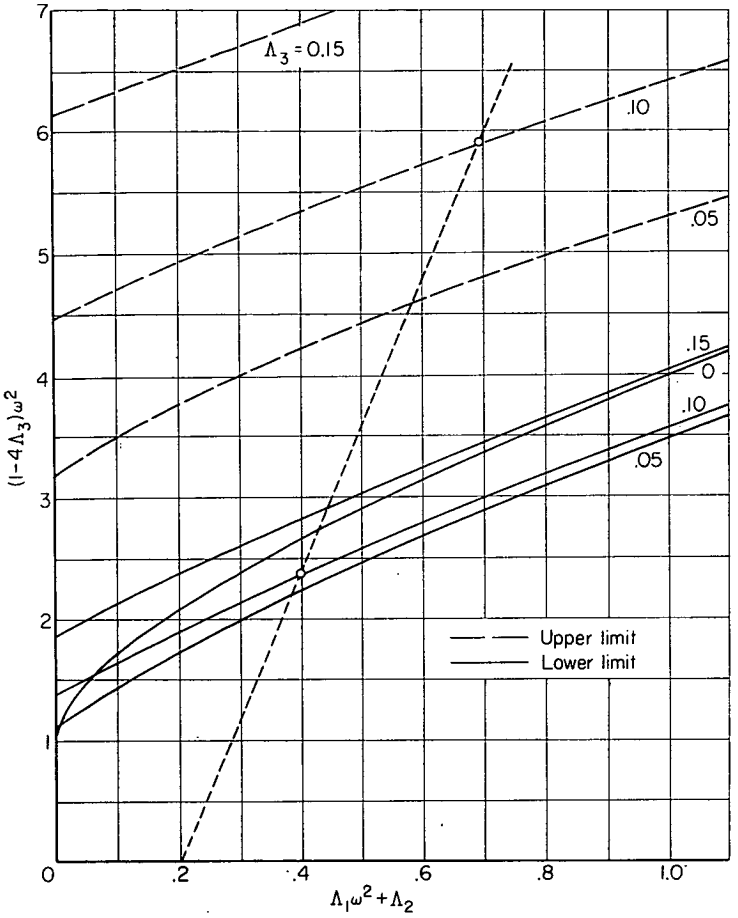

FIGURE II–6.—Stability chart for second instability region.

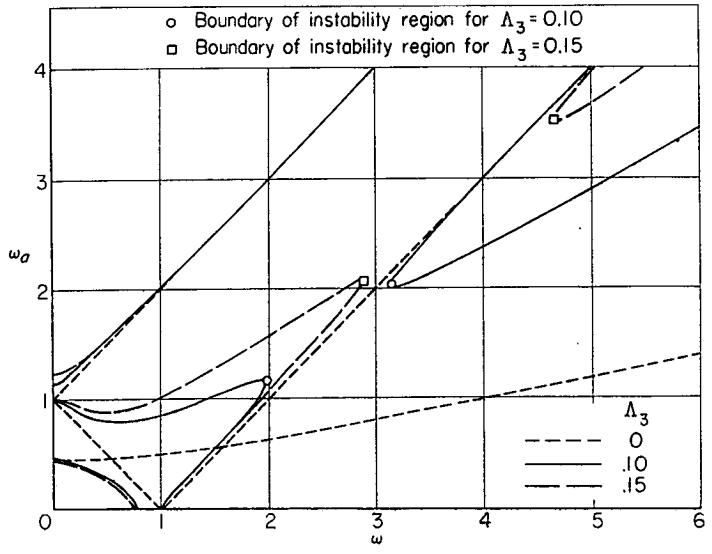

FIGURE II–7.—Effect of coupling parameter Λ_3 for case of $\Lambda_1=0.05$ and $\Lambda_2=0.20$.

real coefficients are

$$2\Lambda_3(\omega^2+\omega_a{}^2-1)+[4\omega^2\omega_a{}^2-(\omega^2+\omega_a{}^2-1)^2][-2\Lambda_3(\omega^2+\omega_a{}^2+1)+\omega_a{}^2-\Lambda_2-\Lambda_1\omega^2]+\lambda^2(-\omega_a{}^2+\Lambda_2+\Lambda_1\omega^2)(\omega^2-\omega_a{}^2)-2\lambda\lambda_\beta\omega_a{}^2(\omega^2-\omega_a{}^2+1) \quad (10)$$

526597—60——20

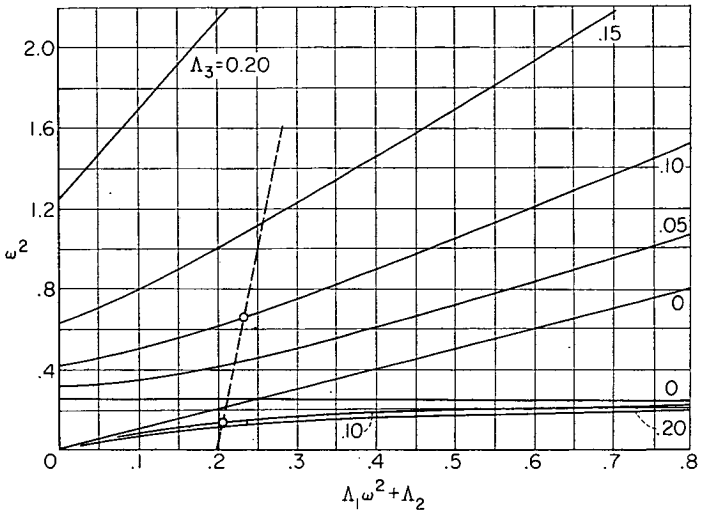

FIGURE II–8.—Rotational speeds at which vibration could be excited by steady force.

The terms with imaginary coefficients are

$$i\lambda_\beta\omega_a\left\{2\frac{\lambda}{\lambda_\beta}[(\omega^2-\omega_a{}^2+1)(\Lambda_1\omega^2+\Lambda_2-\omega_a{}^2)+\Lambda_3(3\omega^4-2\omega^2\omega_a{}^2-\omega_a{}^4)]+\omega^4+\omega_a{}^4+1-2\omega^2\omega_a{}^2-2\omega_a{}^2-2\omega^2-\lambda^2(\omega_a{}^2-\omega^2)\right\} \quad (11)$$

At a boundary between stability and instability, ω_a is real. Such points are the intersections of the equations formed by setting expressions (10) and (11) separately equal to zero and plotting them on the same coordinate axes. Figure II–9 shows a calculated case of damping. The imaginary equation is plotted for several values of the ratio of the damping parameters λ/λ_β, with λ^2 assumed to be negligible. It is seen that, for large values of λ/λ_β, the boundaries of the higher range of instability are not far different from the boundaries found by neglecting damping. Small values of λ/λ_β—that is, when most of the damping is concentrated in the blade

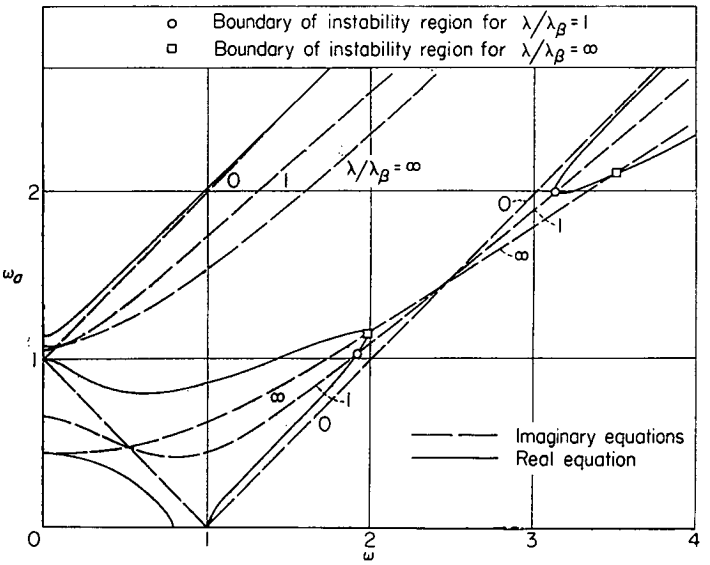

FIGURE II–9.—Plot of real and imaginary equations for case of $\Lambda_1=0.05$, $\Lambda_2=0.20$, $\Lambda_3=0.10$, and $\lambda\lambda_\beta\approx 0$.

hinges—lead to a beginning of the instability at lower rotational speeds.

For small amounts of damping, the plot of the real equation is practically the same as when damping is neglected. By introducing sufficient damping, however, the higher instability region may be eliminated. (See fig. II–10.) The two shaft critical speeds and the instability region between them can also be removed by putting enough damping into the rotor supports, although a large amount of damping is required.

BRIEF DESCRIPTION OF VIBRATION MODES

If damping is neglected, the shape of the free vibration modes can be found from the equations of motion (eqs. (1) to (4)) and the form of the solution (eq. (5)). The rotor hub generally moves in an elliptical path in rotating coordinates although, at certain speeds, the motion may become circular or linear. At zero rotational speed, two of the three modes involve hub motion normal to the line of the blades, with concomitant blade motion. In the third mode, the blades do not move about their hinges and the rotor hub moves in a straight line parallel to the line of the blades at a frequency equal to ω_r.

At the first shaft critical speed, the rotor hub diverges in a direction normal to the line of the blades; whereas, at the second shaft critical speed, the hub diverges parallel to the blades.

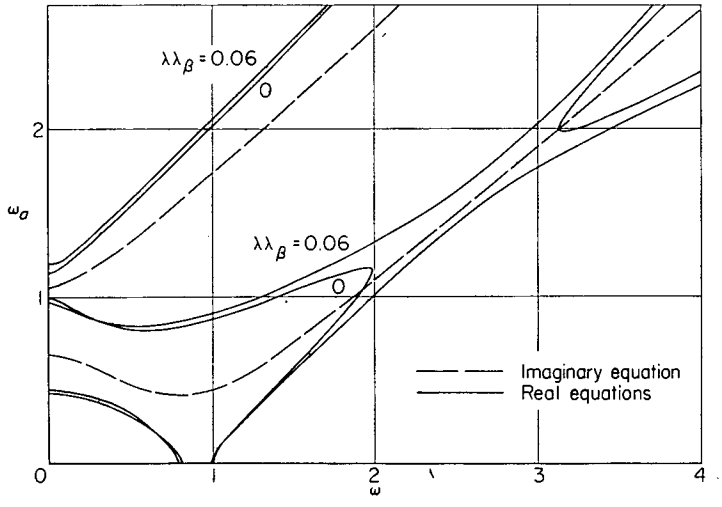

FIGURE II–10.—Plot of real and imaginary equations for case of $\Lambda_1=0.05$, $\Lambda_2=0.20$, $\Lambda_3=0.10$, and $\lambda=\lambda_\beta$.

The forced responses of the system to a vibrator attached to the pylon can also easily be determined and show that those responses lying closest to the lines $\omega_f^2=1$ are the strongest. When the coupling parameter Λ_3 is zero, no response occurs along the lines $\omega_f=|2\omega\pm1|$. This last conclusion is, of course, necessary if the theory is to give the correct results for the degenerate case of massless rotor blades.

CONCLUSIONS

The mechanical stability of a rotor having two vertically hinged blades mounted upon symmetrical supports has been investigated and reported in this chapter. This investigation indicated that the main features of such a rotor system may be summarized as follows:

1. The vibration modes are generally elliptical, as opposed to circular for the three-blade rotor. The ellipse precesses at a speed ω as observed from a fixed position; the result is six resonant or natural frequencies in a fixed coordinate system for a given rotor speed as against four natural frequencies for the three-blade rotor.

2. The asymmetry of the two-blade-rotor system gives rise to a range of rotor speeds in which self-excited divergence of the rotor occurs. This instability region is bounded by two shaft critical speeds. A three-blade rotor, in contrast, has only one shaft critical speed with no associated instability region.

3. The two-blade rotor has a second region of rotational speeds at which self-excited vibrations occur.

CHAPTER III

THEORY OF GROUND VIBRATIONS OF A TWO-BLADE HELICOPTER ROTOR ON ANISOTROPIC FLEXIBLE SUPPORTS (REVISED)

By Robert P. Coleman and Arnold M. Feingold

SUMMARY

An extension of previous work on the theory of self-excited mechanical oscillations of hinged rotor blades has been made. Previously published papers cover the cases of three or more rotor blades on elastic supports (such as landing gear) having either equal or unequal support stiffness in different directions and the case of one- or two-blade rotors on supports having equal stiffness in all horizontal directions. The missing case of one or two blades on unequal supports has been treated.

The mathematical treatment of this case is considerably more complicated than the other cases because of the occurrence of differential equations with periodic coefficients. The characteristic frequencies are obtained from an infinite-order determinant. Recurrence relations and convergence factors are used in finding the roots of the infinite determinant.

The results show the existence of ranges of rotational speed at which instability occurs (changed somewhat in position and extent) similar to those possessed by the two-blade rotor on equal supports. In addition, the existence of an infinite number of instability ranges which occurred at low rotor speeds and which did not occur in the cases previously treated is shown.

Simplifications occur in the analysis for the special cases of infinite and zero stiffness in one of the axes. The case of infinite stiffness in one axis is also of special interest because it is mathematically equivalent to a counterrotating rotor system A design chart for finding the position of the principal self-excited-instability range for the case of infinite support stiffness in one direction is included for the convenience of designers. It is expected that designers will be able to obtain sufficiently accurate information by considering only the cases of infinite and zero support stiffness along one direction together with the cases treated previously.

INTRODUCTION

It is known that rotating-wing aircraft may experience violent vibrations while the rotor is turning and the aircraft is on the ground. It has been found that these vibrations can be explained without considering aerodynamic effects and that they are due to mechanical coupling between horizontal hub displacements and blade oscillations in the plane of rotation. A theoretical analysis of this vibration problem is given in chapters I and II. Chapter I deals with rotors having three or more equal blades on general supports and chapter II deals with two-blade rotors on supports having the same stiffness in all directions.

Although in actual two-blade rotary-wing aircraft, the stiffness of the supports along the longitudinal direction is certainly different from the lateral stiffness, the equality of the stiffnesses was assumed in chapter II because it permitted the mathematical simplification of dealing with differential equations having constant coefficients and it was believed that a theory employing such an assumption would be sufficient to indicate the nature of the most violent types of ground instability.

The present chapter gives a theoretical investigation of the general case of a two-blade rotor mounted upon supports of unequal stiffness along the two stationary principal axes. It thus generalizes the problem of chapter II, and rounds out the studies of ground resonance begun in chapter I. As was shown in chapter II, a two-blade rotor possesses different dynamic properties along and normal to the line of the blades. Equations of motion with constant coefficients for the problem treated in chapter II could be obtained by using a coordinate system rotating with the rotor. This procedure succeeded because the supports were assumed isotropic (equal stiffness in all directions). When the supports are anisotropic, however, it is impossible to avoid the appearance of periodic coefficients in the equations of motion.

The present method of solving the differential equations of motion follows closely the process employed in reference 1 for a vibration problem in two degrees of freedom. The form of solution is expressed by an exponential factor times a complex Fourier series. Substitution of the formal solution into the equations of motion yields an infinite set of algebraic equations and an infinite-order determinant for the determination of the Fourier coefficients and the characteristic frequencies. The subsequent analysis is concerned with methods of finding the roots of the infinite determinant.

Although the present chapter did not originally include the effects of damping on rotor instability, Mr. George W. Brooks has prepared appendix B to indicate how effects of damping may be included in the analyses.

It is expected that designers will be able to obtain sufficiently accurate information by considering only the cases of infinite or zero support stiffness along one direction together with the cases of chapters I and II. In order to avoid the necessity for extensive calculations, a design chart is included giving the location of the principal self-excited-instability range for the case of infinite support stiffness in one direction.

DERIVATION OF THE EQUATIONS OF MOTION

The symbols used in this chapter are defined in appendix A.

The equations of motion are obtained from Lagrange's equations and from the expressions for kinetic and potential

energy. Four degrees of freedom of the rotor system are considered: components of deflection of the rotor hub in the plane of rotation, and hinge deflections of the two rotor blades about their vertical hinges. All motions are thus assumed to occur in the plane of the rotor. The rotor is assumed to rotate at a constant angular velocity ω. The analysis can be applied to rotors without hinges by assuming an effective spring stiffness and hinge position to represent the elastic deflection of the blade.

The pertinent physical parameters are:

a	radial position of vertical hinge
b	distance from vertical hinge to center of mass of blade
m_b	mass of rotor blade
m	effective mass of rotor supports
r	radius of gyration of blade about center of mass
K_x, K_y	spring constants of the rotor supports along the X- and Y-directions, respectively
K_β	spring constant of hinge self-centering spring

Let the origin of the X, Y-coordinate system be placed at the undisturbed position of the rotor hub. At time t equal to 0, the line through the blade hinges and rotor hub is assumed parallel to the X-axis. After a time interval t, let the rotor hub deflection be z and hinge deflections be β_1 and β_2, respectively, where z is the complex position coordinate measured in a coordinate system rotating with the rotor. (See fig. III–1.) Then the positions of the centers of mass of the two blades, as measured in fixed coordinates, will be, respectively,

$$\left.\begin{aligned} z_1&=(z+a+be^{i\beta_1})e^{i\omega t}\\ z_2&=(z-a-be^{i\beta_2})e^{i\omega t}\end{aligned}\right\} \tag{1}$$

The kinetic energy of the rotor system T can be written as

$$T=\frac{1}{2}\,m_b\left\{\dot{z}_1\dot{\bar{z}}_1+\dot{z}_2\dot{\bar{z}}_2+r^2\left[(\omega+\dot{\beta}_1)^2+(\omega+\dot{\beta}_2)^2\right]\right\}+\frac{1}{2}\,m(\dot{z}+i\omega z)(\dot{\bar{z}}-i\omega\bar{z}) \tag{2}$$

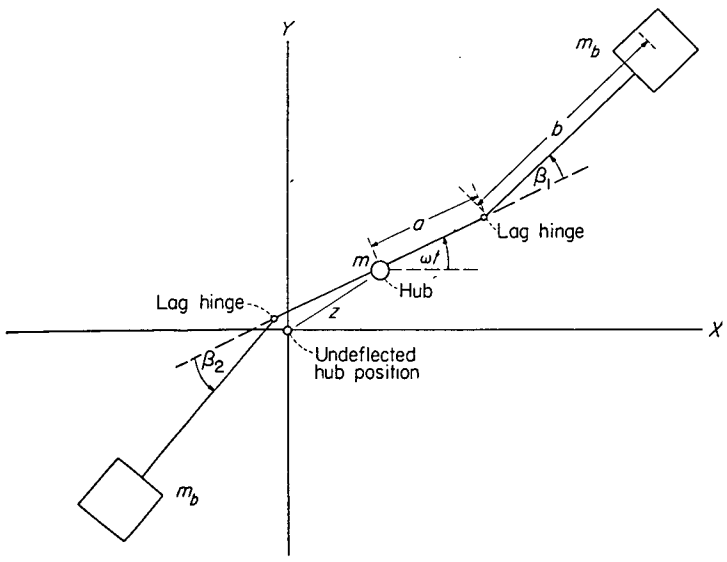

FIGURE III–1.—Simplified mechanical system representing rotor.

The first term in equation (2) represents the kinetic energy of the rotor blades, including the energy due to rotation, and the second term is the contribution of the rotor hub.

Upon expanding equation (1) into power series in β_1 and β_2 (only small deflections from equilibrium being considered) and substituting into equation (2), there is obtained

$$T=\frac{1}{2}\,M(\dot{z}+i\omega z)(\dot{\bar{z}}-i\omega\bar{z})+\frac{1}{2}\,m_b\Big[-(\beta_1-\beta_2)(i\omega^2 bz-i\omega^2 b\bar{z}+\omega b\dot{z}+\omega b\dot{\bar{z}})+(\dot{\beta}_1-\dot{\beta}_2)(bi\dot{\bar{z}}+\omega bz+\omega b\bar{z}-bi\dot{z})+(b^2+r^2)(\dot{\beta}_1^2+\dot{\beta}_2^2)-ab\omega^2(\beta_1^2+\beta_2^2)\Big] \tag{3}$$

where only the terms that are quadratic in the variables have been retained, and M represents the total mass of the rotor system.

The potential energy of the system V is given by

$$V=\frac{K_\beta}{2}\,(\beta_1^2+\beta_2^2)+\frac{K}{2}\,z\bar{z}-\frac{\Delta K}{4}\,(z^2e^{2i\omega t}+\bar{z}^2e^{-2i\omega t}) \tag{4}$$

where K is the average stiffness and ΔK is a measure of the difference of the two principal stiffnesses; that is,

$$K=\frac{K_y+K_x}{2}$$

$$\Delta K=\frac{K_y-K_x}{2}$$

As in chapters I and II, simplifications in the analysis are introduced by replacing the hinge variables β_1 and β_2 by the following new variables:

$$\theta_0=\frac{b}{2}\,(\beta_1+\beta_2)$$

$$\theta_1=\frac{b}{2}\,(\beta_1-\beta_2)$$

In terms of these new variables the expressions (3) and (4) become, respectively,

$$T=\frac{M}{2}\,(\dot{z}+i\omega z)\,(\dot{\bar{z}}-i\omega\bar{z})+m_b\Big[(\dot{\bar{z}}-i\omega\bar{z})\,(i\dot{\theta}_1-\omega\theta_1)-(\dot{z}+i\omega z)\,(i\dot{\theta}_1+\omega\theta_1)+\left(1+\frac{r^2}{b^2}\right)(\dot{\theta}_0^2+\dot{\theta}_1^2)-\frac{a}{b}\,\omega^2\,(\theta_0^2+\theta_1^2)\Big] \tag{5}$$

and

$$V=\frac{K}{2}\,z\bar{z}+\frac{K_\beta}{b^2}\,(\theta_0^2+\theta_1^2)-\frac{\Delta K}{4}\,(z^2e^{2i\omega t}+\bar{z}^2e^{-2i\omega t}) \tag{6}$$

By use of the Lagrangian form of the equations of motion

$$\frac{d}{dt}\left(\frac{\partial T}{\partial\dot{x}}\right)-\frac{\partial T}{\partial x}+\frac{\partial V}{\partial x}=0$$

the following equations of motion for the rotor system are finally obtained:

$$\ddot{\theta}_0+(\omega^2\Lambda_1+\Lambda_2)\theta_0=0 \tag{7}$$

$$(D+i\omega)^2z+i\mu(D+i\omega)^2\theta_1+\frac{K}{M}\,z-\frac{\Delta K}{M}\,\bar{z}e^{-2i\omega t}=0 \tag{8}$$

$$(D-i\omega)^2\bar{z}-i\mu(D-i\omega)^2\theta_1+\frac{K}{M}\bar{z}-\frac{\Delta K}{M}ze^{2i\omega t}=0 \tag{9}$$

$$(D+i\omega)^2z-(D-i\omega)^2\bar{z}+2i\left(1+\frac{r^2}{b^2}\right)(D^2+\Lambda_1\omega^2+\Lambda_2)\theta_1=0 \tag{10}$$

where the notation

$$D=\frac{d}{dt}$$

has been used, and the following combinations of the original parameters have been introduced:

$$\mu=\frac{2m_b}{M}$$

$$\Lambda_1=\frac{a}{b\left(1+\frac{r^2}{b^2}\right)}$$

$$\Lambda_2=\frac{K_\beta}{m_b b^2\left(1+\frac{r^2}{b^2}\right)}$$

Equations (7) to (10) do not include damping terms. The general equations for the damped case are derived in appendix B and it is shown that both the case for no damping and anisotropic supports, which is treated in the present chapter, and the case for damping and isotropic supports, which was treated in chapter II, are readily obtained as special cases of the generalized equations by neglecting appropriate terms.

Equation (7) can be solved independently of the others since it is an equation in θ_0 alone. The equivalent equation appeared also in chapters I and II, and its solution represents in-phase motion of the blades with no resultant reaction (except torsion) at the rotor hub. This motion will not be further considered in this chapter.

The problem is thus resolved into the solution of the three simultaneous equations (8) to (10). It will be noted that the terms with periodic coefficients in equations (8) and (9) disappear if $\frac{\Delta K}{M}=0$, that is, if $K_y=K_x$. Equations (8) and (9) are thus reduced to the problem treated in chapter II.

FORM OF SOLUTION OF EQUATIONS OF MOTION

The equations of motion (eqs. (8) to (10)) are similar in mathematical properties to Mathieu's equation, which occurs in the analysis of vibrating systems of one degree of freedom with variable elasticity. (See ref. 2.) A generalized form of Mathieu's equation was solved analytically by Hill. (See ref. 3, pp. 413–417.) An extension of Hill's method has been applied in reference 1 to a problem involving two degrees of freedom, and a further development of the method of reference 1 is followed in the present paper.

Equations (8) to (10) constitute a system of linear differential equations with periodic coefficients. Three second-order equations possess six linearly independent solutions that, according to the Floquet theory (ref. 3, p. 412), are of the form of an exponential factor times a periodic function of time. Particular solutions are of the form

$$\left.\begin{aligned} z&=e^{i\omega_a t}P(t)+e^{-i\bar{\omega}_a t}\bar{Q}(t)\\ \bar{z}&=e^{i\omega_a t}Q(t)+e^{-i\bar{\omega}_a t}\bar{P}(t)\\ \theta_1&=e^{-i\omega_a t}R(t)+e^{-i\bar{\omega}_a t}\bar{R}(t)\end{aligned}\right\} \tag{11}$$

where ω_a is known as the characteristic exponent, and $P(t)$, $Q(t)$, and $R(t)$ are periodic functions of period π/ω.

Since $P(t)$, $Q(t)$, and $R(t)$ are periodic functions of t, they can be represented by complex Fourier series, and equations (11) become

$$\left.\begin{aligned} z&=\sum_{-\infty}^{\infty}A_l e^{(2l\omega+\omega_a)it}+\sum_{-\infty}^{\infty}\bar{B}_l e^{-(2l\omega+\bar{\omega}_a)it}\\ \bar{z}&=\sum_{-\infty}^{\infty}B_l e^{(2l\omega+\omega_a)it}+\sum_{-\infty}^{\infty}\bar{A}_l e^{-(2l\omega+\bar{\omega}_a)it}\\ \theta_1&=\sum_{-\infty}^{\infty}C_l e^{(2l\omega+\omega_a)it}+\sum_{-\infty}^{\infty}\bar{C}_l e^{-(2l\omega+\bar{\omega}_a)it}\end{aligned}\right\} \tag{12}$$

where A_l, B_l, and C_l are complex constants.

Equations (11) and (12) show that, when the rotor system is stable and ω_a is real, the motion not only is not simple harmonic as was the case in chapters I and II, but, in general, is not even periodic. The motion can be said to consist of a fundamental frequency ω_a plus "harmonics" of frequency $\omega_a+2l\omega$ where l is any integer. From equations (12) it is seen that the value of ω_a is not uniquely determinate, since $\omega_a+2l\omega$ also satisfies equations (12). (The imaginary part of ω_a is definite, however.) It can be shown furthermore that, corresponding to each value of ω_a, $-\omega_a$ is also a solution. Only those three values of ω_a for which the real parts lie between 0 and ω need therefore be considered. These values will be referred to hereinafter as the three "principal" values of ω_a. These values of ω_a differing from the principal value by $2l\omega$, or having opposite sign, will be referred to as "harmonics" of the corresponding principal value.

Since z has been defined as a position coordinate in a rotating frame of reference, the values of ω_a can be interpreted as the natural frequencies of the rotor system in rotating coordinates.

SOLUTION OF EQUATIONS OF MOTION

DETERMINANTAL EQUATION

If the formal solution (eqs. (12)) is combined with the equations of motion (eqs. (8) to (10)), and the coefficients of each exponential time factor is separately equated to zero, an infinite set of homogeneous equations is obtained. These equations can be separated into two independent sets. Each equation of one set is the conjugate of an equation of the other set, and only one set need be considered. Thus

$$\left\{\frac{K}{M}-[\omega_a+(2l+1)\omega]^2\right\}A_l-\frac{\Delta K}{M}B_{l+1}-\mu i[\omega_a+(2l+1)\omega]^2C_l=0 \tag{13}$$

$$\left\{\frac{K}{M}-[\omega_a+(2l-1)\omega]^2\right\}B_l-\frac{\Delta K}{M}A_{l-1}+\mu i[\omega_a+(2l-1)\omega]^2C_l=0 \tag{14}$$

$$-[\omega_a+(2l+1)\omega]^2A_l+[\omega_a+(2l-1)\omega]^2B_l+2i\left(1+\frac{r^2}{b^2}\right)[-(\omega_a+2l\omega)^2+\Lambda_1\omega^2+\Lambda_2]C_l=0 \tag{15}$$

where l takes on all integral values from $-\infty$ to ∞.

In order that the values of A_l, B_l, and C_l not equal zero, the determinant of the coefficients of A_l, B_l, and C_l must be zero. This determinantal equation is

$$\begin{vmatrix}

$$a_{-3,-2}=\left(\frac{\omega_a-\omega}{\omega_a-2\omega}\right)^2 \qquad a_{0,0}=-1+\frac{\Lambda_1\omega^2+\Lambda_2}{\omega_a^2}$$

$$a_{-2,-3}=\Lambda_3 \qquad a_{0,1}=\left(\frac{\omega_a+\omega}{\omega_a}\right)^2$$

$$a_{-2,-2}=-1+\frac{K/M}{(\omega_a-\omega)^2} \qquad a_{1,0}=\Lambda_3$$

$$a_{-2,-1}=\frac{\Delta K/M}{(\omega_a-\omega)^2} \qquad a_{1,1}=-1+\frac{K/M}{(\omega_a+\omega)^2}$$

$$a_{1,2}=\frac{\Delta K/M}{(\omega_a+\omega)^2} \qquad a_{3,2}=\left(\frac{\omega_a+\omega}{\omega_a+2\omega}\right)^2$$

$$a_{2,1}=\frac{\Delta K/M}{(\omega_a+\omega)^2} \qquad a_{3,3}=-1+\frac{\Lambda_1\omega^2+\Lambda_2}{(\omega_a+2\omega)^2}$$

$$a_{2,2}=-1+\frac{K/M}{(\omega_a+\omega)^2} \qquad a_{3,4}=\left(\frac{\omega_a+3\omega}{\omega_a+2\omega}\right)^2$$

$$a_{2,3}=\Lambda_3 \qquad a_{4,3}=\Lambda_3$$

$$a_{4,4}=-1+\frac{K/M}{(\omega_a+3\omega)^2}$$

The determinant has been somewhat simplified by multiplying and dividing the rows and columns by various quantities, and the parameter Λ_3 has been substituted for its equivalent $\frac{\mu/2}{1+(r/b)^2}$.

Let this infinite determinant be $\Delta(\omega_a)$. The problem consists in solving the equation $\Delta(\omega_a)=0$ for its roots ω_a. These roots will be infinite in number, consisting of the three principal values of ω_a plus all their harmonics. The values

of $\omega_a/\sqrt{K/M}$, as a function of $\omega/\sqrt{K/M}$, are seen to depend only on the values of the three nondimensional parameters, Λ_1, $\frac{\Lambda_2}{K/M}$, and Λ_3 and the stiffness-ratio parameter $\Delta K/K$.

A determinant of infinite order has meaning only insofar as it is defined as the limit of a determinant of finite order. Define $\Delta_n(\omega_a)$ as the determinant of order $6n-3$ formed from a square array of $\Delta(\omega_a)$ centered on the term $-1+\frac{\Lambda_1\omega^2+\Lambda_2}{\omega_a^2}$. This term, which originally was associated with C_0 in equation (15), will be referred to hereinafter as the "origin" of the infinite determinant $\Delta(\omega_a)$. The choice of this term as center of $\Delta(\omega_a)$ is purely arbitrary, and it was selected solely for reasons of symmetry.

Thus

$$\Delta(\omega_a)=\lim_{n\to\infty}\Delta_n(\omega_a) \tag{17}$$

The limiting values of the roots of the equation

$$\Delta_n(\omega_a)=0$$

as n becomes infinite will be the values of the roots of the equation

$$\Delta(\omega_a)=0$$

The method of calculating the roots of $\Delta(\omega_a)=0$, by successively calculating the roots of $\Delta_n(\omega_a)=0$ for larger values of n, is entirely too tedious. Instead, the method reference 1 will be followed. This method involves the calculation of the value of $\Delta(\omega_a)$ for several specified values of ω_a. The roots of $\Delta(\omega_a)=0$ can then be obtained from a trigonometric equation involving the roots and the calculated values of $\Delta(\omega_a)$.

AUXILIARY DETERMINANTS AND RECURRENCE RELATIONS FOR CALCULATING $\Delta(\omega_a)$

Before the trigonometric equation is derived, it is convenient to have a systematic numerical procedure for determining the value of $\Delta(\omega_a)$. As n becomes infinite, the terms of $\Delta_n(\omega_a)$ extend to infinity both above and below the origin. By expanding $\Delta_n(\omega_a)$ in terms of the elements of the column containing the origin, it can be expressed in terms of auxiliary determinants that extend to infinity in only one direction. Recurrence relations can then be obtained that give the value of these auxiliary determinants.

The auxiliary determinants are minors of $\Delta_n(\omega_a)$ and are defined as follows:

$C_n(\omega_a)$ determinant of order $3n-2$ consisting of the terms below and to the right of the origin; that is, determinant having first row and column beginning with term $-1+\frac{K/M}{(\omega_a+\omega)^2}$

$D_n(\omega_a)$ determinant of order $3n-3$ formed from $C_n(\omega_a)$ by omitting last row and column

$E_n(\omega_a)$ determinant of order $3n-4$ formed from $D_n(\omega_a)$ by omitting last row and column

$L_n(\omega_a)$ determinant of order $3n-3$ formed from $C_n(\omega_a)$ by omitting first row and column

$M_n(\omega_a)$ determinant of order $3n-4$ formed from $L_n(\omega_a)$ by omitting last row and column

$N_n(\omega_a)$ determinant of order $3n-5$ formed from $M_n(\omega_a)$ by omitting last row and column

The following three determinants will also be needed:

$G_n(\omega_a)$ determinant of order $3n-4$ formed from $L_n(\omega_a)$ by omitting first row and column

$H_n(\omega_a)$ determinant of order $3n-5$ formed from $G_n(\omega_a)$ by omitting last row and column

$I_n(\omega_a)$ determinant of order $3n-6$ formed from $H_n(\omega_a)$ by omitting last row and column

Determinants similar to the foregoing can be formed in the same manner from the upper half of $\Delta_n(\omega_a)$. Denote these determinants by the subscript $-n$ instead of n. It is seen, however, that their values can be obtained from the values of the determinants already defined from the lower half of $\Delta_n(\omega_a)$, by merely replacing ω_a with $-\omega_a$ (for example, $C_{-n}(\omega_a)=C_n(-\omega_a)$).

Expanding $\Delta_n(\omega_a)$ in terms of the elements of the column containing the origin gives

$$\Delta_n(\omega_a)=\left(-1+\frac{\Lambda_1\omega^2+\Lambda_2}{\omega_a^2}\right)C_n(\omega_a)C_n(-\omega_a)-$$
$$\Lambda_3\left[\left(\frac{\omega_a-\omega}{\omega_a}\right)^2L_n(-\omega_a)C_n(\omega_a)+\left(\frac{\omega_a+\omega}{\omega_a}\right)^2L_n(\omega_a)C_n(-\omega_a)\right] \tag{18}$$

The auxiliary determinants $C_n(\omega_a)$, $D_n(\omega_a)$, and $E_n(\omega_a)$ satisfy the following recurrence relations (obtained by expanding each in terms of the elements of its last row):

$$\left.\begin{aligned}
C_n(\omega_a)&=\left\{-1+\frac{K/M}{[\omega_a+(2n-1)\omega]^2}\right\}D_n(\omega_a)-\Lambda_3\left[\frac{\omega_a+(2n-1)\omega}{\omega_a+(2n-2)\omega}\right]^2E_n(\omega_a)\\
D_n(\omega_a)&=\left\{-1+\frac{\Lambda_1\omega^2+\Lambda_2}{[\omega_a+(2n-2)\omega]^2}\right\}E_n(\omega_a)-\Lambda_3\left[\frac{\omega_a+(2n-3)\omega}{\omega_a+(2n-2)\omega}\right]^2C_{n-1}(\omega_a)\\
E_n(\omega_a)&=\left\{-1+\frac{K/M}{[\omega_a+(2n-3)\omega]^2}\right\}C_{n-1}(\omega_a)-\frac{(\Delta K/M)^2}{[\omega_a+(2n-3)\omega]^4}D_{n-1}(\omega_a)
\end{aligned}\right\} \tag{19}$$

The determinants $L_n(\omega_a)$, $M_n(\omega_a)$, and $N_n(\omega_a)$ and also the system $G_n(\omega_a)$, $H_n(\omega_a)$, and $I_n(\omega_a)$ satisfy the same recurrence relations as $C_n(\omega_a)$, $D_n(\omega_a)$, and $E_n(\omega_a)$, respectively.

The values of these nine determinants can be found from the recurrence relations (eqs. (19)) and the following

initial values, obtained directly from equation (16):

$$\left.\begin{aligned} C_1(\omega_a)&=-1+\frac{K/M}{(\omega_a+\omega)^2} \\ E_2(\omega_a)&=\left[-1+\frac{K/M}{(\omega_a+\omega)^2}\right]^2-\frac{(\Delta K/M)^2}{(\omega_a+\omega)^4} \\ N_2(\omega_a)&=-1+\frac{K/M}{(\omega_a+\omega)^2} \\ M_2(\omega_a)&=\left[1-\frac{K/M}{(\omega_a+\omega)^2}\right]\left[1-\frac{\Lambda_1\omega^2+\Lambda_2}{(\omega_a+2\omega)^2}\right]-\Lambda_3\left(\frac{\omega_a+\omega}{\omega_a+2\omega}\right)^2 \\ H_2(\omega_a)&=-1+\frac{\Lambda_1\omega^2+\Lambda_2}{(\omega_a+2\omega)^2} \\ G_2(\omega_a)&=\left[1-\frac{\Lambda_1\omega^2+\Lambda_2}{(\omega_a+2\omega)^2}\right]\left[1-\frac{K/M}{(\omega_a+3\omega)^2}\right]-\Lambda_3\left(\frac{\omega_a+3\omega}{\omega_a+2\omega}\right)^2 \end{aligned}\right\} \quad (20)$$

By use of the initial conditions (eqs. (20)), the recurrence relations (eqs. (19)), and equation (18), the value of $\Delta_n(\omega_a)$ can be calculated. The value of $\Delta(\omega_a)$ will then be the limiting value of $\Delta_n(\omega_a)$ as n becomes infinite.

THE BEHAVIOR OF $\Delta_n(\omega_a)$ FOR LARGE VALUES OF n

So far it has been tacitly assumed that the determinant $\Delta(\omega_a)$, as defined in equations (16) and (17), is convergent, and further, that it remains a function of ω_a in the limit as n becomes infinite; that is, it is not identically equal to zero, independent of the value of ω_a. It will now be shown that the function $\Delta_n(\omega_a)$ does become zero in the limit, independent of ω_a, but that when $\Delta_n(\omega_a)$ is divided by an appropriate function of n, a new function $F_n(\omega_a)$ will be obtained which will be convergent and remain an unambiguous function of ω_a in the limit.

The derivation of the appropriate function by which to divide $\Delta_n(\omega_a)$ evidently depends upon the behavior of $\Delta_n(\omega_a)$ as n becomes very large. As n becomes infinite, the recurrence relations (eqs. (19)) become

$$C_n=-D_n-\Lambda_3E_n \quad (21a)$$

$$D_n=-E_n-\Lambda_3C_{n-1} \quad (21b)$$

$$E_n=-C_{n-1} \quad (21c)$$

with identical equations for L_n, M_n, and N_n and for G_n, H_n, and I_n. Equations (21) are readily solvable since they constitute a system of difference equations with constant coefficients. They are satisfied by solutions of the form

$$C_n=C_0k^n \quad (22a)$$

where C_0 is some arbitrary constant and k is a constant to be determined. From equations (21c) and (21b), respectively,

$$E_n=-C_0k^{n-1} \quad (22b)$$

and

$$D_n=C_0k^{n-1}-\Lambda_3C_0k^{n-1}$$

$$=C_0(1-\Lambda_3)k^{n-1} \quad (22c)$$

Combining equations (22a), (22b), and (22c) with equation (21a) and dividing through by C_0k^{n-1} gives

$$k=2\Lambda_3-1 \quad (23)$$

Thus, by use of equation (18), it is seen that for large values of n, $\Delta_n(\omega_a)$ varies as k^{2n}. Since by definition Λ_3 must have a value between 0 and 1/2, k^2 must lie between 0 and 1. Thus, in the limit,

$$\lim_{n\to\infty}\Delta_n(\omega_a)=0$$

independent of ω_a.

Consider the function

$$F_n(\omega_a)=\frac{\Delta_n(\omega_a)}{k^{2n}}$$

The equation $F_n(\omega_a)=0$ will obviously have the same roots for ω_a as does $\Delta_n(\omega_a)=0$. The function $F_n(\omega_a)$ has the advantage, however, as is seen from the preceding discussion, of remaining an unambiguous function of ω_a in the limit as n becomes infinite. Define this limit as

$$F(\omega_a)=\lim_{n\to\infty}F_n(\omega_a)$$

$$=\lim_{n\to\infty}\frac{\Delta_n(\omega_a)}{k^{2n}} \quad (24)$$

The primary problem can now be redefined as the problem of determining the roots, infinite in number and consisting of ω_{a_1}, ω_{a_2}, and ω_{a_3} and all their harmonics, of the equation

$$F(\omega_a)=0 \quad (25)$$

EVALUATION OF ROOTS OF EQUATION (25)

The following trigonometric expression for $F(\omega_a)$ will now be derived:

$$F(\omega_a)\equiv\lim_{n\to\infty}\frac{\Delta_n(\omega_a)}{k^{2n}}$$

$$=\frac{1}{k}\frac{\prod_{j=1}^{3}\left[\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)-\sin^2\left(\frac{\pi\omega_{a_j}}{2\omega}\right)\right]}{\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)\cos^4\left(\frac{\pi\omega_a}{2\omega}\right)} \quad (26)$$

The function $F(\omega_a)$ is seen from equation (24) and equation (16) to be periodic of period 2ω, to have roots $\pm(\omega_{a_1}\pm2s\omega)$, $\pm(\omega_{a_2}\pm2s\omega)$, and $\pm(\omega_{a_3}\pm2s\omega)$ where s is any integer, to have second-order poles at $\omega_a=\pm2s\omega$, and to have fourth-order poles at $\omega_a=\pm(s+1)\omega$. Liouville's function theorem states that a function of a complex variable (in this case, ω_a) that is analytic everywhere in the complex plane, including the region at infinity, must be a constant. It will be shown that $F(\omega_a)$ is finite at infinity (except if ω_a proceeds to infinity along the real axis). If the poles along the real axis could be eliminated by forming a suitable function of $F(\omega_a)$, without at the same time introducing new poles, then that function, by Liouville's theorem, must be a constant.

Such a function of $F(\omega_a)$, which is analytic everywhere in

the complex plane, is

$$J(\omega_a)=\frac{F(\omega_a)\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)\cos^4\left(\frac{\pi\omega_a}{2\omega}\right)}{\prod_{j=1}^{3}\left[\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)-\sin^2\left(\frac{\pi\omega_{a_j}}{2\omega}\right)\right]} \tag{27}$$

where ω_{a_1}, ω_{a_2}, and ω_{a_3} are the three principal values of ω_a. The function $J(\omega_a)$ is therefore a constant. The value of $J(\omega_a)$ found by making ω_a approach infinity along the imaginary axis is

$$J(\omega_a)=F(\infty)$$

where $F(\infty)$ is the value of $F(\omega_a)$, as ω_a becomes infinite.

The value of $F(\infty)$ can be found by letting $\omega_a\to\infty$ in $\Delta_n(\omega_a)$ and then letting $n\to\infty$. From the form of $\Delta_n(\infty)$ it follows that

$$\Delta_n(\infty)=N_{2n}(\infty)=-C_{2n}(\infty)$$

The recurrence relations defining $C_n(\infty)$ are the same as equations (21). The expressions D_n and E_n may be eliminated from equations (21), and, therefore, C_n may be given as follows:

$$C_n=-(1-2\Lambda_3)C_{n-1}$$

The initial conditions (eqs. (20)) reduce to $C_1=-1$, from which it follows immediately that

$$\Delta_n(\infty)=-(1-2\Lambda_3)^{2n-1}$$
$$=k^{2n-1}$$

from equation (23). Therefore

$$F(\infty)\equiv\lim_{n\to\infty}\frac{\Delta_n(\infty)}{k^{2n}}=\lim_{n\to\infty}\frac{k^{2n-1}}{k^{2n}}=\frac{1}{k} \tag{28}$$

Thus equations (27) and (28) lead to the evaluation of equation (26).

After equation (26) has been obtained, the problem of determining ω_{a_1} ω_{a_2}, and ω_{a_3} may be considered theoretically complete inasmuch as equation (26) is really an identity in ω_a. Suppose that ω_a is assigned any specific value in equation (26) and $F(\omega_a)$ is computed to a certain degree of accuracy. If these computations are made for two more values of ω_a, all different, equation (26) will have yielded three equations in the three unknowns ω_{a_1}, ω_{a_2}, and ω_{a_3}. These equations can then be solved for the principal values of ω_a. Any degree of accuracy may be achieved by carrying out the computations for $F(\omega_a)$ to a sufficiently large value of n.

The foregoing procedure can be systematized by rewriting equation (26) as

$$K\left(\frac{\omega_a}{\omega}\right)\equiv\prod_{j=1}^{3}\left[\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)-\sin^2\left(\frac{\pi\omega_{a_j}}{2\omega}\right)\right]$$
$$=kF(\omega_a)\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)\cos^4\left(\frac{\pi\omega_a}{2\omega}\right) \tag{29}$$

A convenient choice for the three arbitrary values of ω_a is $\omega_a=0$, ω, and $\omega/2$. The explicit definitions of $K(0)$, $K(1)$, and $K(1/2)$ then become

$$\left.\begin{aligned}
K(0)&=-\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)\sin^2\left(\frac{\pi\omega_{a_3}}{2\omega}\right)\\
K(1)&=\left[1-\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\right]\left[1-\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)\right]\left[1-\sin^2\left(\frac{\pi\omega_{a_3}}{2\omega}\right)\right]\\
K(1/2)&=\left[\frac{1}{2}-\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\right]\left[\frac{1}{2}-\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)\right]\left[\frac{1}{2}-\sin^2\left(\frac{\pi\omega_{a_3}}{2\omega}\right)\right]
\end{aligned}\right\} \tag{30}$$

The equations for evaluating $K(0)$, $K(1)$, and $K(1/2)$ are

$$\left.\begin{aligned}
K(0)&=\lim_{\omega_a\to 0}\left[kF(\omega_a)\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)\cos^4\left(\frac{\pi\omega_a}{2\omega}\right)\right]\\
K(1)&=\lim_{\omega_a\to\omega}\left[kF(\omega_a)\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)\cos^4\left(\frac{\pi\omega_a}{2\omega}\right)\right]\\
K(1/2)&=\lim_{\omega_a\to\omega/2}\left[kF(\omega_a)\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)\cos^4\left(\frac{\pi\omega_a}{2\omega}\right)\right]
\end{aligned}\right\} \tag{31}$$

Carrying out the limiting operations indicated in equations (31) and using the auxiliary determinants $C_n(\omega_a)$, $D_n(\omega_a)$, and so forth, give

$$\left.\begin{aligned}
K(0)&=\lim_{n\to\infty}\left\{\frac{\pi^2[(\Lambda_1\omega^2+\Lambda_2)C_n^2(0)-2\Lambda_3\omega^2L_n(0)C_n(0)]}{-4\omega^2(1-2\Lambda_3)^{2n-1}}\right\}\\
K(1)&=\lim_{n\to\infty}\left[\frac{\pi^4\frac{K_x}{M}\frac{K_y}{M}G_n^2(-\omega)}{16(1-2\Lambda_3)^{2n-2}}\right]\\
K(1/2)&=\lim_{n\to\infty}\left\{\frac{\left[-1+\frac{4(\Lambda_1\omega^2+\Lambda_2)}{\omega^2}\right]C_n\left(\frac{\omega}{2}\right)C_n\left(\frac{-\omega}{2}\right)-\Lambda_3\left[L_n\left(\frac{-\omega}{2}\right)C_n\left(\frac{\omega}{2}\right)+9L_n\left(\frac{\omega}{2}\right)C_n\left(\frac{-\omega}{2}\right)\right]}{-8(1-2\Lambda_3)^{2n-1}}\right\}
\end{aligned}\right\} \tag{32}$$

where the quantities in brackets are conveniently represented by $K(0)_n$, $K(1)_n$, and $K(1/2)_n$, respectively. The quantities $K(\ )_n$ are used in numerical computations as approximations to the functions $K(\ )$.

The formulas (32) for $K(0)$, $K(1)$, and $K(1/2)$ converge slowly with increasing n. The convergence can be speeded up greatly by making use of the concept of convergence factors used in reference 1. A convergence factor for $K(\ )_n$ is a function of n approaching the limit 1 as n becomes infinite, which, when multiplied by $K(\ )_n$, gives an expression which converges rapidly with increasing values of n to the values of $K(\ )$. The details of the derivation of an appropriate convergence factor for $K(0)_n$ will be found in appendix C. Convergence factors for $K(1)_n$ and $K(1/2)_n$ are derived in a similar fashion. The resultant expressions are

$$\left.\begin{aligned} K(0)&=\lim_{n\to\infty}\left[\frac{K(0)_n \sin^2\frac{\pi\sqrt{Q}}{2}}{\frac{\pi^2 Q}{4}\prod_{j=1}^{n-1}\left(1-\frac{Q}{4j^2}\right)^2}\right] \\ K(1)&=\lim_{n\to\infty}\left[\frac{K(1)_n \cos^2\frac{\pi\sqrt{Q}}{2}}{\prod_{j=1}^{n-1}\left(1-\frac{Q}{(2j-1)^2}\right)^2}\right] \\ K(1/2)&=\lim_{n\to\infty}\left[\frac{K(1/2)_n \cos\frac{\pi\sqrt{Q}}{2}}{\prod_{j=1}^{2n-1}\left(1-\frac{4Q}{(2j-1)^2}\right)}\right] \end{aligned}\right\} \quad (33)$$

where

$$Q=\frac{2\frac{K}{M}(1-\Lambda_3)+\Lambda_1\omega^2+\Lambda_2+2\Lambda_3\omega^2}{\omega^2(1-2\Lambda_3)}$$

For a given value of n, the quantities in brackets are found to be better approximations to the respective values of $K(\ )$ than $K(\ )_n$ alone.

The method of obtaining the values of ω_a may be summarized as follows. By use of the initial conditions (eqs. (20)) and the recurrence relations (eqs. (19)), the values of the determinants $C_n(0)$, $L_n(0)$, $G_n(-\omega)$, $C_n(\omega/2)$, $C_n(-\omega/2)$, $L_n(\omega/2)$, and $L_n(-\omega/2)$ can be computed for increasing values of n. With the substitution of these values into equations (33) and with the use of equations (32), approximate values of $K(0)$, $K(1)$, and $K(1/2)$ can be computed. The process appears to be rapidly convergent with n, especially for large values of $\omega/\sqrt{K/M}$. The values of ω_{a_1}, ω_{a_2}, and ω_{a_3} can then be found from equations (31), the definitions of $K(0)$, $K(1)$, and $K(1/2)$.

CONDITIONS FOR STABILITY

From equation (13) the condition for stability of the system is seen to be that all three values of ω_a must be real numbers. If any one of them is complex or pure imaginary, then one of the terms in the solution (eqs. (11)) will increase indefinitely with the time, the motion therefore being unstable. This condition implies that the expressions $\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)$, $\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)$, and $\sin^2\left(\frac{\pi\omega_{a_3}}{2\omega}\right)$ all are real positive numbers less than or equal to 1. The conditions for stability can be expressed directly in terms of $K(0)$, $K(1)$, and $K(1/2)$ by means of their definitions (eqs. (30)). The three equations (30) are formally equivalent to a single cubic equation

$$x^3+bx^2+cx+d=0$$

the roots x_1, x_2, and x_3 of which are $\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)$, $\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)$, and so forth, and the coefficients b, c, and d of which are functions of $K(0)$, $K(1)$, and $K(1/2)$ where

$$2b=4K(0)+4K(1)-8K\left(\frac{1}{2}\right)-3$$

$$2c=-6K(0)-2K(1)+8K\left(\frac{1}{2}\right)+1$$

$$d=K(0)$$

After some manipulations involving the Descartes rule of signs, the necessary and sufficient conditions for stability are found to be

$$\left.\begin{aligned} &0\leqq -K(0)\leqq 1 \\ &0\leqq K(1)\leqq 1 \\ &-1\leqq 8K(1/2)\leqq 1 \\ &\Delta=18bcd-4b^3d+b^2c^2-4c^3-27d^3\geqq 0 \end{aligned}\right\} \quad (34)$$

The quantity Δ is the discriminant of the cubic equation.

SPECIAL CASES OF GENERAL THEORY

Three special cases of the general theory are of interest. These cases are the cases for which one of the principal stiffnesses K_y is respectively zero, equal, or infinite in magnitude in comparison with the second principal stiffness K_x.

CASE OF $K_y=K_x$

The case of $K_y=K_x$ has been treated in chapter II. If $K_y=K_x$, equations (8) to (10) reduce to the equations of chapter II. In this special case, the motion of the rotor system becomes simple harmonic, since all the coefficients A_l, B_l, and C_l in equations (12) are identically zero except A_0, B_0, and C_0.

CASE OF $K_y=0$

The special limiting case of $K_y=0$ is of interest in the case of a pylon of which the stiffness is negligible along one principal direction with interest centered on the frequencies involving the other principal stiffness. In the case of $K_y=0$, the function $K(1)$ as given by equations (32) becomes identically zero. This result is also evident from the original definition of $K(1)$ as given in equation (28), because one of the values of ω_a, say ω_{a_3}, is of necessity equal to $\pm\omega$. (It will be recalled that ω_a is the frequency as measured in rotating coordinates. In fixed coordinates it would be zero.)

It is possible to give much simpler stability criterions for this case because there are only two K-functions, $K(0)$ and $K(1/2)$, and two values of ω_a, ω_{a_1} and ω_{a_2}, to be determined. The new K-functions may be defined as follows:

$$\left.\begin{aligned} K_1&=\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)=-K(0)\\ K_2&=\cos^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\cos^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)=\frac{1+2K(0)-8K\left(\frac{1}{2}\right)}{2}\end{aligned}\right\}\quad(35)$$

In terms of K_1 and K_2, the criterions for stability become

$$0\leqq K_1\leqq 1 \qquad (36a)$$

$$0\leqq K_2\leqq 1 \qquad (36b)$$

$$\sqrt{K_1}+\sqrt{K_2}\leqq 1 \qquad (36c)$$

Given the values of K_1 and K_2, the values of ω_{a_1} and ω_{a_2} can be determined from equations (35). A graph of the relation in equations (35) is given in figure III–2 by means of which the real values of ω_{a_1} and ω_{a_2} can be read off directly once K_1 and K_2 are known.

A graph showing the variation of K_1 and K_2 with $\frac{\omega^2}{K_x/M}$, for the typical parameters $\Lambda_1=0.1$, $\Lambda_2=0$, $\Lambda_3=0.1$, and $K_y=0$, is shown in figure III–3. By use of figure III–2 the values of ω_{a_1} and ω_{a_2} can be obtained. These values are shown in figure III–4 plotted against $\omega/\sqrt{K_x/M}$. Calculations are carried down to $\frac{\omega}{\sqrt{K_x/M}}=0.5$. The general behavior below this speed is discussed in the section entitled "General Behavior of Rotor System as a Function of Rotor Speed."

CASE OF $K_y=\infty$

The formulas for the limiting case of $K_y=\infty$ cannot be obtained conveniently from the general theory. Instead of carrying out the limiting process, it appears preferable to begin by treating the problem as one of only three degrees of freedom (two hinge-deflection coordinates and one hub-position coordinate x) and by developing the theory along lines similar to those used for the general treatment. In this way a system of two simultaneous equations with periodic coefficients is obtained, with the variables θ_1 and x. These equations are solved in a manner similar to that for the general case, the treatment being simpler, however, since the solution has only two principal values of ω_a.

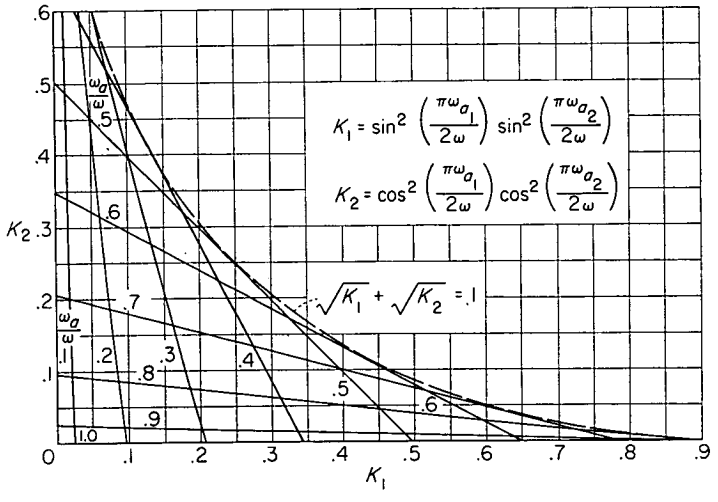

FIGURE III–2.—Chart for obtaining principal value of ω_a from values of K_1 and K_2. $K_y=0$ or $K_y=\infty$.

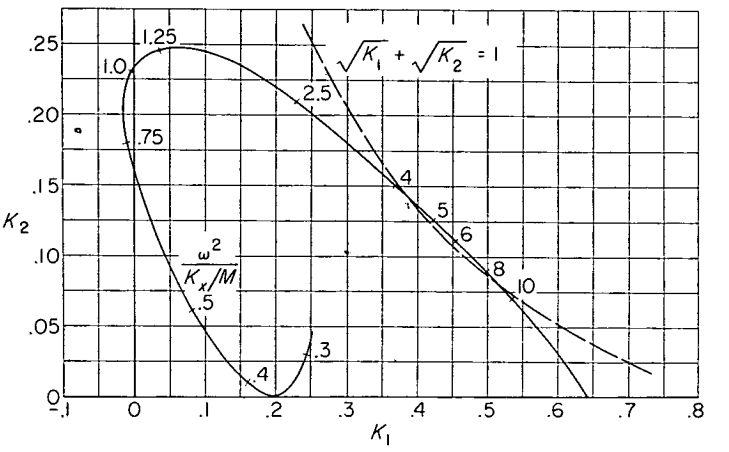

FIGURE III–3.—Graph of K_1 and K_2 as functions of rotor speed ω for $\Lambda_1=0.1$, $\Lambda_2=0$, $\Lambda_3=0.1$, and $K_y=0$.

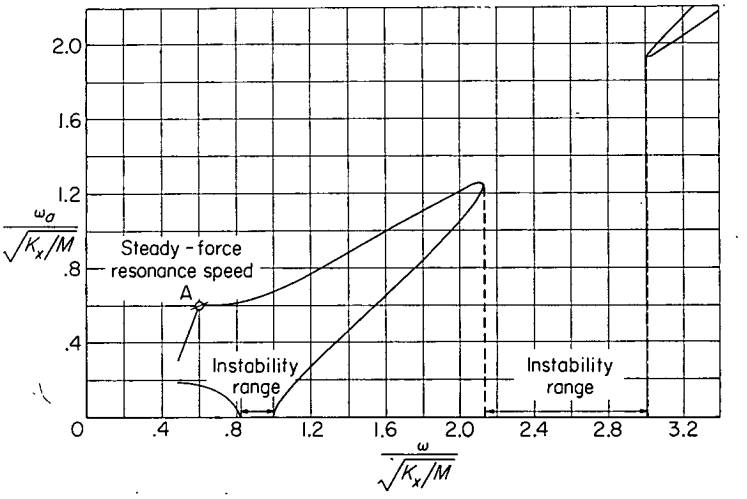

FIGURE III–4.—Principal values of ω_a plotted against rotor speed ω for case of $\Lambda_1=0.1$, $\Lambda_2=0$, $\Lambda_3=0.1$, and $K_y=0$.

The details of the solution of the equations of motion, together with the final formulas for the K-functions, including convergence factors, are given in appendix D. It is found that the same K_1 and K_2 occur as for $K_y=0$. The criterions for stability are exactly the same as those for $K_y=0$, the conditions of equations (36). Figure III–2 can also be used to determine the values of ω_a from the values of K_1 and K_2.

A graph giving the variation of K_1 and K_2 with $\frac{\omega^2}{K_x/M}$ for the parameters $\Lambda_1=0.1$, $\Lambda_2=0$, $\Lambda_3=0.1$, and $K_y=\infty$ is shown in figure III–5. In figure III–6 the values of $\omega_{a_1}/\sqrt{K_x/M}$ and $\omega_{a_2}/\sqrt{K_x/M}$ are shown plotted against $\omega/\sqrt{K_x/M}$.

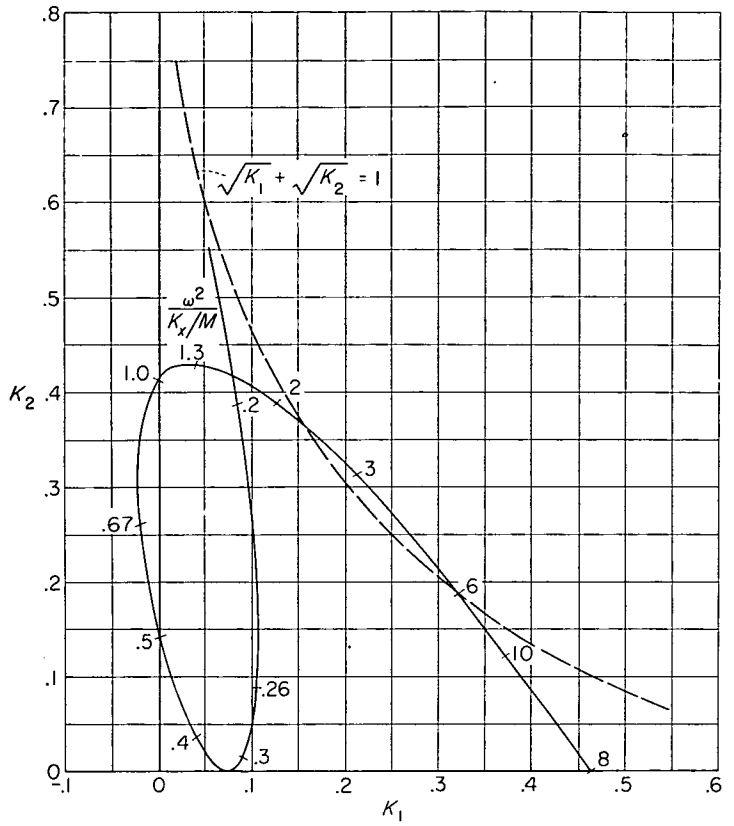

FIGURE III-5.—Graph of K_1 and K_2 as functions of the rotor speed ω for $\Lambda_1=0.1$, $\Lambda_2=0$, $\Lambda_3=0.1$, and $K_y=\infty$.

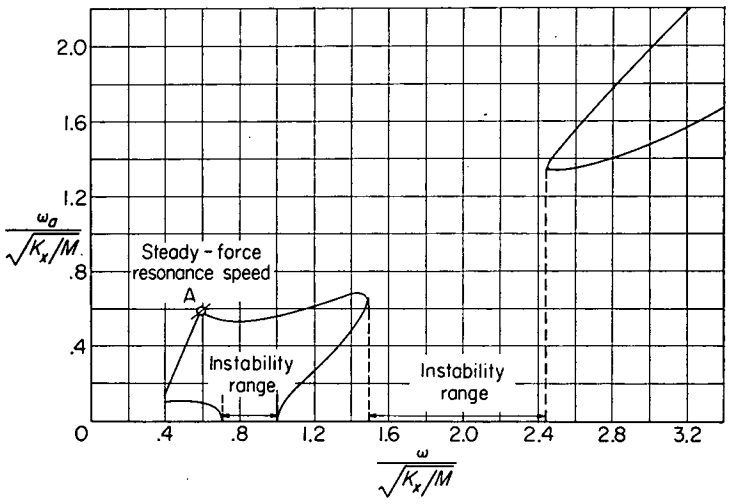

FIGURE III-6.—Principal values of ω_a plotted against rotor speed ω for case of $\Lambda_1=0.1$, $\Lambda_2=0$, $\Lambda_3=0.1$, and $K_y=\infty$.

DISCUSSION OF RESULTS

TYPES OF INSTABILITY

Instability may occur as a result of the violation of any one of the stability criterions of equations (34). Violation of each condition is associated with a different type of instability, which would show up differently in the motion of the rotor system. Experience with computations indicates, however, that the criterions of most practical importance for helicopters are

$$\Delta \geqq 0$$
$$-K(0) \geqq 0$$
$$K(1) \geqq 0$$

Similarly, the important criterions in the limiting cases of $K_y=0$ and $K_y=\infty$ are

$$\sqrt{K_1}+\sqrt{K_2} \leqq 1$$
$$K_1 \geqq 0$$
$$K_2 \geqq 0$$

If the condition $\Delta \geqq 0$ or $(\sqrt{K_1}+\sqrt{K_2} \leqq 1)$ is violated, the other conditions being satisfied, then ω_{a_1} and ω_{a_2} will be complex conjugates, and the rotor system will execute self-excited vibrations at frequencies, in general, incommensurate with the rotor speed. (Higher harmonics will also be present.) This type of instability will be referred to hereinafter as a "self-excited vibration."

If the stability condition $-K(0) \geqq 0$ (or $K_1 \geqq 0$) alone is violated, then one of the values of ω_a will be a pure imaginary number. Physically, the rotor system will execute self-excited vibrations having a basic frequency, as seen in rotating coordinates, of zero. This behavior is similar to the ordinary critical-speed behavior of a shaft. Frequencies at higher harmonics $2n\omega$ will also be present. This type of instability will be referred to as a "self-excited whirling."

The third stability condition $K(1) \geqq 0$ cannot be violated since $K(1)$ as given by equation (32) cannot be negative. However, $K(1)$ can be exactly equal to zero. (A similar statement applies to K_2.) At such a point, where the rotor system is on the border line between stability and instability, one of the values of ω_a will be equal to $\pm\omega$. In fixed coordinates this result means that the rotor system will have a natural frequency equal to zero. The rotor system will, therefore, be in resonance with a steady force—a force of zero frequency. The amplitude of the zero-frequency term for the hub motion in such a situation can be shown to be zero, but the blades will oscillate. Also, higher harmonic terms, notably the term of frequency 2ω (in nonrotating coordinates), will show up in the hub motion. This type vibration, which is a resonance phenomenon and not a self-excited vibration, will be called a "steady-force resonance" vibration.

Each of the vibrations described—self-excited vibrations, self-excited whirling, and a steady-force resonance vibration—appeared in the discussion of the two-blade rotor on equal supports (chapter II); however, there the motions were simple harmonic, no higher harmonics being present.

GENERAL BEHAVIOR OF ROTOR SYSTEM AS A FUNCTION OF ROTOR SPEED

The approximate location of the instability regions can easily be found by examining the limiting case of $\Lambda_3=0$, that is, the case of zero coupling between the blade and hub

motions. For simplicity, the discussion is also restricted to the case of free hinges ($\Lambda_2=0$) and $K_y=\infty$. The K_1 and K_2 functions become

$$\left.\begin{aligned} K_1&=\sin^2\left(\frac{\pi}{2}\sqrt{\Lambda_1}\right)\cos^2\left(\frac{\pi}{2\omega}\sqrt{\frac{K_x}{M}}\right)\\ K_2&=\cos^2\left(\frac{\pi}{2}\sqrt{\Lambda_1}\right)\sin^2\left(\frac{\pi}{2\omega}\sqrt{\frac{K_x}{M}}\right)\end{aligned}\right\} \tag{37}$$

Eliminating the rotor speed ω from equations (37) gives

$$\frac{K_1}{\sin^2\left(\frac{\pi}{2}\sqrt{\Lambda_1}\right)}+\frac{K_2}{\cos^2\left(\frac{\pi}{2}\sqrt{\Lambda_1}\right)}=1$$

which considered as an equation in the variables K_1 and K_2 represents a straight-line segment (one of the lines in fig. III–2) terminated by the K_1 and K_2 axes. The segment can be shown to be tangent to the curve $\sqrt{K_1}+\sqrt{K_2}=1$. As ω decreases, the representative point moves up and down the line segment, performing an infinite number of such oscillations as ω approaches zero. Whenever $K_1=0$, the point is at a self-excited-whirling speed. The corresponding speed is

$$\omega=\frac{\sqrt{K_x/M}}{2s+1}$$

where s represents any positive integer. Thus a self-excited whirling will occur when the rotor speed is approximately equal to 1, ⅓, ⅕, ⅐, and so forth of the natural frequency of the hub $\sqrt{K_x/M}$. Similarly it can be shown that there will be a steady-force resonance vibration whenever the rotor speed is approximately equal to ½, ¼, ⅙, and so forth of the hub natural frequency $\sqrt{K_x/M}$. Finally self-excited vibrations will occur at rotor speeds approximately equal to

$$\omega=\frac{\sqrt{K_x/M}}{2s+1-\sqrt{\Lambda_1}}$$

Figure III–7 shows the general pattern of response frequency plotted against rotor speed for a small value of the mass-ratio parameter Λ_3. Along the horizontal parts of the curves, blade motion predominates over pylon motion. Pylon motion predominates along the slanting parts.

Although the foregoing discussion was developed for the case of $K_y=\infty$, it is believed to apply equally well to the case of $K_y=0$ and also to the general case of $K_y\neq K_x$ if the rotor hub is considered to have two natural frequencies $\sqrt{K_x/M}$ and $\sqrt{K_y/M}$, each frequency having associated with it an infinite set of instability ranges located at approximately the speeds given.

COMPARISON OF RESULTS FOR DIFFERENT VALUES OF K_y/K_x

Figures III–4 and III–6 give the principal values of $\omega_a/\sqrt{K_x/M}$ plotted against the rotor speed $\omega/\sqrt{K_x/M}$ for $K_y=0$ and $K_y=\infty$, respectively, both calculated for the same set of parameters Λ_1, Λ_2, and Λ_3. The calculations have been carried down to $\frac{\omega}{\sqrt{K_x/M}}=0.4$. The similarity between the two curves is striking. So far as the calculations have been carried, each system shows the presence of one self-excited-vibration instability range, one self-excited-whirling instability range, and one steady-force resonance speed A. If the calculations were carried to lower values of ω, further instability ranges and steady-force resonance speeds would appear.

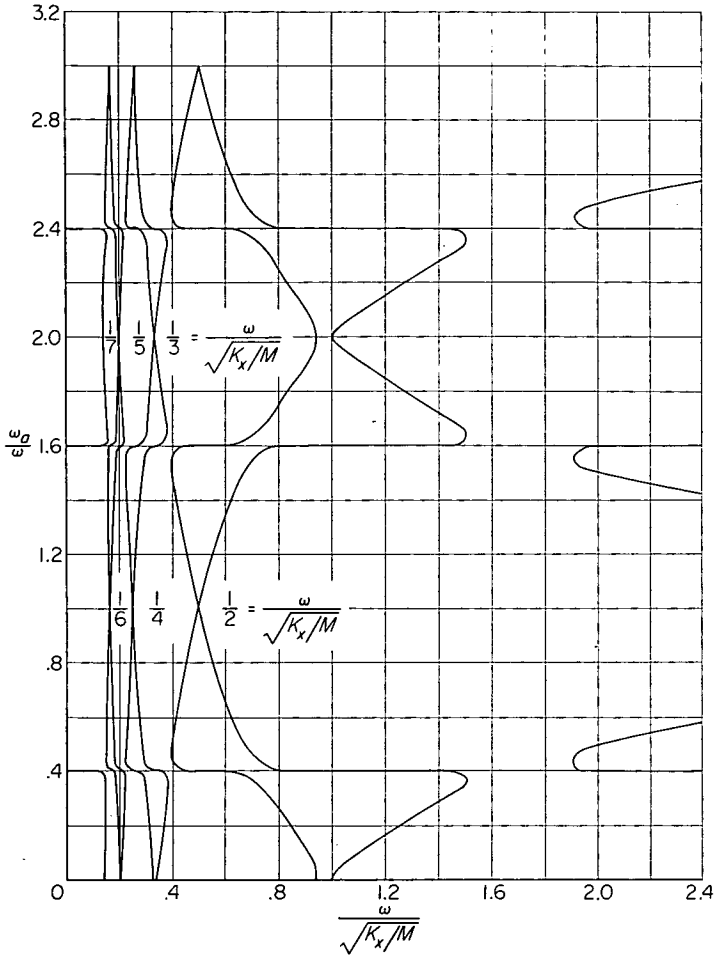

FIGURE III–7.—Typical pattern of response frequencies against rotor speed ω for a small value of the mass-ratio parameter Λ_3.

For comparison, the response frequencies of a two-blade rotor on equal supports ($K_y=K_x$) for the same set of parameters is shown in figure III–8. The frequencies were calculated from the formula in chapter II. Down to $\frac{\omega}{\sqrt{K_x/M}}=0.5$, this chart is very similar to figures III–4 and III–6. In addition it shows one range of rotational speed at which self-excited-vibration instability occurs, one range of rotational speed at which self-excited-whirling instability occurs, and one range of rotational speed at which a steady-force resonance speed occurs. Figure III–8 differs principally from the figures for $K_y\neq K_x$ in that it shows no further instability ranges at low values of ω.

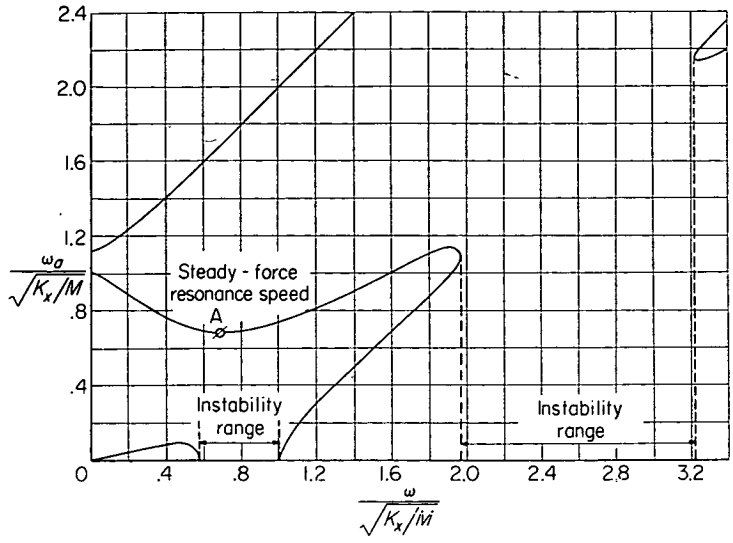

FIGURE III–8.—Response frequencies of a two-blade rotor on symmetric supports for $\Lambda_1=0.1$, $\Lambda_2=0$, $\Lambda_3=0.1$, and $K_y=K_x$.

In chapters I and II charts are presented giving the location of the self-excited-vibration instability range for various values of the parameters Λ_1, Λ_2, and Λ_3. A similar chart for the case of a two-blade rotor with $K_y=\infty$ is given in figure III–9. In using the chart, a straight line is drawn representing the variation of $\frac{\omega^2}{K_x/M}$ with the function $\frac{\Lambda_1\omega^2+\Lambda_2}{K_x/M}$. The intersections of this line with the appropriate Λ_3 curves give the beginning and end points of the instability range. The dashed line in figure III–9 indicates the stability ranges for the parameters of figure III–6.

Some observations concerning the relative location and extent of the various instability ranges in figures III–4, III–6, and III–8 appear to be applicable to a wide range of values of the parameters Λ_1, Λ_2, and Λ_3. Thus the self-excited-vibration instability range in the case of $K_y=K_x$ (fig. III–8) is wider (and hence the vibration probably more severe) than the corresponding ranges in the cases of $K_y=0$ and $K_y=\infty$. (See figs. III–4 and III–6.) Also, this instability range occurs at lower rotor speeds in the case of $K_y=\infty$ than it does in the cases of $K_y=K_x$ and $K_y=0$. The self-excited-whirling instability range is considerably narrower for $K_y=\infty$ than it is for the $K_y=K_x$ case, and it is still narrower in the $K_y=0$ case.

In the general case of $K_y\neq K_x$ the location and extent of the instability ranges can be found fairly accurately by considering the problem as the superposition of two problems, one of finding the significant rotor speeds referred to $\sqrt{K_x/M}$ as reference frequency with K_y assumed infinite and the other of finding the significant rotor speeds referred to $\sqrt{K_y/M}$ as reference frequency with K_x assumed zero. With the foregoing discussion as a guide, sufficiently accurate design information can be obtained without extensive calculations for each value of K_y/K_x encountered in practice.

EFFECT OF DAMPING

Although the effect of damping has not been examined mathematically, because complications would be introduced

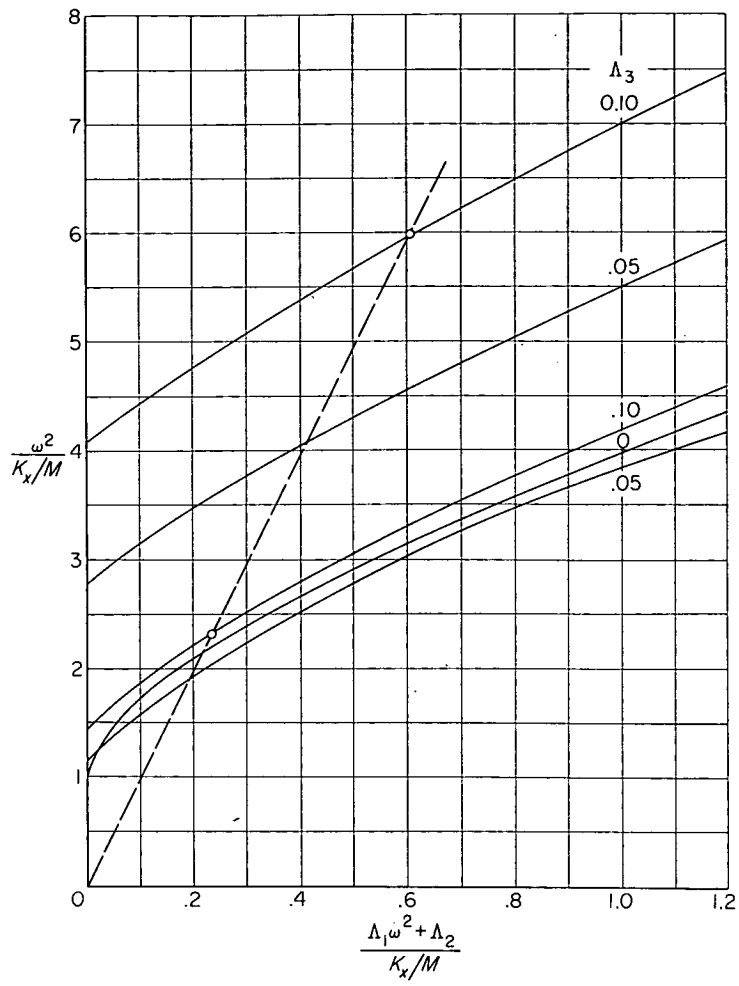

FIGURE III–9.—Chart giving position of the main instability range for $K_y=\infty$.

in the analysis, several inferences from the damping investigations in chapters I and II can probably be safely applied to the rotor-system studies in the present report. The numerous instability ranges occurring at low rotor speeds, which are very narrow and represent a mild type of instability, are probably completely eliminated by the presence of a slight amount of damping in the rotor system. The primary self-excited-vibration instability range can probably be narrowed and eliminated by introducing sufficient damping into both the rotor supports and the blade hinges.

APPLICATION TO DUAL ROTORS

It is easily shown that the analysis for the case of $K_y=\infty$ applies also to the case of a counterrotating rotor system consisting of two equal two-blade rotors revolving at equal speeds and acting equally upon the same flexible member. The rotors may be on the same shaft or on different shafts so long as the nonrotating flexible member is the same for both rotors. The supports, moreover, may have unequal stiffness in the X- and in the Y-directions, provided that the undeflected blade positions make equal angles with a principal stiffness axis.

The proof consists in showing that the energy expressions for the dual-rotating system can be separated into two independent sets of terms, each of which is of the same form as

for a single rotor with $K_y=\infty$. The resulting equations of motion will thus also be the same.

The separation is accomplished by introducing new variables

$$\xi_1=\frac{1}{2}(\theta_{1_{pos}}-\theta_{1_{neg}})$$

$$\xi_0=\frac{1}{2}(\theta_{0_{pos}}-\theta_{0_{neg}})$$

and

$$\eta_1=\frac{1}{2}(\theta_{1_{pos}}+\theta_{1_{neg}})$$

$$\eta_0=\frac{1}{2}(\theta_{0_{pos}}+\theta_{0_{neg}})$$

where the subscripts *pos* and *neg* refer to the θ's defined for the rotor turning in the positive direction and for the rotor turning in the opposite direction, respectively. The energy expressions become

$$\left.\begin{aligned} T=&\frac{1}{2}M\dot{x}^2+2m_b\left[-2\dot{x}(\dot{\xi}_1\sin\omega t+\omega\xi_1\cos\omega t)+\right.\\ &\left.\left(1+\frac{r^2}{b^2}\right)(\dot{\xi}_1^2+\dot{\xi}_0^2)-\frac{a}{b}\omega^2(\xi_1^2+\xi_0^2)\right]+\\ &\frac{1}{2}M\dot{y}^2+2m_b\left[2\dot{y}(\dot{\eta}_1\cos\omega t-\omega\eta_1\sin\omega t)+\right.\\ &\left.\left(1+\frac{r^2}{b^2}\right)(\dot{\eta}_1^2+\dot{\eta}_0^2)-\frac{a}{b}\omega^2(\eta_1^2+\eta_0^2)\right]\\ V=&\frac{2K_\beta}{b^2}(\xi_1^2+\xi_0^2+\eta_1^2+\eta_0^2)+\frac{1}{2}K_xx^2+\frac{1}{2}K_yy^2 \end{aligned}\right\} \quad (38)$$

where M is the total mass of the system ($M=m+4m_b$).

From equations (38) it is seen that ξ is coupled only with x and η is coupled only with y. Equations (38) yield equations of motion of the same form as equations (D2) and (D3).

The stability properties for the dual-rotating case are thus exactly the same as in the case of $K_y=\infty$ for the single-rotating two-blade rotor. In particular, figure III–9 can be used to find the location of the primary self-excited-vibration instability range. The value of Λ_3 for the dual-rotating rotor is defined as $\Lambda_3=\dfrac{2m_b}{(m+4m_b)\left(1+\dfrac{r^2}{b^2}\right)}$ rather than $\Lambda_3=\dfrac{m_b}{(m+2m_b)\left(1+\dfrac{r^2}{b^2}\right)}$ as for the single-rotating rotor. All other parameters are the same for both cases.

The quantity $\xi_1\sin\omega t$ can be interpreted physically as the x-component of the displacement of the center of gravity of the blades due to hinge deflections. The quantity $\eta_1\cos\omega t$ is the corresponding y-component. The separation of the variables means, physically, that the motion of the system can be separated into two independent modes, each of which involves linear motion of the supports along one of the principal stiffness axes.

Similarly, the stability of counterrotating rotor systems of six or more equal blades can be determined from the results of chapter I with $K_y=\infty$.

CONCLUSIONS

The following conclusions are indicated by the results of an investigation of the problem of vibration of a two-blade helicopter rotor on supports that have different stiffnesses along the two principal stiffness axes:

1. Many speed ranges are found in which self-excited oscillations can occur. These oscillations are of two types—self-excited vibration and self-excited whirling. There are also many speeds at which steady-force-resonance vibration may occur.

2. A stability chart which shows the self-excited vibration, self-excited whirling, and steady-force resonance speeds of the highest rotor speed for each support natural frequency for a two-blade rotor on anisotropic supports is similar in appearance to a stability chart for a two-blade rotor on isotropic supports. However, for the same rotor parameters, the instability regions are changed somewhat in position and extent.

3. Mild self-excited-whirling speed ranges exist at rotor speeds approximately ⅓, ⅕, ⅐, and so forth of each support natural frequency. Steady-force resonance speeds exist at approximately ½, ¼, ⅙, and so forth of each support frequency. Self-excited vibrations also occur at certain low rotor speeds. All these mild instability ranges are probably eliminated by the presence of moderate amounts of damping in the system.

4. A familiarity with typical results of limiting cases of the support-spring constants $K_y=\infty$, $K_y=K_x$, and $K_y=0$ should enable a designer to avoid extensive calculations of cases of unequal support stiffness. In the general case of unequal support stiffness, the location and extent of the instability ranges can be found fairly accurately by considering the problem as the superposition of two problems, one of finding significant rotor speeds referred to one support frequency $\sqrt{K_x/M}$ as reference frequency with K_y assumed infinite and the other of finding the significant rotor speeds referred to the other support frequency $\sqrt{K_y/M}$ as reference frequency with K_x assumed zero.

5. The analysis of a four-blade counterrotating rotor system in which the rotors cross along the principal stiffness axes of the rotor supports leads to the same equations as those considered for the special case of $K_y=\infty$, and the stability properties are given by the investigation of that special case.

APPENDIX A

SYMBOLS

a	radial position of vertical hinge
$a_{0,0}$, $a_{0,1}$, and so forth	elements of determinant defined in equation (16)
A_l, B_l, C_l	Fourier coefficients in equations (12)
$\overline{A}_l$, $\overline{B}_l$, $\overline{C}_l$	complex conjugates of A_l, B_l, and C_l, respectively
b	distance from vertical hinge to center of mass of blade
$C_n(\omega_a)$, $D_n(\omega_a)$, and so forth	minors of the determinate $\Delta_n(\omega_a)$
D	time-derivative operator, $\frac{d}{dt}$
$F(\omega_a)=\lim_{n\to\infty} F_n(\omega_a)$	
$F_n(\omega_a)=\frac{\Delta_n(\omega_a)}{k^{2n}}$	
j, n, s	integers
$J(\omega_a)$	function of $F(\omega_a)$ defined by equation (27)
$k=2\Lambda_3-1$	
$K(\omega_a/\omega)$	function of ω_a/ω defined in equation (29)
$K(0)$, $K(1)$, $K(1/2)$	functions defined by equations (30)
K_1, K_2	functions defined by equations (35)
K_x, K_y	spring constants of the rotor supports along the X- and Y-directions, respectively
K	average stiffness of rotor supports, $\frac{K_y+K_x}{2}$
$\Delta K=\frac{K_y-K_x}{2}$	
K_β	spring constant of blade self-centering spring
m	effective mass of rotor supports
m_b	mass of rotor blade
M	total mass of two-blade rotor system, $m+2m_b$
$P(t)$, $Q(t)$, $R(t)$	periodic functions defined in equations (11)
$\overline{P}(t)$, $\overline{Q}(t)$, $\overline{R}(t)$	complex conjugates of $P(t)$, $Q(t)$, and $R(t)$, respectively
Q	constant defined in equations (33)
r	radius of gyration of blade about center of mass
t	time
T	kinetic energy
V	potential energy
x, y	deflection of rotor hub measured in fixed X,Y-coordinate system
x_r,y_r	deflection of rotor hub measured in rotating X,Y-coordinate system
X, Y	fixed rectangular coordinate axes taken parallel to the principal stiffness directions of the rotor hub
z	complex position coordinate of the rotor hub in rectangular coordinate system rotating with angular velocity, x_r+iy_r
$\overline{z}$	complex conjugate of z, x_r-iy_r
β_1, β_2	angular hinge deflections of rotor blades, respectively
Δ	discriminant of cubic equation $x^3+bx^2+cx+d=0$
$\Delta(\omega_a)$	determinant of infinite order defined by equation (16)
$\Delta_n(\omega_a)$	determinant of order $6n-3$ formed from $\Delta(\omega_a)$
$\theta_0=\frac{b}{2}(\beta_1+\beta_2)$	
$\theta_1=\frac{b}{2}(\beta_1-\beta_2)$	
$\Lambda_1=\frac{a}{b\left(1+\frac{r^2}{b^2}\right)}$	
$\Lambda_2=\frac{K_\beta}{m_b b^2\left(1+\frac{r^2}{b^2}\right)}$	
$\Lambda_3=\frac{\mu}{2\left(1+\frac{r^2}{b^2}\right)}$	
ξ_1, ξ_0, η_1, η_0	blade variables for counterrotating rotor
μ	mass ratio, $\frac{2m_b}{M}$
ω	constant angular velocity of rotor
ω_a	characteristic exponent or natural frequency of rotor system as viewed in coordinates rotating at angular velocity ω
ω_{a_1}, ω_{a_2}, ω_{a_3}	principle values of ω_a

APPENDIX B

THE GENERAL EQUATIONS OF MOTION FOR TWO-BLADE ROTORS

By George W. Brooks

GENERAL CASE

The present chapter, although it generalizes the theory of ground vibrations of two-blade rotors by treating the case of anisotropic supports, does not consider the effects of damping. Chapter II treated the case of isotropic supports or equal pylon stiffness in all horizontal directions and included damping. The more general case is one which involves the treatment of the two-blade rotor with anisotropic supports and damping. The equations of motion for this case, derived in the complex coordinate notation of the present report, are given in this appendix.

The equations for the kinetic and potential energies of the rotor system are given by equations (5) and (6) of chapter III as follows:

$$T=\frac{M}{2}(\dot{z}+i\omega z)(\dot{\bar{z}}-i\omega\bar{z})+m_b\Big[(\dot{\bar{z}}-i\omega\bar{z})(i\dot{\theta}_1-\omega\theta_1)-(\dot{z}+i\omega z)(i\dot{\theta}_1+\omega\theta_1)+\Big(1+\frac{r^2}{b^2}\Big)(\dot{\theta}_0^2+\dot{\theta}_1^2)-\frac{a}{b}\omega^2(\theta_0^2+\theta_1^2)\Big] \tag{B1}$$

$$V=\frac{K}{2}z\bar{z}+\frac{K_\beta}{b^2}(\theta_0^2+\theta_1^2)-\frac{\Delta K}{4}(z^2e^{2i\omega t}+\bar{z}^2e^{-2i\omega t}) \tag{B2}$$

Two types of damping of the rotor system are assumed to exist: (1) damping in the rotor supports which is proportional to the translational velocity of the rotor hub and (2) damping of the rotation of the blades about the drag hinges. The damping dissipation function is then

$$F=\frac{B}{2}[\dot{z}\dot{\bar{z}}+\omega^2z\bar{z}+i\omega(z\dot{\bar{z}}-\bar{z}\dot{z})]+\frac{B_\beta}{b^2}(\dot{\theta}_0^2+\dot{\theta}_1^2) \tag{B3}$$

where B is the damping force per unit velocity of rotor-hub displacements and B_β is the damping torque per unit angular velocity of blade motion about the drag hinge.

By using the Lagrangian form of the equations of motion

$$\frac{d}{dt}\Big(\frac{\partial T}{\partial\dot{x}}\Big)-\frac{\partial T}{\partial x}+\frac{\partial F}{\partial\dot{x}}+\frac{\partial V}{\partial x}=0 \tag{B4}$$

and using as variables θ_0, $\bar{z}$, z, and θ_1, respectively, the following equations of motion for the rotor system are obtained:

$$(D^2+D\lambda_\beta+\omega^2\Lambda_1+\Lambda_2)\theta_0=0 \tag{B5}$$

$$\Big[(D+i\omega)^2+\lambda(D+i\omega)+\frac{K}{M}\Big]z-\frac{\Delta K}{M}\bar{z}e^{-2i\omega t}+i\mu(D+i\omega)^2\theta_1=0 \tag{B6}$$

$$-\frac{\Delta K}{M}ze^{2i\omega t}+\Big[(D-i\omega)^2+\lambda(D-i\omega)+\frac{K}{M}\Big]\bar{z}-i\mu(D-i\omega)^2\theta_1=0 \tag{B7}$$

$$(D+i\omega)^2z-(D-i\omega)^2\bar{z}+2i\Big(1+\frac{r^2}{b^2}\Big)(D^2+D\lambda_\beta+\Lambda_1\omega^2+\Lambda_2)\theta_1=0 \tag{B8}$$

where two additional combinations of parameters have been introduced, namely,

$$\lambda_\beta=\frac{B_\beta}{m_bb^2\Big(1+\frac{r^2}{b^2}\Big)}$$

and

$$\lambda=\frac{B}{M}$$

SPECIAL CASE—ZERO DAMPING

If damping is neglected, $\lambda_\beta=\lambda=0$ and the equations of motion, (B5) to (B8), reduce to

$$(D^2+\omega^2\Lambda_1+\Lambda_2)\theta_0=0 \tag{B9}$$

$$\Big[(D+i\omega)^2+\frac{K}{M}\Big]z-\frac{\Delta K}{M}\bar{z}e^{-2i\omega t}+i\mu(D+i\omega)^2\theta_1=0 \tag{B10}$$

$$-\frac{\Delta K}{M}ze^{2i\omega t}+\Big[(D-i\omega)^2+\frac{K}{M}\Big]\bar{z}-i\mu(D-i\omega)^2\theta_1=0 \tag{B11}$$

$$(D+i\omega)^2z-(D-i\omega)^2\bar{z}+2i\Big(1+\frac{r^2}{b^2}\Big)(D^2+\Lambda_1\omega^2+\Lambda_2)\theta_1=0 \tag{B12}$$

which are the equations of motion (eqs. (7) to (10)) for the case treated in the present chapter.

SPECIAL CASE OF ISOTROPIC SUPPORTS

If $K_x=K_y$, then $\Delta K=0$ and equations (B5) to (B8) reduce to

$$(D^2+D\lambda_\beta+\omega^2\Lambda_1+\Lambda_2)\theta_0=0 \tag{B13}$$

$$\Big[(D+i\omega)^2+\lambda(D+i\omega)+\frac{K}{M}\Big]z+i\mu(D+i\omega)^2\theta_1=0 \tag{B14}$$

$$\Big[(D-i\omega)^2+\lambda(D-i\omega)+\frac{K}{M}\Big]\bar{z}-i\mu(D-i\omega)^2\theta_1=0 \tag{B15}$$

$$(D+i\omega)^2z-(D-i\omega)^2\bar{z}+2i\Big(1+\frac{r^2}{b^2}\Big)(D^2+D\lambda_\beta+\Lambda_1\omega^2+\Lambda_2)\theta_1=0 \tag{B16}$$

Equation (B13) involves only the in-phase motion of the blades, can be solved separately, and will not be further considered here. If z and $\bar{z}$ are expressed in the equivalent notations $x+iy$ and $x-iy$, respectively, and equations (B14) and (B15) are added together, equation (1) of chapter II is obtained. Equation (2) of chapter II is obtained by direct substitution and equation (3) is obtained by subtraction of equation (B15) from equation (B14). Thus the equations of motion for the case treated in chapter II as well as for the case treated in the present report are shown to be special cases of the general equations of motion, equations (B5) to (B8), for a rotor mounted on anisotropic supports with hub and blade-hinge damping.

APPENDIX C

DERIVATION OF THE CONVERGENCE FACTOR FOR $K(0)$

A convergence factor for $K(0)$ is found by finding a simpler function G_n that changes with n in nearly the same way as $K(0)_n$. Then, if G denotes $\lim_{n\to\infty} G_n$, the expression

$$\frac{K(0)_n G}{G_n}$$

for a given value of n is a better approximation to $K(0)$ than is $K(0)_n$ alone. A suitable form for G_n is found from a study of the behavior of $K(0)_n$ for large values of n.

The behavior of $K(0)_n$ is studied by first observing the behavior of $C_n(0)$ and $L_n(0)$ for large values of n and then inferring the behavior of $K(0)_n$ from the appropriate relation of equations (32). In the discussion of equations (22) it was shown that, as n becomes infinite, the ratio C_{n+1}/C_n approaches the value k (eq. (22a)). A closer approximation to the value of this ratio can be written as

$$\frac{C_{n+1}(0)}{C_n(0)} = k\left(1 - \frac{P}{n} - \frac{Q}{4n^2}\right) \tag{C1}$$

where P and Q are constants to be determined.

Equations (19) become, for $\omega_a = 0$,

$$\left.\begin{aligned} C_{n+1}(0) &= \left[-1 + \frac{K/M}{(2n+1)^2\omega^2}\right] D_n(0) - \Lambda_3\left(\frac{2n+1}{2n}\right)^2 E_n(0) \\ D_{n+1}(0) &= \left[-1 + \frac{\Lambda_1\omega^2 + \Lambda_2}{(2n)^2\omega^2}\right] E_n(0) - \Lambda_3\left(\frac{2n-1}{2n}\right)^2 C_n(0) \\ E_{n+1}(0) &= \left[-1 + \frac{K/M}{(2n-1)^2\omega^2}\right] C_n(0) \end{aligned}\right\} \tag{C2}$$

where the second term in the equation for $E_n(\omega_a)$ in equations (19) has been neglected as being of higher order in powers of $1/n$ than the terms retained. Eliminating $E(0)$ and $D(0)$ from the equations (C2) results in

$$\frac{C_{n+1}(0)}{C_n(0)} = \left[-1 + \frac{K/M}{(2n+1)^2\omega^2}\right]\left[-1 + \frac{\Lambda_1\omega^2 + \Lambda_2}{(2n)^2\omega^2}\right]\left[-1 + \frac{K/M}{(2n-1)^2\omega^2}\right] - \Lambda_3\left\{\left(\frac{2n-1}{2n}\right)^2\left[-1 + \frac{K/M}{(2n+1)^2\omega^2}\right] + \left(\frac{2n+1}{2n}\right)^2\left[-1 + \frac{K/M}{(2n-1)^2\omega^2}\right]\right\}$$

Upon expanding this expression into powers of $1/n$ and retaining terms up to and including those in $1/n^2$

$$\frac{C_{n+1}(0)}{C_n(0)} = -1 + 2\Lambda_3 - \frac{1}{(2n)^2}\left[-\frac{2\frac{K}{M} + \Lambda_1\omega^2 + \Lambda_2}{\omega^2} + 2\Lambda_3\left(\frac{K/M}{\omega^2} - 1\right)\right] \tag{C3}$$

Comparing equation (C3) with equation (C1) results in

$$P = 0$$

$$Q = \frac{2\frac{K}{M}(1-\Lambda_3) + \Lambda_1\omega^2 + \Lambda_2 + 2\Lambda_3\omega^2}{\omega^2(1-2\Lambda_3)}$$

Similarly

$$\frac{L_{n+1}(0)}{L_n(0)} = k\left[1 - \frac{Q}{(2n)^2}\right]$$

Therefore, from equations (32)

$$\frac{K(0)_{n+1}}{K(0)_n} = \left(1 - \frac{Q}{4n^2}\right)^2$$

Hence, an approximate value of $K(0)$ can be obtained from

$$\frac{K(0)}{K(0)_n} \equiv \frac{K(0)_{n+1}}{K(0)_n}\frac{K(0)_{n+2}}{K(0)_{n+1}}\frac{K(0)_{n+3}}{K(0)_{n+2}}\cdots$$

$$\approx \prod_{j=n}^{\infty}\left(1 - \frac{Q}{4j^2}\right)^2 = \frac{\sin^2\left(\frac{\pi\sqrt{Q}}{2}\right)}{\frac{\pi^2 Q}{4}\prod_{j=1}^{n-1}\left(1 - \frac{Q}{4j^2}\right)^2} \tag{C4}$$

The right-hand side of equation (C4), which is seen to be of the form G/G_n, is a convergence factor. This convergence factor is the one used in equations (33).

APPENDIX D

MATHEMATICAL ANALYSIS FOR THE CASE OF $K_y = \infty$

In terms of the variables θ_0, θ_1, and x, the expressions for the kinetic and potential energy are

$$T=\frac{M}{2}\dot{x}^2+m_b\left[\left(1+\frac{r^2}{b^2}\right)(\dot{\theta}_0^2+\dot{\theta}_1^2)-\omega^2\frac{a}{b}(\theta_0^2+\theta_1^2)-2\dot{x}(\theta_1\sin\omega t+\omega\theta_1\cos\omega t)\right]$$

$$V=\frac{K_x}{2}x^2+\frac{K_\beta}{b^2}(\theta_0^2+\theta_1^2)$$

The three equations of motion are

$$\ddot{\theta}_0+(\omega^2\Lambda_1+\Lambda_2)\theta_0=0 \tag{D1}$$

$$\ddot{x}+\frac{K_x}{M}x-\mu\frac{d^2}{dt^2}(\theta_1\sin\omega t)=0 \tag{D2}$$

$$-\frac{1}{1+\frac{r^2}{b^2}}\ddot{x}\sin\omega t+\ddot{\theta}_1+(\omega^2\Lambda_1+\Lambda_2)\theta_1=0 \tag{D3}$$

Equation (D1) is identical with equation (7). Equations (D2) and (D3) constitute a system of two linear second-order differential equations with periodic coefficients.

Equations (D2) and (D3) are satisfied by solutions of the form

$$\left.\begin{aligned} x&=\sum_{l=-\infty}^{\infty}A_l e^{i(\omega_a+l\omega)t}\\ \theta_1&=\sum_{l=-\infty}^{\infty}B_{l+1}e^{i[\omega_a+(l+1)\omega]t}\end{aligned}\right\} \tag{D4}$$

where l takes on all odd integral values and A_l and B_{l+1} are constants to be determined along with the two principal values of ω_a (ω_{a_1} and ω_{a_2}). The constants A_l and B_{l+1} in equations (D4) are, of course, different from those in equations (12).

Combining equations (D4) with equations (D2) and (D3) and setting the coefficients of the various exponential time factors equal to zero give

$$\left[-1+\frac{K_x/M}{(\omega_a+l\omega)^2}\right]A_l-\frac{\mu}{2i}(-B_{l-1}+B_{l+1})=0$$

$$-\frac{1}{2i\left(1+\frac{r^2}{b^2}\right)}\left\{-\left[\frac{\omega_a+(l-2)\omega}{\omega_a+(l-1)\omega}\right]A_{l-2}+\left[\frac{\omega_a+l\omega}{\omega_a+(l-1)\omega}\right]^2A_l\right\}+\left\{-1+\frac{\omega^2\Lambda_1+\Lambda_2}{[\omega_a+(l-1)\omega]^2}\right\}B_{l-1}=0$$

The determinantal equation is then equal to

$$\begin{vmatrix}
\cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \\
\cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \\
\cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \\
\cdots & a_{-3,-3} & a_{-3,-2} & 0 & 0 & 0 & 0 & 0 & \cdots \\
\cdots & a_{-2,-3} & a_{-2,-2} & a_{-2,-1} & 0 & 0 & 0 & 0 & \cdots \\
\cdots & 0 & a_{-1,-2} & a_{-1,-1} & a_{-1,0} & 0 & 0 & 0 & \cdots \\
\cdots & 0 & 0 & a_{0,-1} & a_{0,0} & a_{0,1} & 0 & 0 & \cdots \\
\cdots & 0 & 0 & 0 & a_{1,0} & a_{1,1} & a_{1,2} & 0 & \cdots \\
\cdots & 0 & 0 & 0 & 0 & a_{2,1} & a_{2,2} & a_{2,3} & \cdots \\
\cdots & 0 & 0 & 0 & 0 & 0 & a_{3,2} & a_{3,3} & \cdots \\
 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \\
 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \\
 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot &
\end{vmatrix} = \Delta(\omega_a)=0$$

where

$$a_{-3,-3}=-1+\frac{K_x/M}{(\omega_a-3\omega)^2} \qquad a_{0,0}=-1+\frac{\Lambda_1\omega^2+\Lambda_2}{\omega_a^2}$$

$$a_{-3,-2}=\frac{\Lambda_3}{2} \qquad a_{0,1}=\left(\frac{\omega_a+\omega}{\omega_a}\right)^2$$

$$a_{-2,-3}=\left(\frac{\omega_a-3\omega}{\omega_a-2\omega}\right)^2 \qquad a_{1,0}=\frac{\Lambda_3}{2}$$

$$a_{-2,-2}=-1+\frac{\omega^2\Lambda_1+\Lambda_2}{(\omega_a-2\omega)^2} \qquad a_{1,1}=-1+\frac{K_x/M}{(\omega_a+\omega)^2}$$

$$a_{-2,-1}=\left(\frac{\omega_a-\omega}{\omega_a-2\omega}\right)^2 \qquad a_{1,2}=\frac{\Lambda_3}{2}$$

$$a_{-1,-2}=\frac{\Lambda_3}{2} \qquad a_{2,1}=\left(\frac{\omega_a+\omega}{\omega_a+2\omega}\right)^2$$

$$a_{-1,-1}=-1+\frac{K_x/M}{(\omega_a-\omega)^2} \qquad a_{2,2}=-1+\frac{\omega^2\Lambda_1+\Lambda_2}{(\omega_a+2\omega)^2}$$

$$a_{-1,0}=\frac{\Lambda_3}{2} \qquad a_{2,3}=\frac{\omega_a+3\omega}{(\omega_a+2\omega)^2}$$

$$a_{0,-1}=\left(\frac{\omega_a-\omega}{\omega_a}\right)^2 \qquad a_{3,2}=\frac{\Lambda_3}{2}$$

$$a_{3,3}=-1+\frac{K_x/M}{(\omega_a+3\omega)^2}$$

The term $-1+\frac{\omega^2\Lambda_1+\Lambda_2}{\omega_a^2}$ will be taken as the origin of the determinant.

Define $\Delta_n(\omega_a)$ as the determinant of order $4n-1$ formed by taking a square array from $\Delta(\omega_a)$ centered on the origin. Then

$$\Delta(\omega_a)=\lim_{n\to\infty}\Delta_n(\omega_a)$$

Define auxiliary determinants from $\Delta_n(\omega_a)$ as follows:

$C_n(\omega_a)$ determinant of order $2n-1$ consisting of the terms to the right of and below the origin term

$D_n(\omega_a)$ determinant of order $2n-2$ obtained from $C_n(\omega_a)$ by omitting its last row and column

$M_n(\omega_a)$ determinant of order $2n-2$ obtained from $C_n(\omega_a)$ by omitting its first row and column

$N_n(\omega_a)$ determinant of order $2n-3$ obtained from $D_n(\omega_a)$ by omitting its first row and column

The determinants $C_n(\omega_a)$ and $D_n(\omega_a)$ satisfy the following recurrence relations:

$$\left.\begin{aligned} C_n(\omega_a)&=\left\{-1+\frac{K_x/M}{[\omega_a+(2n-1)\omega]^2}\right\}D_n(\omega_a)-\\ &\quad\frac{\Lambda_3}{2}\left[\frac{\omega_a+(2n-1)\omega}{\omega_a+(2n-2)\omega}\right]^2 C_{n-1}(\omega_a)\\ D_n(\omega_a)&=\left\{-1+\frac{\omega^2\Lambda_1+\Lambda_2}{[\omega_a+(2n-2)\omega]^2}\right\}C_{n-1}(\omega_a)-\\ &\quad\frac{\Lambda_3}{2}\left[\frac{\omega_a+(2n-3)\omega}{\omega_a+(2n-2)\omega}\right]^2 D_{n-1}(\omega_1) \end{aligned}\right\} \quad (D5)$$

The recurrence relations (eqs. (D5)) are also satisfied by $M_n(\omega_a)$ and $N_n(\omega_a)$, with M and N replacing C and D respectively. The initial values are

$$C_1(\omega_a)=-1+\frac{K_x/M}{(\omega_a+\omega)^2}$$

$$D_2(\omega_a)=\left[1-\frac{K_x/M}{(\omega_a+\omega)^2}\right]\left[1-\frac{\omega^2\Lambda_1+\Lambda_2}{(\omega_a+2\omega)^2}\right]-\frac{\Lambda_3}{2}\left(\frac{\omega_a+\omega}{\omega_a+2\omega}\right)^2$$

$$N_2(\omega_a)=-1+\frac{\omega^2\Lambda_1+\Lambda_2}{(\omega_a+2\omega)^2}$$

$$M_2(\omega_a)=\left[1-\frac{\omega^2\Lambda_1+\Lambda_2}{(\omega_a+2\omega)^2}\right]\left[1-\frac{K_x/M}{(\omega_a+3\omega)^2}\right]-\frac{\Lambda_3}{2}\left(\frac{\omega_a+3\omega}{\omega_a+2\omega}\right)^2$$

Expanding $\Delta_n(\omega_a)$ in terms of the elements of the column containing the origin gives

$$\Delta_n(\omega_a)=\left(-1+\frac{\omega^2\Lambda_1+\Lambda_2}{\omega_a^2}\right)C_n(-\omega_a)C_n(\omega_a)-$$
$$\frac{\Lambda_3}{2}\left[\left(\frac{\omega_a-\omega}{\omega_a}\right)^2 C_n(\omega_a)M_n(-\omega_a)-\left(\frac{\omega_a+\omega}{\omega_a}\right)^2 C_n(-\omega_a)M_n(\omega_a)\right]$$

As n becomes infinite, or as ω_a becomes infinite, the recurrence relations (eqs. (D5)) approach

$$\left.\begin{aligned} C_n&=-D_n-\frac{\Lambda_3}{2}C_{n-1}\\ D_n&=-C_{n-1}-\frac{\Lambda_3}{2}D_{n-1} \end{aligned}\right\} \quad (D6)$$

Equations (D6) are satisfied by a solution of the form

$$\left.\begin{aligned} C_n&=Ck^n\\ D_n&=-C\left(k+\frac{\Lambda_3}{2}\right)k^{n-1} \end{aligned}\right\} \quad (D7)$$

where k satisfies the equation

$$k^2-(1-\Lambda_3)k+\frac{\Lambda_3^2}{4}=0 \quad (D8)$$

The larger root of equation (D8) will be denoted by k and the smaller root by k_1. Although the complete solution of equation (D6) is of the form

$$C_n=Ck^n+C'k_1^n$$

for large values of n the term in k_1 becomes negligible compared with the term in k.

With the same values for k, M_n and N_n will have solutions similar to those of equations (D7). Thus as n becomes infinite $\Delta_n(\omega_a)$ will vary as the quantity k^{2n}.

Define the function

$$F(\omega_a)=\lim_{n\to\infty}F_n(\omega_a)=\lim_{n\to\infty}\frac{\Delta_n(\omega_a)}{k^{2n}}$$

The function $F(\omega_a)$ is periodic in ω_a of period 2ω, has roots

$\pm(\omega_{a_1}\pm 2s\omega)$, $\pm(\omega_{a_2}\pm 2s\omega)$, and second-order poles at $(\omega_a\pm s\omega)$ for all integral values of s. Furthermore, $F(\omega_a)$ approaches the limit

$$E=\lim_{\omega_a\to\infty} F(\omega_a)=\lim_{n\to\infty} F_n(\infty)$$

$$=\lim_{n\to\infty}\frac{C_{2n}(\infty)}{k^{2n}}=\frac{k^2}{k_1^2-k^2}$$

as ω_a becomes infinite in a direction other than along the real axis.

Form the function

$$J(\omega_a)=F(\omega_a)\frac{\sin^2\left(\frac{\pi\omega_a}{\omega}\right)}{\left[\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)-\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\right]\left[\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)-\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)\right]} \tag{D9}$$

The function $J(\omega_a)$ is an analytic function of ω_a everywhere. Hence, by Liouville's theorem, $J(\omega_a)$ is a constant. By letting $\omega_a\to+\infty$ along the imaginary axis, it is seen that $J(\omega_a)=-4E$.

Substituting $-4E$ for $J(\omega_a)$ into equation (D9) results in

$$\lim_{n\to\infty}\frac{\Delta_n(\omega_a)}{k^{2n}}=F(\omega_a)$$

$$=-4E\frac{\left[\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)-\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\right]\left[\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)-\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)\right]}{\sin^2\left(\frac{\pi\omega_a}{\omega}\right)}$$

Introducing K functions defined similarly to those used for the case $K_y=0$ gives

$$\left.\begin{aligned} K_1&\doteq\sin^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\sin^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)\\ &=\lim_{\omega_a\to 0}\left[\frac{\sin^2\left(\frac{\pi\omega_a}{\omega}\right)F(\omega_a)}{-4E}\right]\\ K_2&=\cos^2\left(\frac{\pi\omega_{a_1}}{2\omega}\right)\cos^2\left(\frac{\pi\omega_{a_2}}{2\omega}\right)\\ &=\lim_{\omega_a\to\omega}\left[\frac{\sin^2\left(\frac{\pi\omega_a}{2\omega}\right)F(\omega_a)}{-4E}\right] \end{aligned}\right\} \tag{D10}$$

Carrying out the limit processes indicated in equations (D10) gives

$$K_1=\lim_{n\to\infty}K_{1_n}$$

$$=\lim_{n\to\infty}\left[\frac{\pi^2(\omega^2\Lambda_1+\Lambda_2)C_n^2(0)-\Lambda_3\pi^2\omega^2C_n(0)N_n(0)}{-4\omega^2C_{2n}(\infty)}\right]$$

$$K_2=\lim_{n\to\infty}K_{2_n}$$

$$=\lim_{n\to\infty}\left[\frac{\pi^2\frac{K_z}{M}kN_n^2(-\omega)}{-4\omega^2C_{2n}(\infty)}\right]$$

Finally, upon introducing appropriate convergence factors, the following quantities needed in equations (36) are obtained:

$$K_1=\lim_{n\to\infty}\left[\frac{K_{1_n}\sin^2\left(\frac{\pi R}{2}\right)}{\frac{\pi^2R^2}{4}\prod_{j=1}^{n}\left(1-\frac{R^2}{4j^2}\right)^2}\right]$$

$$K_2=\lim_{n\to\infty}\left\{\frac{K_{2_n}\cos^2\left(\frac{\pi R}{2}\right)}{\prod_{j=1}^{n}\left[1-\frac{R^2}{(2j-1)^2}\right]^2}\right\}$$

where

$$R^2=\frac{\frac{K_z}{M}+\omega^2\Lambda_1+\Lambda_2+\omega^2(1+k_1-k)}{\omega^2(k-k_1)}$$

REPORT 1352

EFFECT OF FUEL VARIABLES ON CARBON FORMATION IN TURBOJET-ENGINE COMBUSTORS[1]

By Edmund R. Jonash, Jerrold D. Wear, and William P. Cook

SUMMARY

The effects of fuel properties and of a number of fuel additives on combustion-chamber carbon deposition and exhaust-gas smoke formation were investigated in a single tubular turbojet-engine combustor. Limited tests were conducted with a number of the fuels in several full-scale turbojet engines to verify single-combustor data.

At operating conditions simulating an engine with a compressor pressure ratio of 4 at an altitude of 20,000 feet and zero flight speed (condition A), carbon deposits and exhaust-gas smoke densities in the single combustor correlated with three empirical fuel factors: smoke-volatility index, smoke point, and NACA K factor (function of distillation characteristics and hydrogen-carbon ratio). The best correlations of deposits were obtained with smoke point and NACA K factor. At a condition of higher inlet air pressure and temperature simulating an engine with a compressor pressure ratio of 7 at sea level and a flight Mach number of 0.87 (condition B), the deposits and smoke densities did not satisfactorily correlate with any of the fuel factors considered. Further, only the data obtained at condition A correlated with limited full-scale-engine deposit data obtained with the same fuels. Deposits obtained at the higher pressure and temperature were considerably less uniform, and it is likely that large formations broke off the combustor walls during the test runs.

Carbon deposits in the single combustor were significantly reduced at condition A by the addition of organo-metallic compounds, commercial fuel additives that usually contained organo-metallic compounds, and oxygen-bearing compounds. Organo-metallic compounds, particularly those containing lead or iron, were most effective: dicyclopentadienyliron reduced deposits of a base fuel as much as 80 percent. The relative effectiveness of the additives depended on the properties of the base fuel. None of the additives significantly affected exhaust-gas smoke concentration.

INTRODUCTION

Carbon deposition in the combustors of turbojet engines constitutes an important operational problem, since such deposition can impair (1) combustion performance by affecting air and fuel distribution, (2) starting performance by fouling ignition electrodes, and (3) liner durability by causing liner cracking and warping. The presence of carbon as smoke in the exhaust gases of turbojet engines is less important; it does not, in general, impair engine performance, but it may be objectionable from a tactical or a nuisance standpoint. Deposits and smoke may be minimized by proper combustor design and by selection of fuel properties. However, presently known remedies are not completely compatible with other combustor performance requirements and with fuel availability. Experiments aimed toward developing means of controlling carbon formation by limiting fuel characteristics and by using fuel additives are reported herein.

Many investigations have been conducted in both small-scale and full-scale combustors in an effort to develop a satisfactory means of predicting the carbon-forming propensity of turbojet fuels from results of simple laboratory fuels tests. Much of this work is summarized in reference 1. Approximate relations were found between deposits and several empirical factors derived from fuel properties. Smoke point, measured with a simple laboratory wick lamp, and NACA K factor, an empirical function of distillation characteristics and hydrogen-carbon ratio, gave the most accurate predictions of deposits for the data presented in reference 1. A "smoke-volatility index" (*SVI*) is currently included in military procurement specifications to limit carbon-deposition tendencies of jet fuels. This index, which is a function of the distillation characteristics and smoke point of the fuel, is easily determined and also has shown a satisfactory degree of correlation with deposits. The relation between smoke-volatility index and carbon formation in turbojet combustors with jet fuels varying widely in physical and chemical properties is examined herein. Also the relations obtained with the smoke-volatility index are compared with those obtained with smoke point and the NACA K factor.

Twenty fuels were tested in a single tubular turbojet combustor operated at conditions simulating an engine with a compressor pressure ratio of 4 at zero flight speed and an altitude of 20,000 feet. The fuels included a number of production JP–3 and JP–4 fuel samples and a number of fuels specially blended to provide wide variations in "fuel quality." In order to examine the effect of operating conditions on deposition, and hence on the general applicability of the fuel factors, six fuels were tested in the same combustor at conditions simulating operation in an engine with a compressor pressure ratio of 7 at a flight Mach number of 0.87 at sea level. The data obtained are generally limited to carbon deposition in the combustion chamber; however, some information is included on exhaust-gas smoke concentration with several of the fuels. Limited data obtained with some of the fuels in several full-scale engines are presented and compared with the single-combustor results.

Preceding Page Blank

The use of a fuel additive capable of markedly reducing carbon deposition in combustion chambers would allow wider variations in jet fuel properties and hence greater fuel availability. A large variety of fuel additives has been suggested for preventing and removing carbon deposits in commercial furnaces and diesel engines. Several investigations in turbojet combustors have indicated at least moderate success with materials such as amyl nitrate, thiophene, and organo-metallic compounds (refs. 2 to 8). Carbon-deposition studies with some of the more promising fuel additives were conducted at the NACA Lewis laboratory, and the results of these studies are presented herein. The additives included four organo-metallic compounds, ten commercial fuel additives (most of which contained organo-metallic compounds), and nine oxygen-bearing compounds. The additives were blended, in most cases, with a No. 2 furnace oil. Limited data were also obtained with some of the additives blended with JP–3 and JP–4 fuels. Several additives were examined in more than one concentration to determine the effect of concentration. All experiments were conducted at the conditions simulating an engine with a pressure ratio of 4. The exhaust-gas smoke concentration was also measured.

FUELS AND ADDITIVES

The fuels used in this investigation are described in table I. They are designated by NACA-assigned numbers. Engine operating experience with fuels containing small concentrations of high-boiling aromatic hydrocarbons has shown that these components contribute markedly to carbon deposition.

TABLE I.—FUELS USED IN INVESTIGATION

Fuel (a)	Fuel type (b)	Description
50–264	JP–3	"Low quality"
51–353	JP–3	90 Weight-percent 50–264 plus 10 weight-percent triisopropylbenzene; high-boiling single-ring aromatic blend
52–50	JP–3	90 Weight-percent 50–264 plus 10 weight-percent of mixture of α- and β-monomethylnaphthalene; high-boiling dycyclic aromatic blend
52–32	JP–4	60 Weight-percent 50–264 plus 40 weight-percent triisopropylbenzene; high-boiling single-ring aromatic blend with H–C ratio very similar to 52–50
52–53	JP–4	"High-quality"
52–105	JP–4	90 Weight-percent 52–53 plus 10 weight-percent of mixture of α- and β-monomethylnaphthalene; high-boiling dicyclic aromatic blend; base fuel for additive tests
52–117	JP–4	"High quality"; blended from high-purity isoparaffinic hydrocarbons
52–118	JP–4	52–117 With low-boiling aromatic substituted for 15 percent isoparaffins of corresponding boiling range
52–119	JP–4	52–118 With polyethylbenzene substituted for isoparaffins of corresponding boiling range
52–120	JP–4	52–118 With methylnaphthalene substituted for isoparaffins of corresponding boiling range
52–166	JP–3	"Low quality"
52–28	JP–4	Used in single-combustor and full-scale-engine tests
52–30	JP–3	
52–76	JP–4	
54–108	JP–4	
54–109	JP–4	
54–110	JP–4	
54–111	JP–4	
52–288	JP–4	"High quality"
53–49	JP–4	
54–41	JP–4	"Low quality"; base fuel for additive tests
49–162	JP–3	Base fuels for additive tests
49–224	High-boiling aromatic	
53–193	Furnace oils	
55–89		

[a] NACA designation.
[b] "Fuel type" refers only to volatility characteristics. Many of these fuels do not fall within MIL–F–5624B specifications in all respects.

The effects of high-boiling single-ring and dicyclic aromatic hydrocarbons on deposition were investigated with fuels 50–264, 51–353, 52–32, 52–50, 52–53, and 52–105 prepared at the NACA Lewis laboratory. The effects of low- and high-boiling single-ring aromatics and high-boiling dicyclic aromatics on deposition were investigated with fuels 52–117, 52–118, 52–119, and 52–120, which were distributed by the Coordinating Research Council as a part of a cooperative research program on carbon deposition. Fuels 54–108, 54–109, 54–110, and 54–111 were similarly distributed by the Coordinating Research Council to study the reliability of the smoke-volatility index as a measure of the carbon-forming propensity of JP–4 fuels. Most of the remaining fuels were JP–3 and JP–4 fuels of both high and low quality with respect to carbon-forming tendencies; many were obtained from refinery production batches. Fuels 49–162, 49–224, 53–193, and 55–89 were base fuels for most of the additive tests; 52–105 and 54–41 were also used as base fuels in some of these tests.

Fuel 52–30 (JP–3) is indicated herein as a fuel tested in both the single combustor and in a full-scale engine. Actually, the full-scale test was conducted with two different batches of JP–3 fuel. Fuel 52–30 was blended from these two batches, in the same proportions as used in the full-scale engine. The components of the blend had similar physical and chemical properties.

Analyses of the fuels examined are presented in table II. Smoke-volatility index (*SVI*) is defined as

$$SVI = \text{Smoke point} + 0.42(\text{vol.-percent fuel boiling under } 400^\circ \text{ F})$$

Military fuel procurement specification MIL–F–5624B, which contains an *SVI* limitation, requires that smoke point be determined by method 2107 of specification VV–L–791. Most of the fuels listed in table II were tested before the acceptance of this method. The smoke points reported for these fuels were measured with the modified Davis factor lamp described in reference 9. The two test methods agree reasonably well, and no distinction is made between them in this report.

The NACA *K* factor (table II) is a function of the volatility and hydrogen-carbon ratio of the fuel:

$$K = (t+600)(0.7)\,\frac{(\text{H/C})-0.207}{(\text{H/C})-0.259}$$

where t is the volumetric average boiling temperature (°F), and H/C is the hydrogen-carbon ratio. Values of the *K* factor were estimated from an enlargement of figure 3 of reference 1.

Although the mechanism by which additives might reduce carbon formation is not understood, it has been suggested that the presence of an oxygen-bearing compound in the area where carbon is formed may result in oxidation of the carbon. Some success has been obtained in experiments with alkyl nitrates, particularly amyl nitrate (ref. 5). Other means of providing an oxygen-bearing compound would be fuel-soluble organo-metallic compounds, which, when burned, will produce a metallic oxide. The additives listed in table

526507—60——21

[1] Composition is result of qualitative spectroscopic analyses.

III that are of known composition were chosen to represent a variety of oxygen-bearing organic materials, including four alkyl nitrates, an alkyl nitrite, two nitro-compounds, a peroxide, an ether, and a variety of organo-metallic compounds of iron, cadmium, or lead. Two different compounds of lead were tested, lead naphthenate and tetraethyl lead. The commercial additives listed in table III varied in their intended application. They included diesel fuel additives, gasoline additives, and oil furnace cleaners. None were developed specifically for turbojet combustor application, but all were intended to remove or retard carbon and soot formation resulting from the combustion of low-grade fuels. In most cases these additives contained only a small concentration of an active ingredient in a fuel-soluble carrier. They were examined spectroscopically to determine their principal elemental constituents.

The additive concentrations investigated (table III) were based on published and unpublished test data obtained from other laboratories and on recommendations by the manufacturers of the additives. In several cases a number of

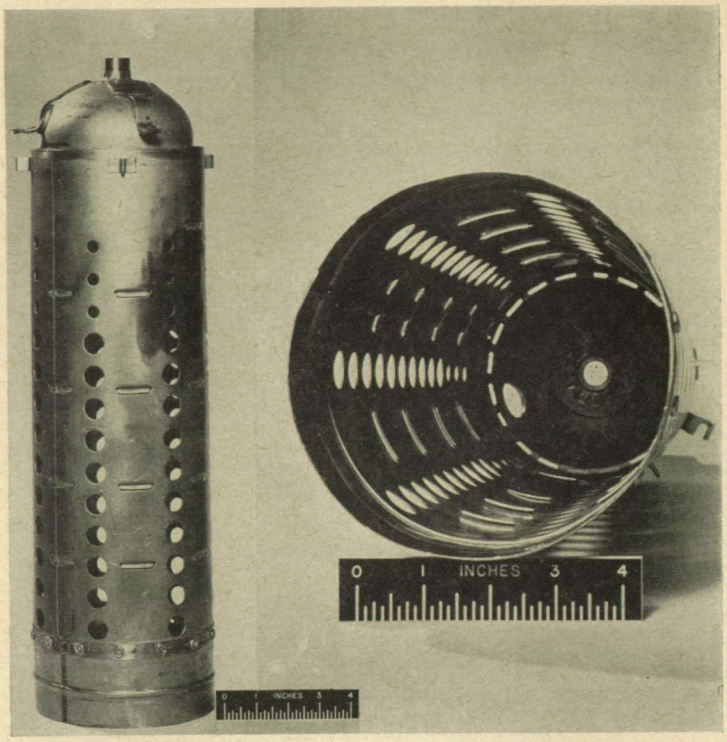

FIGURE 1.—Liner and dome of J33 single combustor used in carbon-deposition investigation.

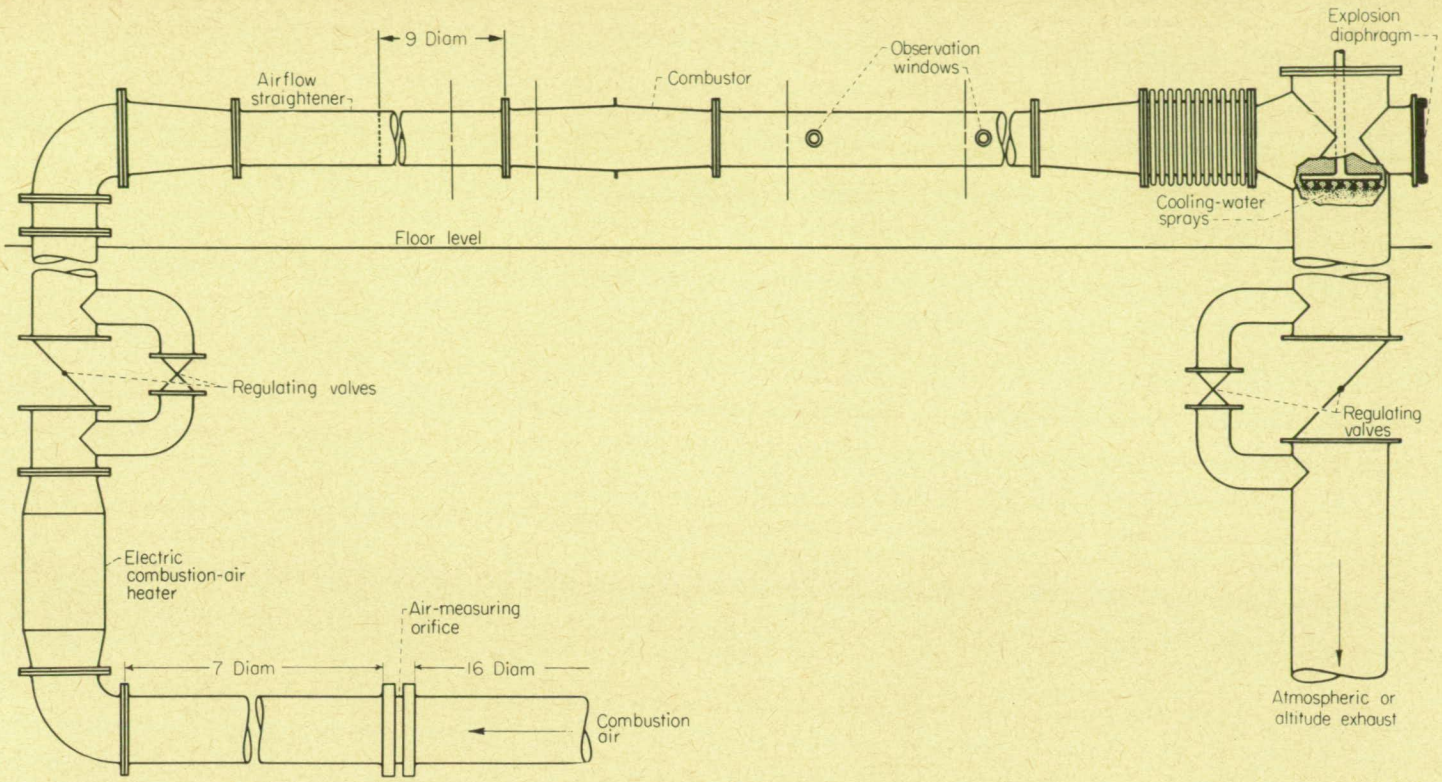
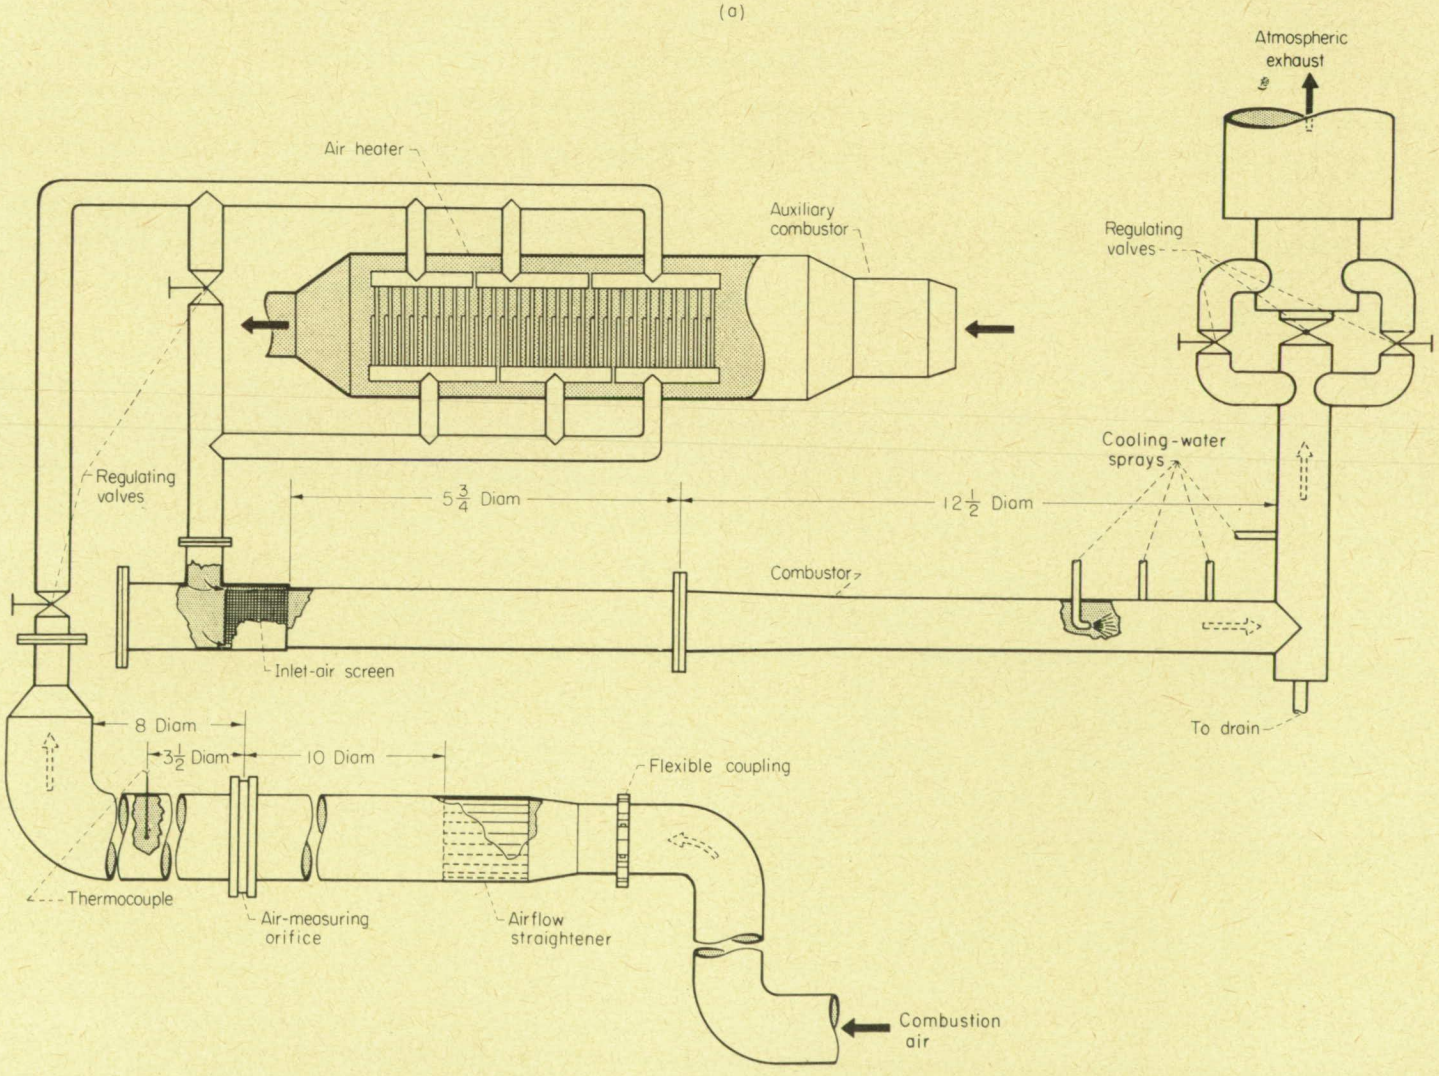
additive concentrations were investigated; in many cases the quantity of additive available limited the number of tests conducted. Since the experiments were made over a period of years, several different base fuels were employed. The base fuels were chosen for their high carbon-forming propensity.

APPARATUS AND PROCEDURE



SINGLE COMBUSTORS

Installation.—The single-combustor tests were conducted with the J33 liner and dome assembly shown in figure 1. The liner and dome from a production engine were welded together to assure consistent alinement of parts in each test. The facility in figure 2(a) was used for tests at low inlet air pressure and temperature, and that in figure 2(b) for the higher inlet air pressure and temperature. The combustor liner and dome were installed in a housing similar to the J33 combustor housing, except that circular inlet and exhaust transition sections were used. Airflow rate and air pressure in the combustor were controlled by remotely operated valves in the combustor inlet and outlet ducting. Water-spray nozzles in the exhaust ducts cooled the gases prior to their passage through the exhaust control valves.



The desired combustor-inlet air temperature was obtained by using either electric preheaters (fig. 2(a)) or a gasoline-fired heat exchanger (fig. 2(b)). The gasoline-fired heat exchanger consisted of a series of coiled Inconel tubes, connected in parallel, through which the high-pressure air flowed. The tubes were heated externally, in crossflow, by combustion gases from an auxiliary turbojet combustor. Airflow and fuel-flow rates to the combustor were measured by means of square-edged orifice plates (installed according to ASME specifications) and calibrated rotameters, respectively.

FIGURE 3.—Cross section of single-combustor installation showing auxiliary ducting and location of temperature- and pressure-measuring instruments in instrumentation planes.

Combustor temperature and pressure instrumentation.— Diagrammatic cross sections of the combustor and its auxiliary ducting and the position of instrumentation planes in the test installation are shown in figure 3. Thermocouples and total-pressure tubes in each instrumentation plane were located at centers of equal areas. Construction details of the temperature- and pressure-measuring instruments are shown in figure 4. In the low-pressure installation iron-constantan thermocouples were used to measure combustor-inlet air temperature (sec. B–B, fig. 3(a)), and Chromel-Alumel thermocouples to measure combustor-outlet gas temperature (sec. C–C, fig. 3(a)). The pressure and temperature data were obtained by means of manometers and automatic-balancing potentiometers, respectively. In the high-pressure facility the inlet air and exhaust gas temperatures were measured by Chromel-Alumel thermocouples (plane y–y, fig. 3(b)), and by platinum-13-percent-rhodium–platinum thermocouples (sec. B–B, fig. 3(b)), respectively. The supports for the platinum-rhodium–platinum thermocouples were made of brass and were cooled by a stream of high-pressure air bled from the combustion-air supply upstream of the orifice. Inlet air and exhaust gas total pressures were measured by the probes shown in figure 4(b) connected to strain-gage pressure transducers. All combustor pressures and temperatures were indicated on automatic-balancing potentiometers.

(a) Low-pressure facility.

(b) High-pressure facility.

FIGURE 4.—Construction details of temperature- and pressure-measuring instruments.

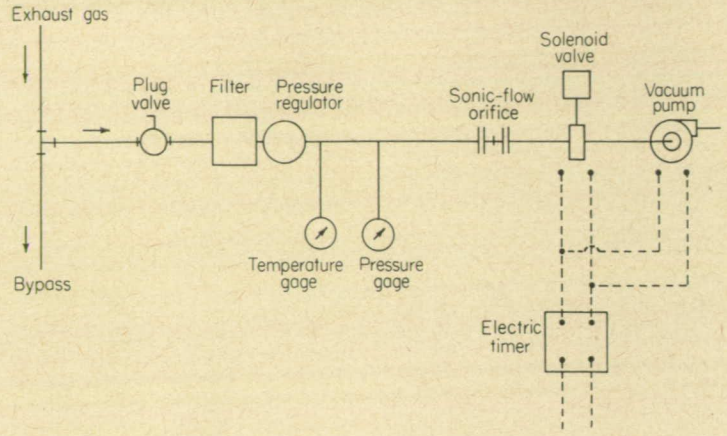

FIGURE 5.—Diagram of smoke meter.

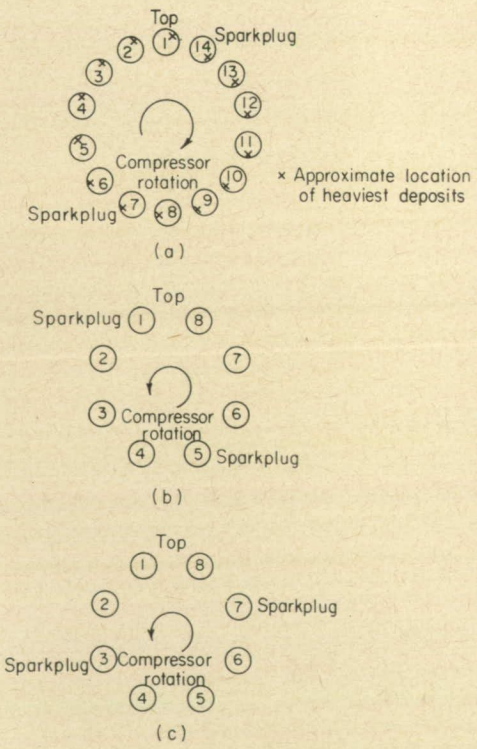
Smoke measurements.—In the low-pressure facility, exhaust gas samples were withdrawn through a single total-head probe centrally located in the exhaust duct. In the high-pressure facility the samples were obtained from a three-point total-head probe located in the exhaust duct. The apparatus used to determine the relative quantity of smoke in the exhaust gases was a modification of a commercially available smoke tester (shown diagrammatically in fig. 5). The meter consisted essentially of an air-cooled filter press containing a paper filter disk, and an automatic metering system. The gas sample was metered through a sonic-flow orifice; the flow duration was controlled by a solenoid valve actuated by an electric timer. A pressure-regulating valve maintained constant upstream orifice pressure. Location of the filter upstream of the control equipment eliminated the possibility of depositing soot on the control valves and orifice. The relative amounts of exhaust-gas smoke, reported as "smoke density," were measured by a transmission densitometer. The values reported represent the difference in optical density between the smoke-covered and the clean filters.

Experimental procedure.—The single-combustor tests were conducted at the following combustor operating conditions:

	Condition	
	A	B
Inlet air total pressure, lb/sq in. abs	26.5	141.0
Inlet air temperature, °F	271	640
Airflow rate, lb/sec	2.87	12.0
Exhaust gas temperature, °F	1100	1800
Combustor reference velocity, ft/sec	110	130
Approximate fuel-air ratio	0.012	0.018
Run time, hr	4	1.5
Approximate simulated full-scale-engine conditions:		
Compressor pressure ratio	4	7
Engine rpm, percent rated	90	100
Altitude, ft	20,000	0
Flight Mach number	0	0.87



Combustor reference velocity is based on the maximum cross-sectional area of the combustor, the weight flow of air, and the density of the air at combustor-inlet conditions. The conditions were chosen to represent two widely different test conditions; no attempt was made to investigate the effect of any individual operating parameter. Twenty fuels were tested at condition A, and six JP–4 fuels were tested at condition B. The run time was decreased to 1.5 hours at condition B because of limited supplies of several of the fuels and because of the limited life of the combustor liner at the higher pressure and temperature. All additive tests were conducted at condition A.

For carbon-deposition measurements, the combustor liner and dome assembly, including the ignition plug, was cleaned with mechanical rotating brushes and weighed on a torsion-type balance before the test run. After the prescribed period of operation the assembly was reweighed; the difference in weight represented the amount of carbon deposition reported herein. Generally, at least one check test was conducted. The exhaust-gas smoke density was measured at intervals during each run. The values of smoke density reported herein are averages of the several individual measurements made during each test run.

After each test with a fuel-additive blend, the fuel system was drained and purged with the base fuel to remove any residual additive. One or more check runs with the base fuel were made between tests with each of the additives to determine the effectiveness of the purge and the reproducibility of the base-fuel deposits.

FULL-SCALE ENGINES

Three full-scale turbojet engines were run at various engine conditions in the carbon-deposition investigation.

(a) Engine I.
(b) Engine II.
(c) Engine III.

FIGURE 6.—Diagrams showing relative locations of combustors in full-scale engines (looking downstream).

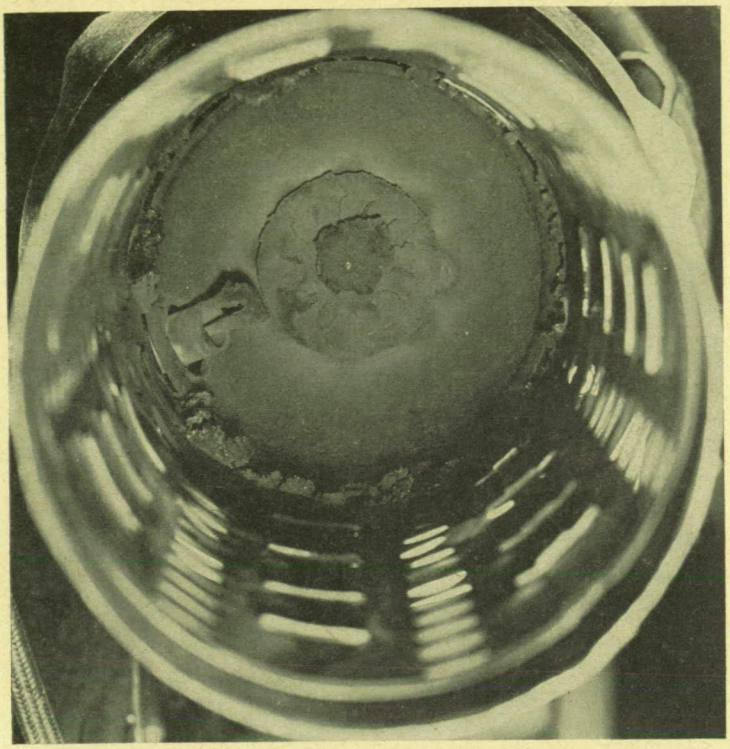


FIGURE 7.—Carbon deposits in J33 single-combustor liner after 4-hour run with fuel 49–224.

Engine I.—Engine I had a centrifugal-flow compressor with a pressure ratio of 4 and 14 individual tubular combustors. The combustor numbers, sparkplug locations, and direction of compressor rotation are shown schematically in figure 6(a). The engine was operated at sea level at zero flight speed on a cyclic operating schedule. The operating cycle consisted in approximately 5 minutes at idle engine speed (4000 rpm) followed by 15 minutes at takeoff speed (11,500 rpm). The idle time included the time for acceleration and deceleration. There was no regularly scheduled shutdown period. The performance of the engine was investigated at 6000 rpm before each day of operation to ascertain constancy of performance. The intended run time for each test was 50 hours. Both new and used combustor liners and used domes were cleaned, if necessary, but not weighed before any one test. After the completion of the test, the liners and domes were weighed, cleaned with wire brushes, and reweighed. The difference in weight was considered the weight of the carbon deposited.

Engine II.—Engine II had an axial-flow compressor with a pressure ratio of 5 and eight individual tubular combustors (fig. 6(b)). The engine was operated at sea-level static conditions for a total time of 25 hours. This time was divided into seven 3-hour periods followed by a 4-hour period. At the beginning and end of each period, the engine was operated for 5 minutes at rated conditions (7600 rpm); during the rest of each period, it was operated at 90-percent rated speed. Following each period of operation, the engine was shut down for approximately 2 hours. The new combustor liners used for the investigation were weighed before and after 25 hours of operation, and the increase in weight was considered as the weight of the carbon deposited.

Engine III.—Engine III had an axial-flow compressor with a pressure ratio of 5.2 and eight individual tubular combustors (fig. 6(c)). This engine was operated at sea-level static conditions for a total time of 37 hours and 47 minutes. The maximum running time for any one day was about 1½ hours, which included running at engine speeds from 3000 to 7950 rpm. About 75 percent of the total operating time was at 7950 (rated) rpm, and the other 25 percent at engine speeds varying between 3000 and 7950 rpm. The complete test covered a time period of about 1½ months. Combustor liners, which had been previously used, were cleaned with wire brushes and then weighed before and after the complete test. The increase in weight was considered as the weight of the carbon deposited.

RESULTS

EFFECT OF FUEL PROPERTIES ON CARBON DEPOSITS IN SINGLE COMBUSTORS

A photograph of carbon deposits obtained in the J33 combustor during a 4-hour test run with fuel 49–224 is presented in figure 7. The deposits, which were concentrated in the upstream end of the liner around the fuel-injection nozzle and the sparkplug, weighed about 34 grams. Carbon-deposition data obtained in this type combustor with 21 fuels are presented in table IV. At the lower inlet air pressure and temperature (condition A), average deviations in individual test results from average test results varied from 1 to 16 percent. At condition B the average deviations were greater, varying from 8 to 30 percent.

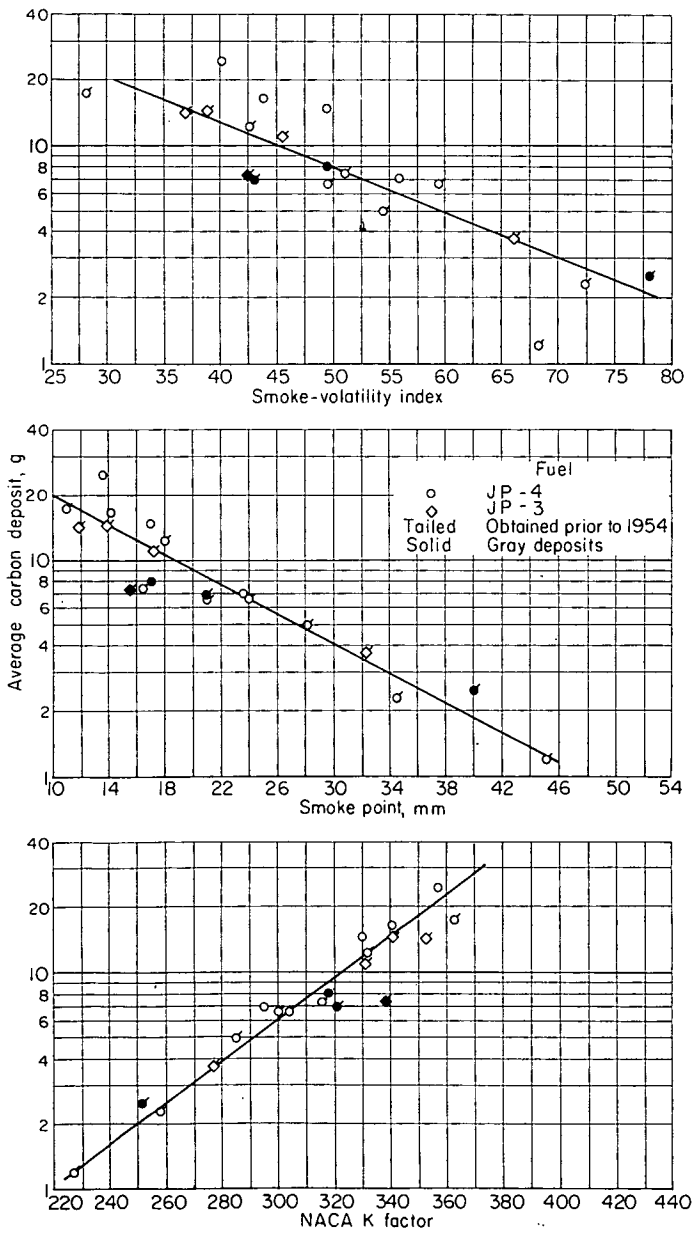
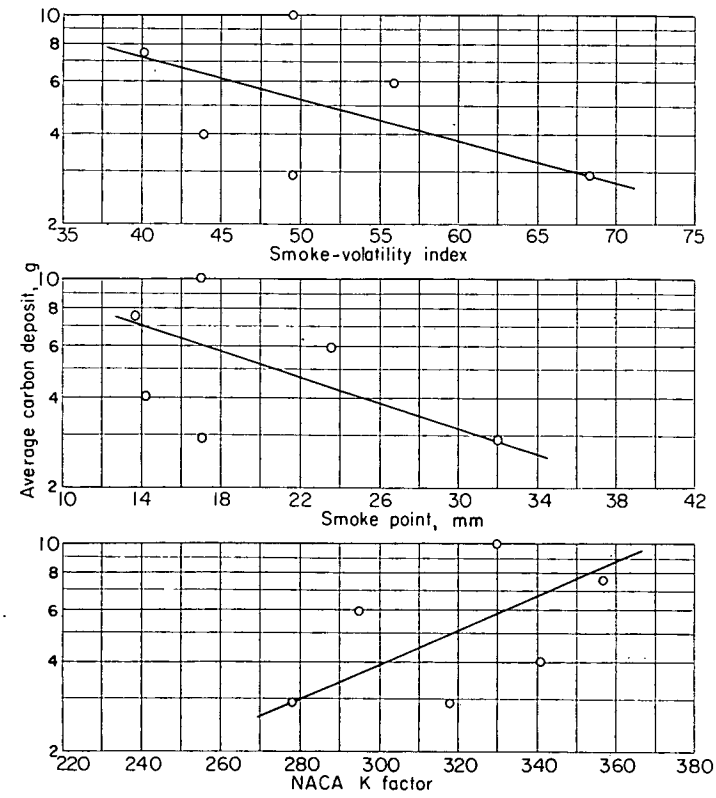
[a] Arithmetical average percent variation of individual carbon-deposition value from arithmetical average deposition.
[b] Gray deposits.
[c] Average of two or more tests.



Gray deposits were obtained with fuels 52–28, 52–166, 53–49, and 54–111. As will be noted in a later section of this report, similar-colored deposits were observed in tests with fuels containing small amounts of lead or cadmium. Spectrographic analysis of the deposits with fuel 54–111 at condition A indicated lead, which is assumed to have been present in the fuel as a contaminant. The deposits with this fuel at condition B showed no evidence of lead. It is very possible that the lead was present in the fuel as tetraethyl lead, the antiknock additive used in aviation gasoline. The high inlet air temperature at condition B may have vaporized this volatile compound so rapidly that no significant quantity reached the carbon-forming areas of the liner walls. Another possible explanation for the inconsistency is that the fuel was received in fourteen 55-gallon drums, only a part of which may have been contaminated.

Average deposits obtained at conditions A and B are plotted against smoke-volatility index, smoke point, and NACA K factor in figure 8. At condition A the deposits generally increased with decreasing smoke-volatility index or smoke point and with increasing K factor. The solid symbols of figure 8 denote deposits that showed evidence of metal contamination. These data points were not considered in the fairing of the correlation curves. Tailed symbols in figure 8 denote deposit data obtained in earlier phases of the investigation. At condition B the general trends are the same as those at condition A; however, the deviations from a mean correlation curve are much greater.



EFFECT OF FUEL PROPERTIES ON CARBON DEPOSITS IN FULL-SCALE ENGINES

Engine I.—The carbon deposits obtained with three test fuels in engine I are presented in table V(a). The values represent results of a single test with each fuel. Locations of the heaviest deposits are as shown in figure 6(a). No relation between the relative quantities of carbon and the circumferential position of the combustor is evident. Emission spectra of gray powder deposits obtained from the downstream end of liners after the test with fuel 52–28 indicated that these deposits contained a large amount of lead. Similar deposits were noted with this fuel in the single-combustor tests (table IV).

Fuel-nozzle filter plugging during the first test with fuel 52–76 limited the fuel flow to the engine to such an extent that the desired engine speed could not be maintained; the test was terminated after 37 hours and 54 minutes. This

(a) Condition A: Inlet air pressure, 26.5 pounds per square inch absolute; inlet air temperature, 271° F; reference velocity, 110 feet per second; outlet temperature, 1100° F.

(b) Condition B: Inlet air pressure, 141.0 pounds per square inch absolute; inlet air temperature, 640° F; reference velocity, 130 feet per second; outlet temperature, 1800° F.

FIGURE 8.—Relation between average carbon deposits in single tubular combustor and empirical fuel factors.

run is not included in the analysis of data but is shown in table V(a) only to indicate, approximately, the effect of time and the reproducibility of the amount of carbon obtained from a single fuel. In a second test with fuel 52–76 the desired number of running hours was obtained, although some filter plugging did occur. A considerable amount of carbon remained on the ignition plugs after fuel 52–76 was used.

Engine II.—The carbon deposits obtained in engine II with a minimum-quality JP–3 fuel (50–264) are presented in table V(b). The values represent results of a single test. Carbon deposits were found in the dome end of the combustor and on the fuel nozzle. There was some evidence of greater

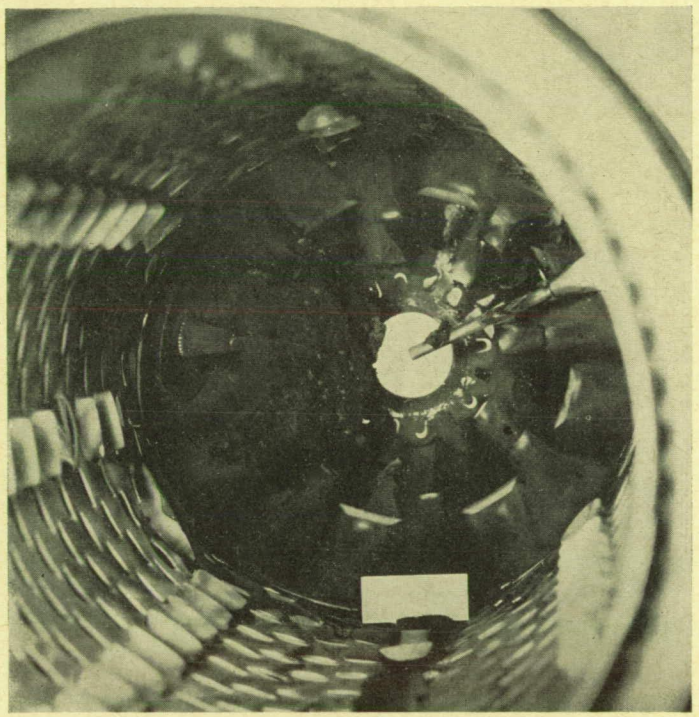


FIGURE 9.—Carbon deposits obtained in combustor 7 of full-scale engine III with fuel 52–76.

deposition in combustion chambers located at the bottom of the engine. A much larger amount of soot was found in the exhaust muffler than had been obtained from previous tests of this duration with a production JP–3 fuel.

Engine III.—Carbon deposits obtained in engine III with a minimum-quality JP–4 fuel (52–76) are shown in table V(c). The values represent results of a single test. The large deposit weight obtained in combustor 7 (fig. 6(c)) was caused by a large deposit on one of the sparkplugs, as shown in figure 9. Abnormally large deposits in combustors using the type of sparkplug shown in figure 9 have been obtained previously. Several of the liners were severely warped after the test and had to be replaced.

During the test with this fuel, the exhaust cooling water draining from the exhaust muffler was black. Inspection of the inside of the muffler showed large quantities of soot; one total-pressure rake was plugged with soot. This amount of exhaust soot was much greater than that normally encountered with production JP–4 fuel.

EFFECT OF FUEL PROPERTIES ON SMOKE FORMATION

Exhaust-gas smoke data were obtained only in the single combustor with fuels 54–108, 54–109, 54–110, and 54–111 (table VI). In most cases two or three determinations were made during each carbon-deposit test run. Average percentage deviations varied from 12 to 30 percent. Because of inaccuracies in the smoke measurement technique, the

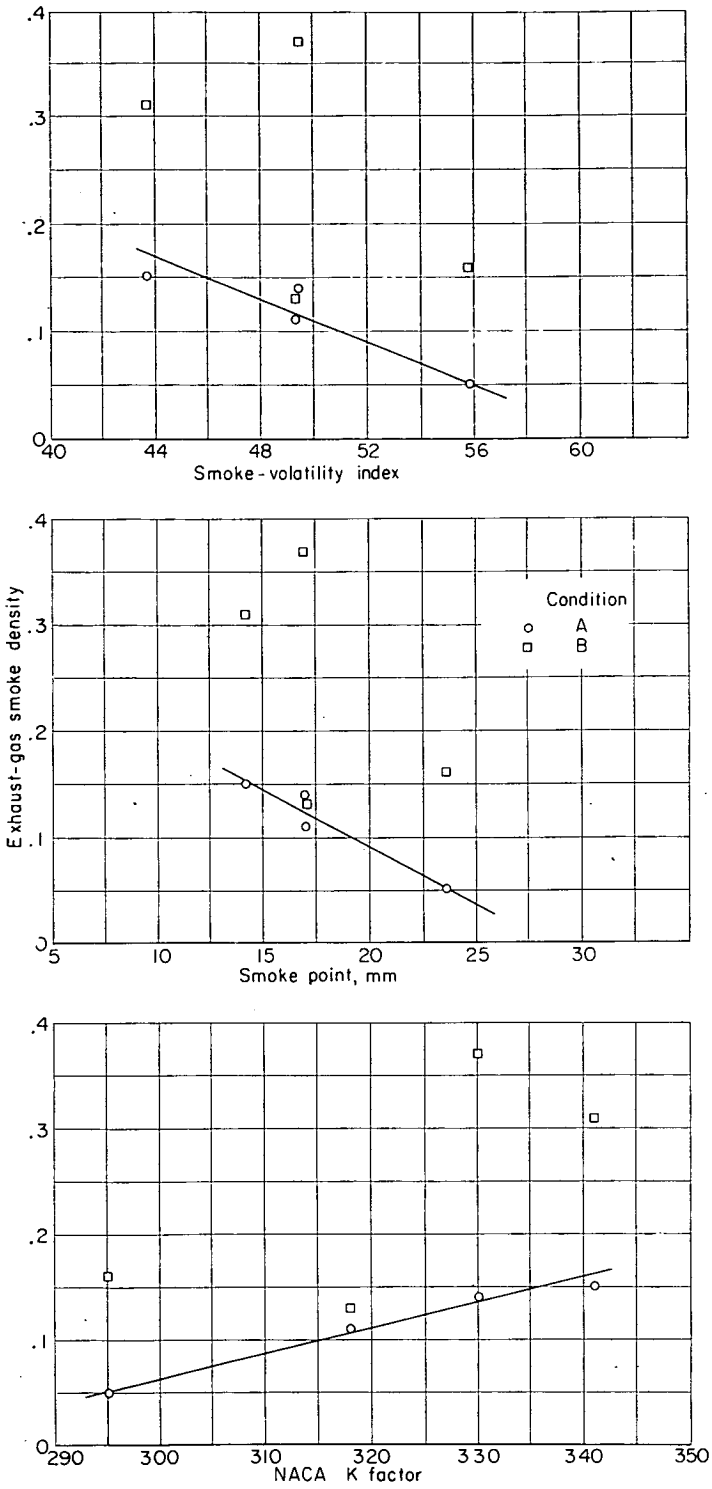

FIGURE 10.—Relation between exhaust-gas smoke density obtained with JP–4 fuels and empirical fuel factors.

larger percentage deviations generally occurred at lower values of smoke density. Average smoke densities are plotted in figure 10 against smoke-volatility index, smoke point, and NACA K factor. At both conditions exhaust-gas smoke density decreased with increasing smoke-volatility index or smoke point and with decreasing K factor. A reasonable correlation was obtained only at condition A, however; and only the data for this test condition were used to fair the curves in figure 10.

EFFECT OF ADDITIVES ON CARBON DEPOSITION AND EXHAUST-GAS SMOKE

The effect of a number of fuel additives on carbon deposition and exhaust-gas smoke concentration was investigated in the single turbojet combustor at condition A. The tests were conducted over a considerable period of time with a number of different base fuels. In some cases the base fuel was changed to determine the effect of some additives on the carbon-forming properties of different fuel compositions. In other cases, the supply of base fuel was depleted and new supplies varied in composition.

The results obtained in tests with 23 different additives are presented in table VII. With base fuels 49–162, 49–224, 52–105, 54–41, and 55–89, representing a wide variety of fuel properties, reproducibility was considered satisfactory; the average deviations in individual test runs from the average deposit obtained in all runs with the particular base fuel ranged from 2 to 21 percent. Base fuel 53–193 was used during several periods of the investigation. During any one period, reproducibility with this fuel was also satisfactory, with average deviations from 1 percent (run series 15) to 14 percent (run series 28 through 43). However, the average base-fuel deposit obtained in each of the several periods of operation differed considerably: The average deposit in run series 15 was 20.5 grams; in run series 28 through 43 it was 28.3 grams; and in run series 44 through 53, 35.6 grams. The large difference may be partly attributed to aging, which would increase the gum content of the fuel and may affect deposits (ref. 10).

Multiple additive test runs were conducted where sufficient quantities of the additive were available. For the multiple

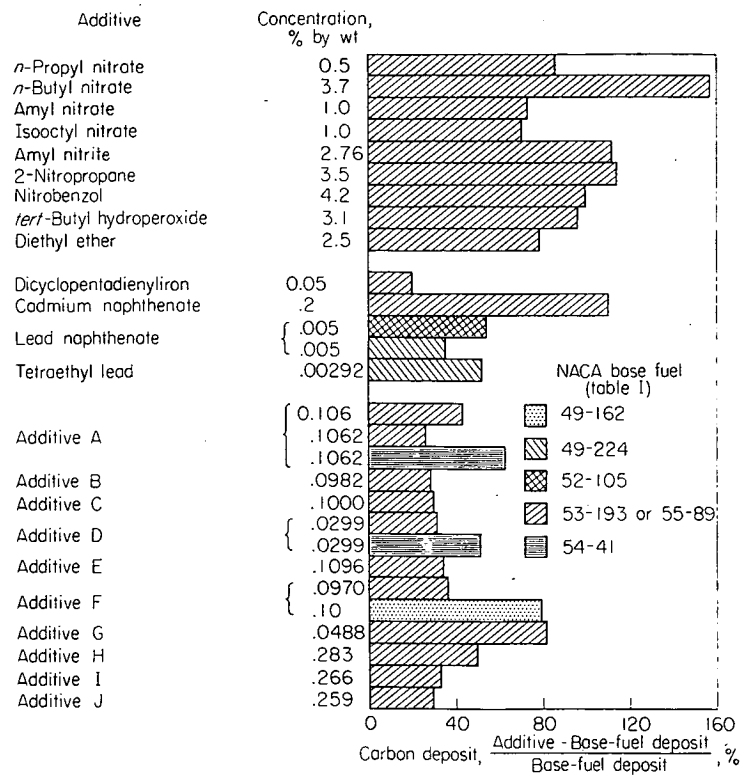

FIGURE 11.—Relative effectiveness of 23 additives in reducing turbojet combustion-chamber carbon deposits.

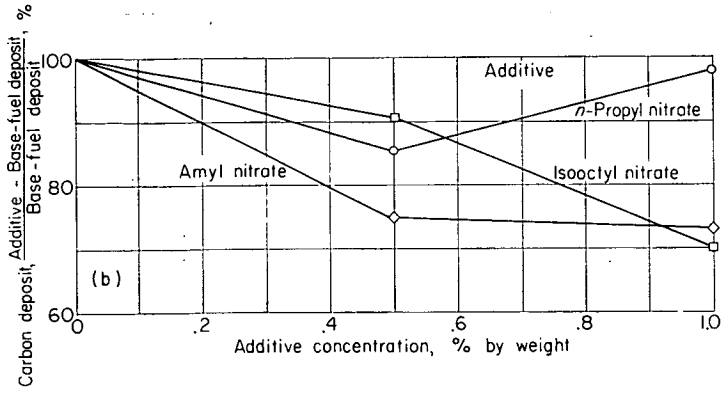
[a] Average variation of individual carbon-deposit values from average deposit value.



[b] $\frac{\text{Average deposit minus over-all average base-fuel deposit}}{\text{Over-all average base-fuel deposit}}$

tests the mean deviation of deposits in individual test runs from the average deposit values varied from 0 to 18 percent. The percent changes in deposit from the base-fuel deposit are based upon average deposit values obtained with the base fuel during the period of testing with the particular additive. For test run series 28 through 43 the average base-fuel deposit value of 28.3 (obtained from runs 28, 30, 33, 36, 37, and 43) was used for additive data obtained in intervening test runs. Similarly, for runs 44 through 53 an average base-fuel deposit value of 35.6, obtained from run series 46, 49, 51, and 53, was used.

The relative effectiveness of the additives in reducing carbon deposits is compared in figure 11. Average carbon deposits, in percentage of base-fuel deposits, are shown only for the additive concentrations that gave the largest reductions in deposit. In general, the oxygenated compounds (alkylated nitrates, amyl nitrite, nitropropane, nitrobenzol, *tert*-butyl hydroperoxide, and diethyl ether) were considerably less effective than the organo-metallic compounds and the commercial additives, which were also primarily organo-metallic. The most effective oxygenated compound, isooctyl nitrate, reduced base-fuel deposits almost 30 percent, while the most effective organo-metallic compound, dicyclopentadienyliron, reduced base-fuel deposits about 80 percent. Additive A, the most effective of the commercial additives, reduced base-fuel deposits 74 percent. A qualitative spectroscopic analysis of additive A showed that it contained lead and copper (table III).

(a) Organo-metallic and commercial compounds.

(b) Oxygenated compounds. Base fuel, 53–193.

FIGURE 12.—Effect of additive concentration on carbon deposit in single J33 combustor.

A comparison of results obtained with a number of additives (A, D, and lead naphthenate) that were tested in more than one base fuel indicates that the relative effectiveness of an additive varied markedly with the base fuel. For example, additive A in No. 2 furnace oil (53–193) reduced deposits 74 percent; the same concentration of additive A in the same furnace oil at a much later date (aged fuel) reduced deposits 57 percent; and the same additive in a high-carbon-forming JP–4 fuel (54–41) reduced deposits 38 percent.

The effect of additive concentration on carbon deposits was determined with nine of the additives. Figure 12 shows that the effect of additive concentration on deposits was not consistent. For some additives (dicyclopentadienyliron and lead naphthenate), small concentrations produced the large reductions in deposits. A high concentration of lead naphthenate in fuel 52–105 produced deposits greater than those obtained with the base fuel alone.

Deposits obtained with additive blends containing lead or cadmium were colored gray or yellow-gray in some areas of the combustor liner. The deposits obtained with dicyclopentadienyliron were reddish. These colorations indicate the presence of metal and metal oxides. The deposits were not chemically analyzed.

Exhaust-gas smoke data were obtained with many of the base fuels and additive–base-fuel blends; these data are presented in table VII. Large variations in smoke ratings were observed with the base fuels, and the smoke ratings of the additive blends were generally within the ranges obtained with the base fuels. Hence, no effect of the additives on smoke concentration is apparent.

DISCUSSION

EMPIRICAL RELATIONS BETWEEN CARBON DEPOSITS AND FUEL PROPERTIES

Single-combustor carbon deposits obtained at inlet air temperature and pressure simulating operation of an engine with a compressor pressure ratio of 4 at a 20,000-foot altitude (condition A) correlated reasonably well with any of three empirical fuel factors—smoke-volatility index, smoke point, and NACA *K* factor. The data included in the correlations were obtained over a considerable period of time, and there is some indication that the more recent data (plain symbols, fig. 8(a)) define a correlation curve at a slightly higher level of deposit. The correlations applied equally well to JP–3 and JP–4 fuels.

The relative accuracy of the three fuel-factor correlations can be judged by examining deviations of the deposit data from the correlation curve. The deviations for condition A are as follows:

Fuel factor	Av. deviation, %	Max. deviation, %
Smoke-volatility index	27	95
Smoke point	17	67
NACA *K* factor	12	30

The average deviations were calculated from the equation

$$\text{Average deviation} = \frac{\sum \frac{y-y_c}{y_c}}{n} \times 100$$

where $y-y_c$ is the absolute difference between the determined and predicted values of carbon deposit, y_c is the predicted value, and n is the number of determinations.

Data for fuels suspected of being contaminated were not included in these calculations. Based on average deviation or maximum deviation, both the smoke point and the K factor gave more accurate deposit correlations than the smoke-volatility index; the smallest deviations were obtained with the K factor. Smoke point and K factor were also the most accurate of about ten factors examined in reference 1. It should be pointed out that simplicity, as well as accuracy, is an important criterion for a satisfactory fuel procurement specification. The determination of an accurate value of hydrogen-carbon ratio, required to compute the K factor, is considerably more difficult than the measurement of smoke point.

The range of fuel properties included in the correlations of figure 8(a) is much greater than that normally considered for jet-engine fuels. For example, fuel 54–41 had accelerated and existent gum contents about 6 times those allowed by current procurement specifications. This particular fuel produced the high values of maximum deviation noted in the smoke-point and smoke-volatility-index correlations. Data of reference 10 show that high values of gum content can cause increased deposits that may not be predicted by empirical fuel factors. Restricting the range of fuel properties, in order to maintain other desirable fuel characteristics, would be expected to reduce deviations considerably.

At a higher inlet air temperature and pressure simulating an engine with a compressor pressure ratio of 7 operating at sea level (condition B), deposits did not satisfactorily correlate with any of the fuel factors. Preliminary examination of other fuel characteristics that could affect carbon deposition (ref. 1) did not yield any better correlation of the data. The mean straight lines drawn through the data in figure 8(b) are, however, approximately parallel to the corresponding correlation lines for condition A (fig. 8(a)). In reference 11 deposit data obtained at several different operating conditions in an annular combustor also gave approximately parallel correlation lines with K factor. The poor correlation obtained with the condition B data may be the result of more erratic carbon-deposition patterns that were observed at high inlet air temperature. At this condition carbon was deposited in isolated areas around the upstream end of the combustion chamber, and some of the heavier deposits may have broken away from the walls. In comparison, at low inlet air temperature conditions carbon was generally found uniformly deposited in a sizable area around the fuel nozzle of this combustor.

The full-scale-engine data obtained in this investigation are too limited to ascertain the applicability of the correlations to full-scale engines. Additional unpublished carbon-deposit data for three full-scale engines are presented in table VIII. Two of the engines (types I and III) were of the same type as used in the present investigation. Engine IV had an axial-flow compressor of 6.8 pressure ratio and an annular prevaporizing combustor. The engines were operated 10 hours at static sea-level conditions on cyclic operating schedules. The deposits listed are average values for each combustion chamber of engine types I and III or each vaporizer tube of the annular vaporizing combustor (type IV). Comparison of the data of tables VIII and IV shows that deposit deviations in the full-scale engines are considerably greater than those in the single combustor.

TABLE VIII.—FULL-SCALE-ENGINE CARBON DEPOSITS

NACA fuel	Average carbon deposit, g (a)	Average variation, percent (b)
Engine I		
54-108	45.9	16

[a] Arithmetical average deposits in each combustor or fuel vaporizer.
[b] Arithmetical average percent variation of deposits in individual combustion chambers, or fuel vaporizers, from arithmetical average deposit values.

The carbon-deposit data obtained with three fuels in the type I full-scale engine at the NACA Lewis laboratory (table V(a)) and the full-scale-engine data of table VIII are plotted against smoke-volatility index, smoke point, and NACA K factor in figure 13. Data for the two type I engines would not be expected to fall on a single curve, since different operating conditions were used. The three fuel factors correlated the limited full-scale-engine (types I, III, and IV) deposit data with about equal accuracy. Percentage deviations for the full-scale-engine correlations were not computed because of the limited number of fuels tested. Carbon deposition in the full-scale engines was affected to a varying degree by changes in fuel properties. For example, deposits in engine IV increased only about 46 percent and those in engine III about 450 percent when the smoke-volatility index was decreased from 56 to 44.

Although less quantitative in nature, the results obtained in full-scale engines II and III tested at the NACA Lewis laboratory exhibited similar trends. In engine II (table V(b)), much more soot was observed in the exhaust muffler with fuel 50–264 (SVI=45.5, smoke point=17.2, K=331) than with a number of production batches of JP–3 having

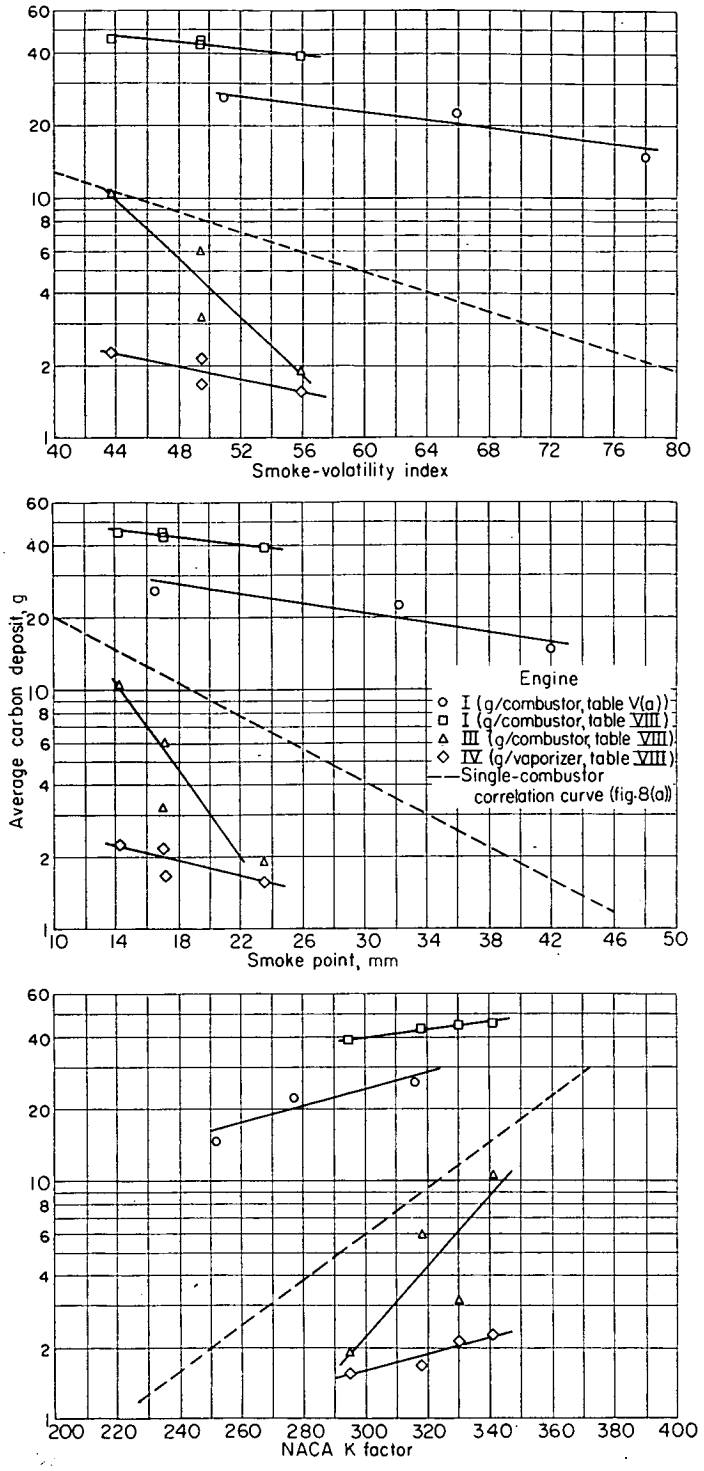

FIGURE 13.—Relation between carbon deposits in full-scale turbojet engines and empirical fuel factors.

properties very similar to those of fuel 52–30 (SVI=66, smoke point=32.3, K=277). In the type III full-scale engine (table V(c)) much more soot was observed in the exhaust muffler, along with a greater tendency toward spark-plug fouling, with fuel 52–76 (SVI=51, smoke point=16.5, K=316) than with production fuels similar to 52–28 (SVI=78, smoke point=40.0, K=252).

The order of carbon deposition among the fuels in the single combustor at condition A was the same as in the full-scale engines; however, figure 13 shows that percentage changes in the deposit values between the fuels were not the same. Except for engine III, deposits in the single combustor increased at a more rapid rate as "fuel quality" decreased. The variation in sensitivity between the single combustor and the full-scale engine is at least partly attributable to differences in operating conditions. The full-scale engines were operated on cyclic test schedules, whereas the single combustor was operated at constant test conditions. Also, the combustor inlet and outlet passage configurations were different in the single combustor and in the full-scale engines. At the higher pressure and temperature single-combustor condition B, no relation between single-combustor and full-scale-engine data is apparent. The reasons for this inconsistency are probably related to the erratic deposition in the single combustor at condition B.

Neither the absolute level of deposition nor the relative effects of fuel factors on these deposits should be used to distinguish between good and bad combustor design in the full-scale engines tested. In addition to carbon deposition, a number of other performance requirements (e.g., combustion efficiency and stability, structural durability, and ease of manufacture) enter into final combustor designs for turbojet engines.

The empirical fuel factors examined in this investigation represent the volatility characteristics, the hydrogen-carbon ratio, and the smoke point of the fuel. In reference 1, which summarizes early carbon-deposit research in laboratory combustors, many additional fuel properties were observed to affect deposits. Approximate relations between deposits and fuel properties such as aromatic content, aniline point, and specific gravity are reported. Many of these other properties are, for petroleum fuels, interrelated with distillation characteristics, hydrogen-carbon ratio, or smoke point. For example, aromatic content of a fuel directly influences the hydrogen-carbon ratio. Tests to determine the effects of adding specific single-ring and dicyclic aromatic hydrocarbons to jet-type fuels (fuel blends 51–353, 52–32, 52–50, 52–105, 52–118, 52–119, and 52–120) revealed that the smoke-volatility index, smoke point, and K factor satisfactorily predicted changes in carbon deposition.

Other properties of jet fuels (e.g., sulfur content and gum content) are not related to the fuel factors. The effects of sulfur and gum on deposits were investigated in studies reported in reference 10. Limited data indicated that moderate amounts of gum did not influence deposits; very high gum contents, well above those permitted in current

jet fuels, will cause increased deposits. Although the data were not conclusive, it appeared that one form of sulfur (mercaptan) significantly increased deposits while another form (disulfide) had no effect.

EMPIRICAL RELATIONS BETWEEN EXHAUST-GAS SMOKE AND FUEL PROPERTIES

The measured values of smoke density were generally very low and may be of questionable significance. Nevertheless, they did vary with fuel properties in much the same way as did carbon deposition; that is, smoke formation generally decreased with an increase in smoke-volatility index or smoke point and with a decrease in K factor. Satisfactory relations were obtained only at condition A. While these results indicate that smoke formation and carbon deposition are affected by the same factors, experience has shown that design features tending to alleviate the carbon-deposition problem frequently aggravate the smoke problem, and vice versa. Also, data presented in reference 12 show that, while fuel volatility affected smoke density in a single combustor, the effects were very different at different operating fuel-air ratios. This might explain the fact that correlations with fuel factors were obtained at one condition and not at another in the present investigation. It should also be pointed out that the empirical fuel factors considered were developed for carbon deposition and not for exhaust-gas smoke.

EFFECT OF ADDITIVES ON CARBON FORMATION

The fuel additives investigated represent a fairly wide variety of organo-metallic compounds, oxygen-bearing compounds, and commercial compounds recommended for use in reciprocating engines and furnaces to reduce carbonaceous deposits and smoke. Spectroscopic analyses of the commercial compounds showed that most of them contained some organo-metallic materials. Most of the additives tested significantly reduced carbon deposits of the base fuel. None of them produced effects on exhaust-gas smoke concentration that could be considered significant in view of the variations in smoke concentrations observed with the base fuel.

Among the additives tested, the oxygenated compounds were generally the least effective in reducing deposits in the single combustor. The most effective oxygenated compound, isooctyl nitrate, reduced base-fuel deposits almost 30 percent in a 1-percent-by-weight blend. Most of the organo-metallic compounds and the commercial additives reduced deposits 50 percent or more. Additives A, B, and J, which reduced base-fuel deposits around 70 percent, were the most effective of the commercial additives. Tests with tetraethyl lead and with lead naphthenate showed smaller but still very significant reductions. The most effective compound tested was dicyclopentadienyliron, known commercially as "Ferrocene." This material reduced deposits in all concentrations tested; the largest reduction was 80 percent, obtained with the highest additive concentration tested (0.05 percent by weight) in a No. 2 furnace oil (fuel 53–193).

The weights of deposits reported include any metallic deposits; therefore, actual reductions in carbon deposits obtained with additives containing organo-metallic compounds may have been somewhat greater than reported. Furthermore, since the density of metallic deposits would be expected to exceed the density of carbon deposits, the volume of deposits may be reduced. The volume, rather than the weight, of deposits probably determines the effects on combustor performance.

The results showed that the relative effectiveness of additives varied when they were used with different base fuels. However, the experimental data do not indicate a relation between the effectiveness of an additive and the carbon-forming propensity of the fuel. Thus, the choice of the best additive for use in jet fuels must result from tests with as many widely different fuels as are obtainable under the existing fuel procurement specifications.

The effectiveness of an additive may also be expected to vary with combustor design, since the environment in which the carbon is formed may vary considerably. For example, in a vaporizing-type combustor carbon forms inside the vaporizing tubes as well as in the flame zone. The deposits have been found to be of different composition, indicating differences in mode of formation. Unpublished data have in fact shown different effects of additives on deposits in the flame zone and in the vaporizing tubes of prevaporizing combustors.

Effectiveness in reducing deposits is not the only factor to be considered in choosing an additive. Other factors include possible effects on fuel- and combustion-system components, ease of handling, solubility in jet fuel, storage and high-temperature stability, availability, and cost. There is no information available to indicate whether the additives would be affected by a water-displacement storage system. Very limited data obtained with fuel 52–105 and the blend of 0.005-percent lead naphthenate in 52–105 indicated that the addition of the lead naphthenate caused small increases in both preformed gum (3 to 6 mg/100 ml) and accelerated gum (10 to 14 mg/100 ml). These data indicate the need to investigate this factor.

Limited field experience has indicated marked corrosion difficulties in the exhaust section of turbojet engines operating with fuels containing tetraethyl lead, such as high-octane aviation gasoline. Effects of other metallic additives, such as the dicyclopentadienyliron, on engine operation have not been examined.

All the additives tested are relatively easy to handle and sufficiently soluble in jet fuel, but the relative availability and cost of the additives are unknown.

SUMMARY OF RESULTS

An investigation of the effects of fuel properties and fuel additives on carbon deposition of JP–3 and JP–4 type fuels in turbojet-engine combustors gave the following results:

1. At operating conditions simulating an engine with a compressor pressure ratio of 4 at a 20,000-foot altitude and zero flight speed, carbon deposits and exhaust-gas smoke density correlated with three empirical fuel factors: smoke-volatility index, smoke point, and NACA K factor. More accurate correlations of deposits were obtained with smoke point and NACA K factor.

2. Single-combustor deposit data at the preceding conditions also correlated reasonably well with limited full-scale-engine deposit data. Deposition in different engines and in the single combustor was not, however, equally sensitive to changes in fuel properties.

3. At higher pressure and temperature operating conditions simulating an engine with a compressor pressure ratio of 7 at sea level and Mach 0.87, neither deposits nor smoke density satisfactorily correlated with any of the fuel factors considered. Also, the deposit data obtained at these conditions did not correlate with full-scale-engine data.

4. A number of fuel additives, including organo-metallic compounds, commercial additives, and oxygenated compounds, significantly reduced combustion-chamber carbon deposits. The most effective additives were those containing organo-metallic compounds, particularly lead and iron compounds. The most effective additive, dicyclopentadienyliron, reduced deposits of the base fuel by approximately 80 percent.

5. Limited tests showed that the relative effectiveness of the additives may vary markedly with properties of the base fuel.

6. None of the additives tested produced significant effects on the exhaust-gas smoke concentration.

REPORT 1353

AN EXPERIMENTAL INVESTIGATION OF STING-SUPPORT EFFECTS ON DRAG AND A COMPARISON WITH JET EFFECTS AT TRANSONIC SPEEDS [1]

By Maurice S. Cahn

SUMMARY

Results are presented of an investigation of sting-support interference on afterbody drag at transonic speeds. Stings with varying diameter, cone angle, and cylindrical length were tested at the rear of a model with various afterbody shapes. The data were obtained at an angle of attack of 0° and at Mach numbers from 0.80 to 1.10. In general, the addition of a sting was found to cause a drag reduction. A method is presented whereby approximate sting-interference corrections may be made to models with afterbodies and sting supports of size and scale similar to those of this investigation, provided the boundary layer is turbulent at the model base and the Reynolds numbers are of the same order of magnitude. Reynolds number of the tests presented varied from 15.0×10⁶ to 17.4×10⁶ based on body length.

Sting effects are compared with data of jet effects on the same afterbodies. The results of this comparison indicate that, for the more gradually contoured afterbodies, a sting shape can be found which will duplicate the jet effects, but that for blunt afterbodies no solid sting shape will duplicate the jet effects.

INTRODUCTION

A large part of wind-tunnel testing involves the use of rear sting-supported models. Experimental data for sting-support effects on model characteristics are needed in order to estimate more exactly free-flight conditions. A recent summary of information on sting-support interference (ref. 1) presents a comprehensive study of sting effects at supersonic speeds; however, as noted in reference 1, the acute problem at transonic speeds requires more experimental data. An investigation has been conducted in the Langley 8-foot transonic tunnel to evaluate some of the effects of sting-support configuration on the drag characteristics of a systematic series of afterbodies. The tests were conducted at an angle of attack of 0° through the Mach number range from 0.80 to 1.10 for stings with varying cone-angle, length, and diameter. The sting effects determined are compared with data of jet effects on the same afterbodies.

APPARATUS AND METHODS

WIND TUNNEL

This investigation was conducted in the Langley 8-foot transonic tunnel, which has a dodecagonal slotted test section. Continuous testing up to a Mach number of 1.10 was possible for these models. Details of the test section are presented in reference 2. Characteristics of the airstream are given in reference 3, wherein the maximum deviation from the indicated free-stream Mach number is shown to be ±0.003.

[1] Supersedes recently declassified NACA Research Memorandum L56F18a by Maurice S. Cahn, 1956.

MODELS

The models used in the investigation were bodies of revolution that consisted of a single forebody with interchangeable afterbodies. These bodies had fineness ratios of 10 or 10.6, depending on the choice of afterbody. They were supported in the tunnel as shown in figure 1 by two 45° swept struts. These struts had chords of 11.25 inches and NACA 65-010 airfoil sections measured parallel to the airstream. Their leading edges intersected the bodies 21.7 inches from the nose.

Eight afterbody configurations (identified herein as afterbodies A to H) were designed, with the exception of afterbody E, on the basis of the following equation (see fig. 2):

$$r=r_{max}-(r_{max}-r_b)\left(\frac{x_a-x_0}{x_1-x_0}\right)^{\left(\frac{x_1-x_0}{r_{max}-r_b}\right)\tan\beta} \quad (1)$$

where

x_a distance from afterbody origin to any station
x_0 distance from afterbody origin to end of cylindrical section
x_1 distance from afterbody origin to body base
β boattail angle

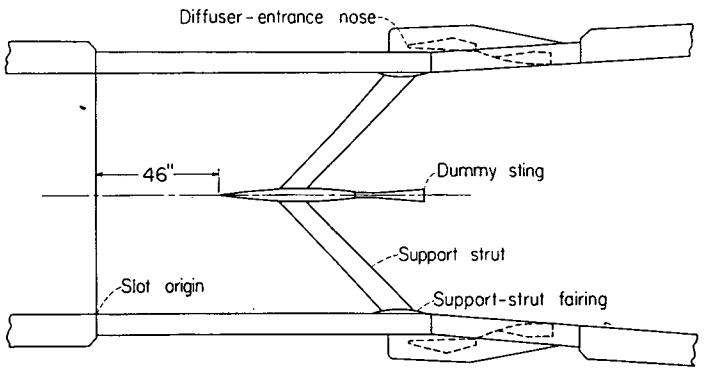

FIGURE 1.—Sting-interference model in Langley 8-foot transonic tunnel.

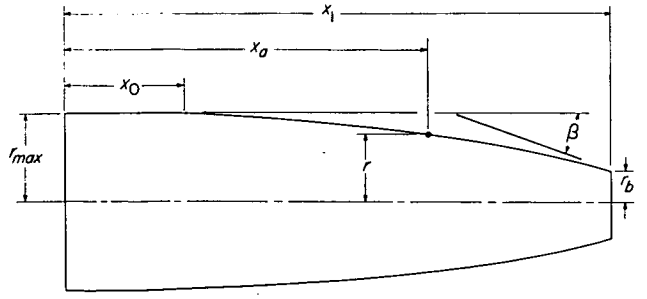

FIGURE 2.—Afterbody shape.

The design values of the afterbody variables are given in table I. Drawings of the afterbody shapes are shown in figure 3. Afterbody E, while not of this afterbody family, is included since it provides a low boattail angle otherwise not available for the bodies having a fineness ratio of 10.0. Tabulated in table II are the ordinates from which the body shapes were constructed. A sketch of the body shapes appears as figure 4.

The models were instrumented with 26 static-pressure orifices in each of three rows located 0°, 45°, and 72° from the plane of symmetry. Orifice distribution was the same in each row. Also, two diametrically opposite base-pressure orifices were located a short distance inside the model base annulus.

STINGS

The stings were constructed of wood and were attached to the rear of the models by means of an adapter contained within the sting and the afterbody. The models were tested with no sting and with the stings shown in figure 5. These stings included configurations having conical half-angles from 0° to 10° and no cylindrical sections ahead of the cone, stings with conical half-angles of 5° and cylindrical sections ahead of the cone varying from 0 to 13.40 inches, and cy-

lindrical stings with diameters varying from 0.84 to 2.36 inches. The overall length of all stings was 26 inches.

TESTS AND MEASUREMENTS

Various stings were tested with each afterbody at an angle of attack of 0°. For each configuration, the Mach number was varied in 0.05 increments from 0.80 to 1.10. In order to compare sting effects with jet effects, an ethylene-air burner was exhausted through the base of the model with no sting in place. The total temperature of the jet exhaust gas was 1,200° F. Data were taken for ratios of the jet total pressure to free-stream static pressure varying from 2 to approximately 10 at free-stream Mach numbers of 0.80, 0.90, 1.00, and 1.10. Reynolds number based on body length varied from 15.0×10^6 to 17.4×10^6. (See fig. 6.) All pressures were photographically recorded from multiple tube manometers.

REDUCTION OF DATA

The pressure coefficients of these tests were numerically integrated to obtain values of afterbody pressure drag coefficient which are based on body frontal area. The stings used in this investigation had no effect on the forebody pressure drag as will be shown in the section entitled "Results and Discussion." Base drags were obtained by assuming that measured base pressures acted over the entire model base.

PRECISION

Total-drag-coefficient errors due to possible inaccuracies in measurement and to tunnel-empty stream nonuniformities are estimated generally to be less than 0.005 at subsonic speeds and not more than 0.010 at supersonic speeds.

The magnitude of the sting effects may be somewhat affected by tunnel-wall disturbances above $M=1.0$. A detailed analysis of shock reflections of this type may be found in reference 3.

RESULTS AND DISCUSSION

DESCRIPTION OF FLOW PHENOMENA

Prior to presentation of these results, a brief discussion of the flow mechanism occurring at the model base is considered to be desirable. Inasmuch as the flow separates from the body at the model base, a region of low-energy air is created immediately behind the base. As a consequence, the streamline adjacent to the wake has essentially a constant pressure. The way in which the pressure at the base arrives at its steady value can be illustrated by considering a cylindrical afterbody. If in some way an external stream is immediately imposed on this afterbody, the base pressure

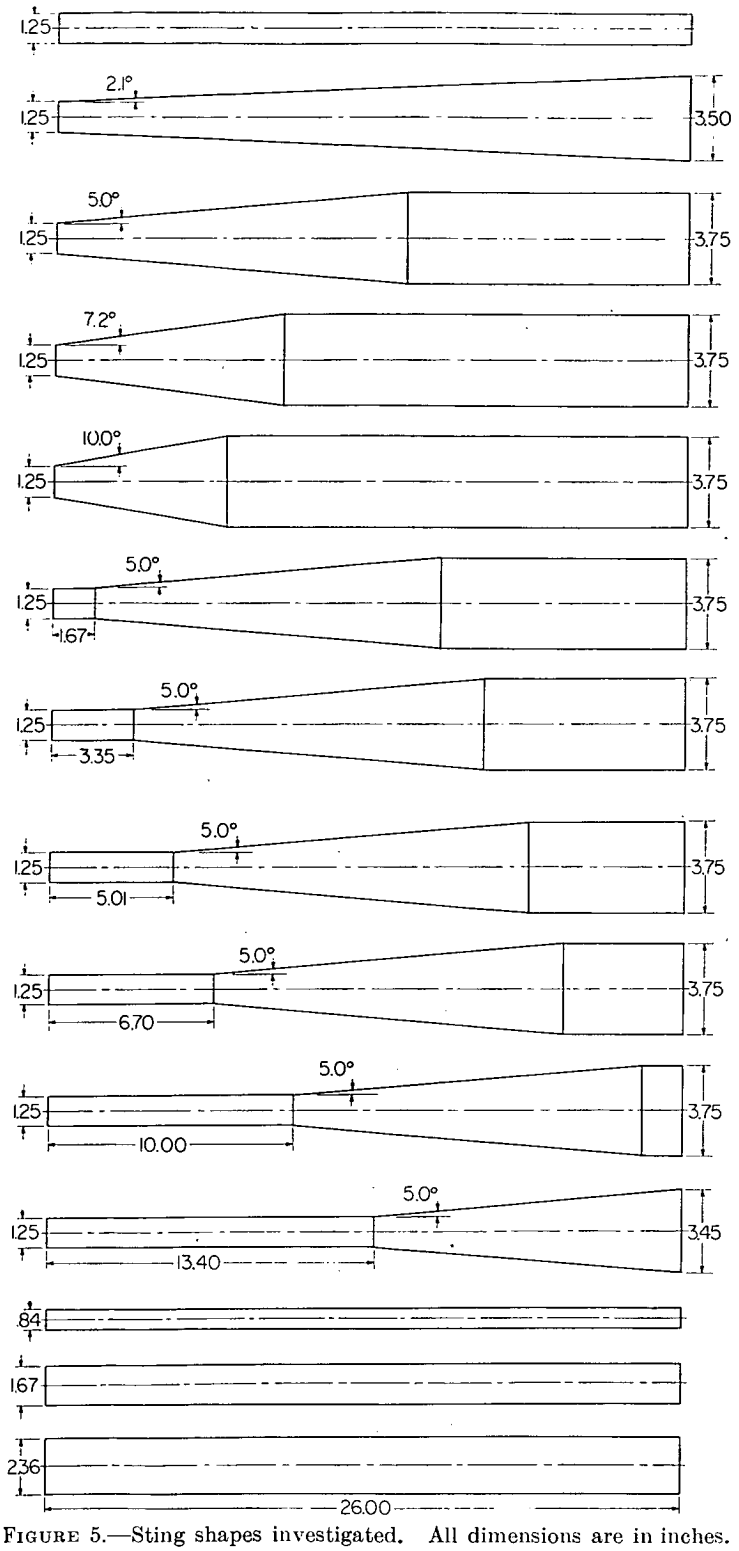

FIGURE 5.—Sting shapes investigated. All dimensions are in inches.

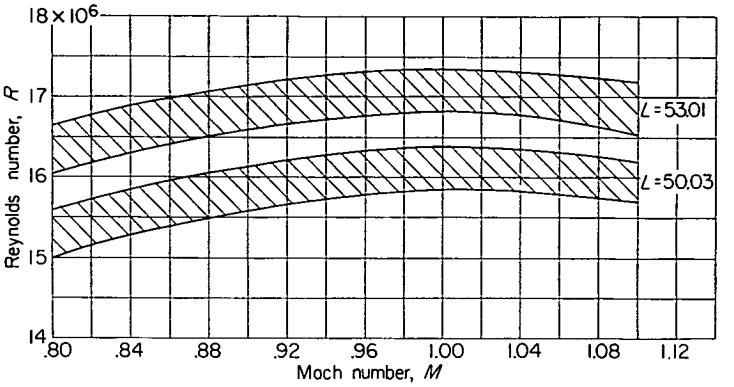
will in the first instant be equal to the free-stream static pressure. (See fig. 7 (a).) After some time, because of viscous mixing, the external stream aspirates the base region and lowers its pressure. The free stream is turned inward with an accompanying increase in velocity. Viscous mixing, now being strengthened, causes more aspiration of the base region with further turning inward of the free stream. Opposing this effect is the increase in pressure in the wake where the external stream must be turned to become horizontal again. Since the base region is also affected by this wake pressure rise, a base pressure is established when the two opposing effects are in equilibrium. (See fig. 7 (b).)



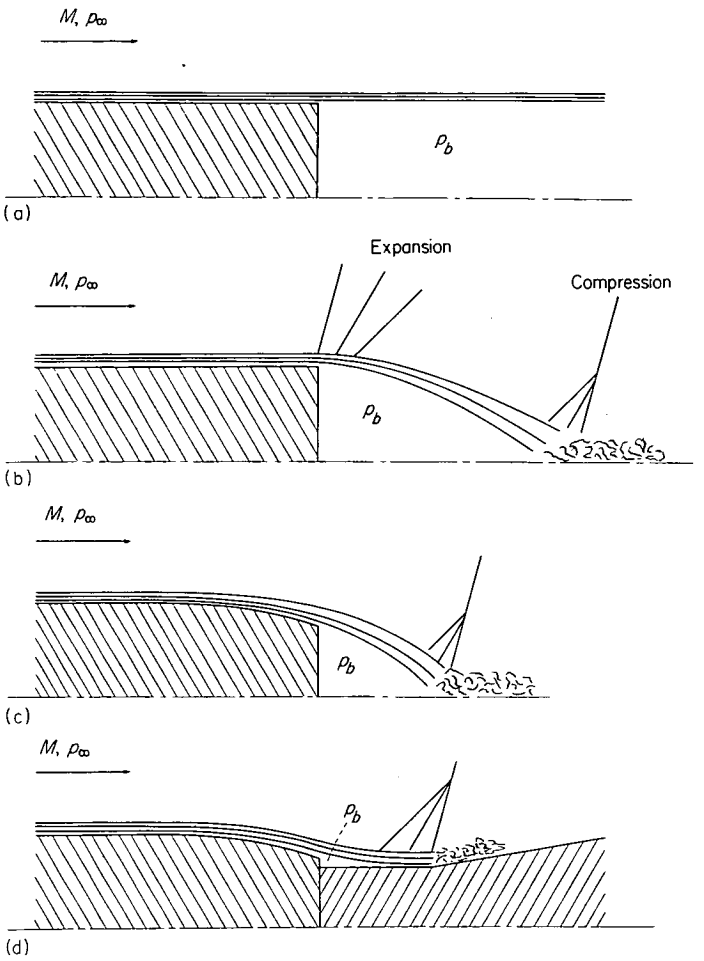


FIGURE 6.—Variation of Reynolds number, based on body length, with Mach number.

Boattailing, if not so great as to cause separation ahead of the base, will cause an increase in base pressure. (See fig. 7 (c).) This increase in base pressure results from an increase in compression over the body as well as from the fact that less wake region is exposed to the aspiration effects of the external stream. Placing a sting in the rear of a model, in addition to causing less wake exposure, requires the external stream to be turned outward more rapidly. (See fig. 7 (d).) These effects result in a base-pressure increase. Increasing the sting cone angle or moving the sting cone closer to the base thus causes a further increase in the turning rate of the external stream near the base and results in a further base-pressure increase.

A sting also has effects on the body pressures ahead of the model base that are similar to the sting effects on base pressure. These effects, which are transmitted through the body boundary layer, become smaller with increasing distance upstream of the base, as is shown in figure 8. In figure 8 are typical pressure distributions over the body with and without a sting. The pressure coefficients for the orifice row along the plane of symmetry are shown for afterbodies B and D at four Mach numbers. The two afterbodies represent a blunt and a gradually contoured rear end configuration, and the sting is the one which had the largest effect. These results indicate that the sting did not affect the body pressures forward of the 60-percent station.

EFFECT OF STING CONFIGURATION ON BASE PRESSURE

In figure 9, base pressure coefficients are presented as a function of sting half-angle, length, and cross-sectional-area parameters. As previously stated, the presence of a sting

(a) Cylindrical afterbody immediately after starting of external stream.
(b) Cylindrical afterbody fully developed flow.
(c) Boattailed afterbody.
(d) Boattailed afterbody with sting.

FIGURE 7.—Sketch of flow mechanism at base.

results in changes in base pressure as well as similar changes in body pressures upstream of the base. Consequently, as would be expected, the variations in afterbody drag, which will be discussed in the following sections, are similar to changes in base pressure.

EFFECT OF STING CONFIGURATION ON DRAG

Sting cone-angle effect.—Figure 10 shows the effect of sting half-angle on afterbody pressure drag. Presented at Mach numbers from 0.80 to 1.10 are curves of base, boattail, and total afterbody pressure drag coefficients as a function of sting half-angle for each body tested. The length l of the cylindrical section ahead of the sting cone is zero. These data show that in spite of the large differences in absolute drag values, the curves are similar for all afterbodies in that the drag became lower with increasing sting cone angle. This trend occurred primarily because of the more rapid rate of turning of the external stream with increasing sting cone angle. It should be pointed out that the downstream end of the sting cones was limited to a diameter of 3.75 inches.

Since the curves of figure 10 tended to be linear, slopes of the total afterbody drag curves were taken. These slopes are plotted in figure 11 and can be used to summarize the sting cone angle effect. For the cases where the variation of drag with sting cone angle was not linear, the slopes were taken so as to favor the low-angle portion of the curves. For afterbodies B, C, and D, the curves indicate that the sting cone angle effect near the speed of sound can be double the effect noted at higher and lower speeds. The subsonic and supersonic levels of the angle effect, $\partial C_{D,A}/\partial\theta$, for all bodies were of the order of -0.006 with the exception of afterbody H. Afterbody H was effectively the most blunt afterbody tested. It can be seen that increasing boattail angle in general caused an increase in sting-angle effect. This result was attributed to the increased turning rate required by the external stream at the model base.

Sting-cone-position effect.—Figure 12 shows the effect of varying sting-cone position along the sting on base, boattail, and afterbody pressure drag coefficients. These data were obtained with cones of 5° half-angle behind varying lengths of constant-diameter cylindrical sting sections. A drag reduction always occurred as the sting cone was moved toward the base (increasing D_b/l) and caused an increased rate of turning of the external flow. Similar trends, although of different magnitude, were noted in reference 4 for a somewhat different configuration. It should again be pointed out that the downstream end of the sting cones was limited to a diameter of 3.75 inches.

The effect of sting-cone position has been determined only for stings with a 5° cone half-angle. However, it is believed that reasonable approximations of the effect of varying cone position for stings with other cone angles can be obtained by proper interpolation of the results presented herein. A simple method of achieving this can be illustrated by use of a typical plot of drag coefficient against sting angle. (See fig. 13.) The entire range of angles and lengths is bounded by the two linear curves for $D_b/l=0$ and $D_b/l=\infty$. The curves for the intermediate values of D_b/l cannot cross over each other since the variation of drag with sting length is a monotonic function. Therefore, it would appear that the drag for intermediate values of D_b/l could be reasonably approximated with linear curves. Having the drag values for the intermediate D_b/l values for $\theta=5°$ will allow these approximation lines to be determined.

Let ΔC_D be defined as the difference between total afterbody drag coefficient at any given D_b/l and at $D_b/l=0$, and let $\Delta C_{D,max}$ be the difference between total afterbody drag coefficient at $D_b/l=\infty$ and $D_b/l=0$. Then, on the basis of the foregoing discussion $\Delta C_D/\Delta C_{D,max}$ for any D_b/l may be considered to be approximately a constant for all values of θ.

FIGURE 12.—Concluded.

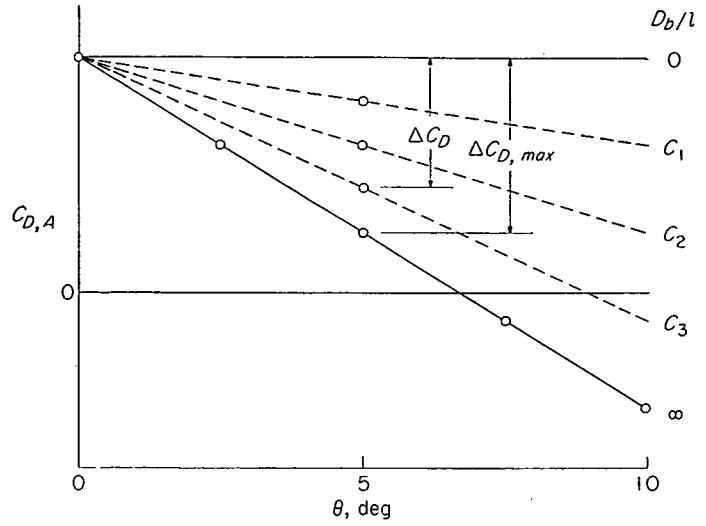

FIGURE 13.—Illustrative plot of $C_{D,A}$ against θ for various values of D_b/l.

The parameter $\Delta C_D/\Delta C_{D,max}$ represents the ratio of sting-cone effect on drag for a given sting length (D_b/l) to the maximum sting-cone effect on drag. The maximum effect is obtained when the sting length is zero ($D_b/l=\infty$). Values of $\Delta C_D/\Delta C_{D,max}$ obtained from the data of figure 12 are presented in figure 14 (a). Their variation with D_b/l is shown for each afterbody configuration through the Mach number range. Values of $\Delta C_D/\Delta C_{D,max}$ for configurations having larger values of D_b/l than those shown in figure 14 (a) may be obtained in figure 14 (b). These values are plotted against the reciprocal of D_b/l for each afterbody configuration through the Mach number range. Figure 15 presents the slopes of the linear portion of the curves shown in figure 14 (a). The magnitude of these slopes is about 1.0 for all configurations tested.

Sting-size effect.—The effect on the base, boattail, and afterbody pressure drag coefficients of varying the cross-sectional area of a cylindrical sting is presented in figure 16 for each afterbody. No sting cone was present on the sting for these data and the effect of limiting the sting length to 26 inches is believed to be negligible. In general, the effect of increasing the sting size was to decrease the drag. Average slopes of total afterbody pressure drag with the sting size parameter are plotted against Mach number in figure 17. The slopes are seen to vary from approximately zero to −0.05.

STING-INTERFERENCE CORRECTIONS

Inasmuch as a large number of afterbodies and stings were tested in combination, a general equation has been derived from the results to provide corrections to wind-tunnel drag measurements for sting-interference effects. Although the scope of the present investigation was rather large, it was necessarily limited. Therefore, any corrections obtained empirically from these results should be restricted to stings and afterbodies similar in scale and shape to those investigated. It is also recommended that the results be used only for models having Reynolds number and boundary-layer conditions that comply with those of the present tests. (See ref. 1.) The boundary layer was turbulent ahead of the model base for the present tests.

Provided the previously mentioned limitations apply, it is suggested that the derived general equation be used for obtaining sting interference corrections in the following manner. An afterbody shape should be selected from this report similar to the one for which corrections are desired. The correction due to the presence of the sting cone is

$$\Delta C_D=\left(\frac{\Delta C_D}{\Delta C_{D,max}}\right)\Delta C_{D,max} \tag{2}$$

where $\Delta C_D/\Delta C_{D,max}$ can be read from figure 14 for the proper values of D_b/l and M; or for D_b/l less than 0.5, $\Delta C_D/\Delta C_{D,max}$ can be approximated by using figure 15.

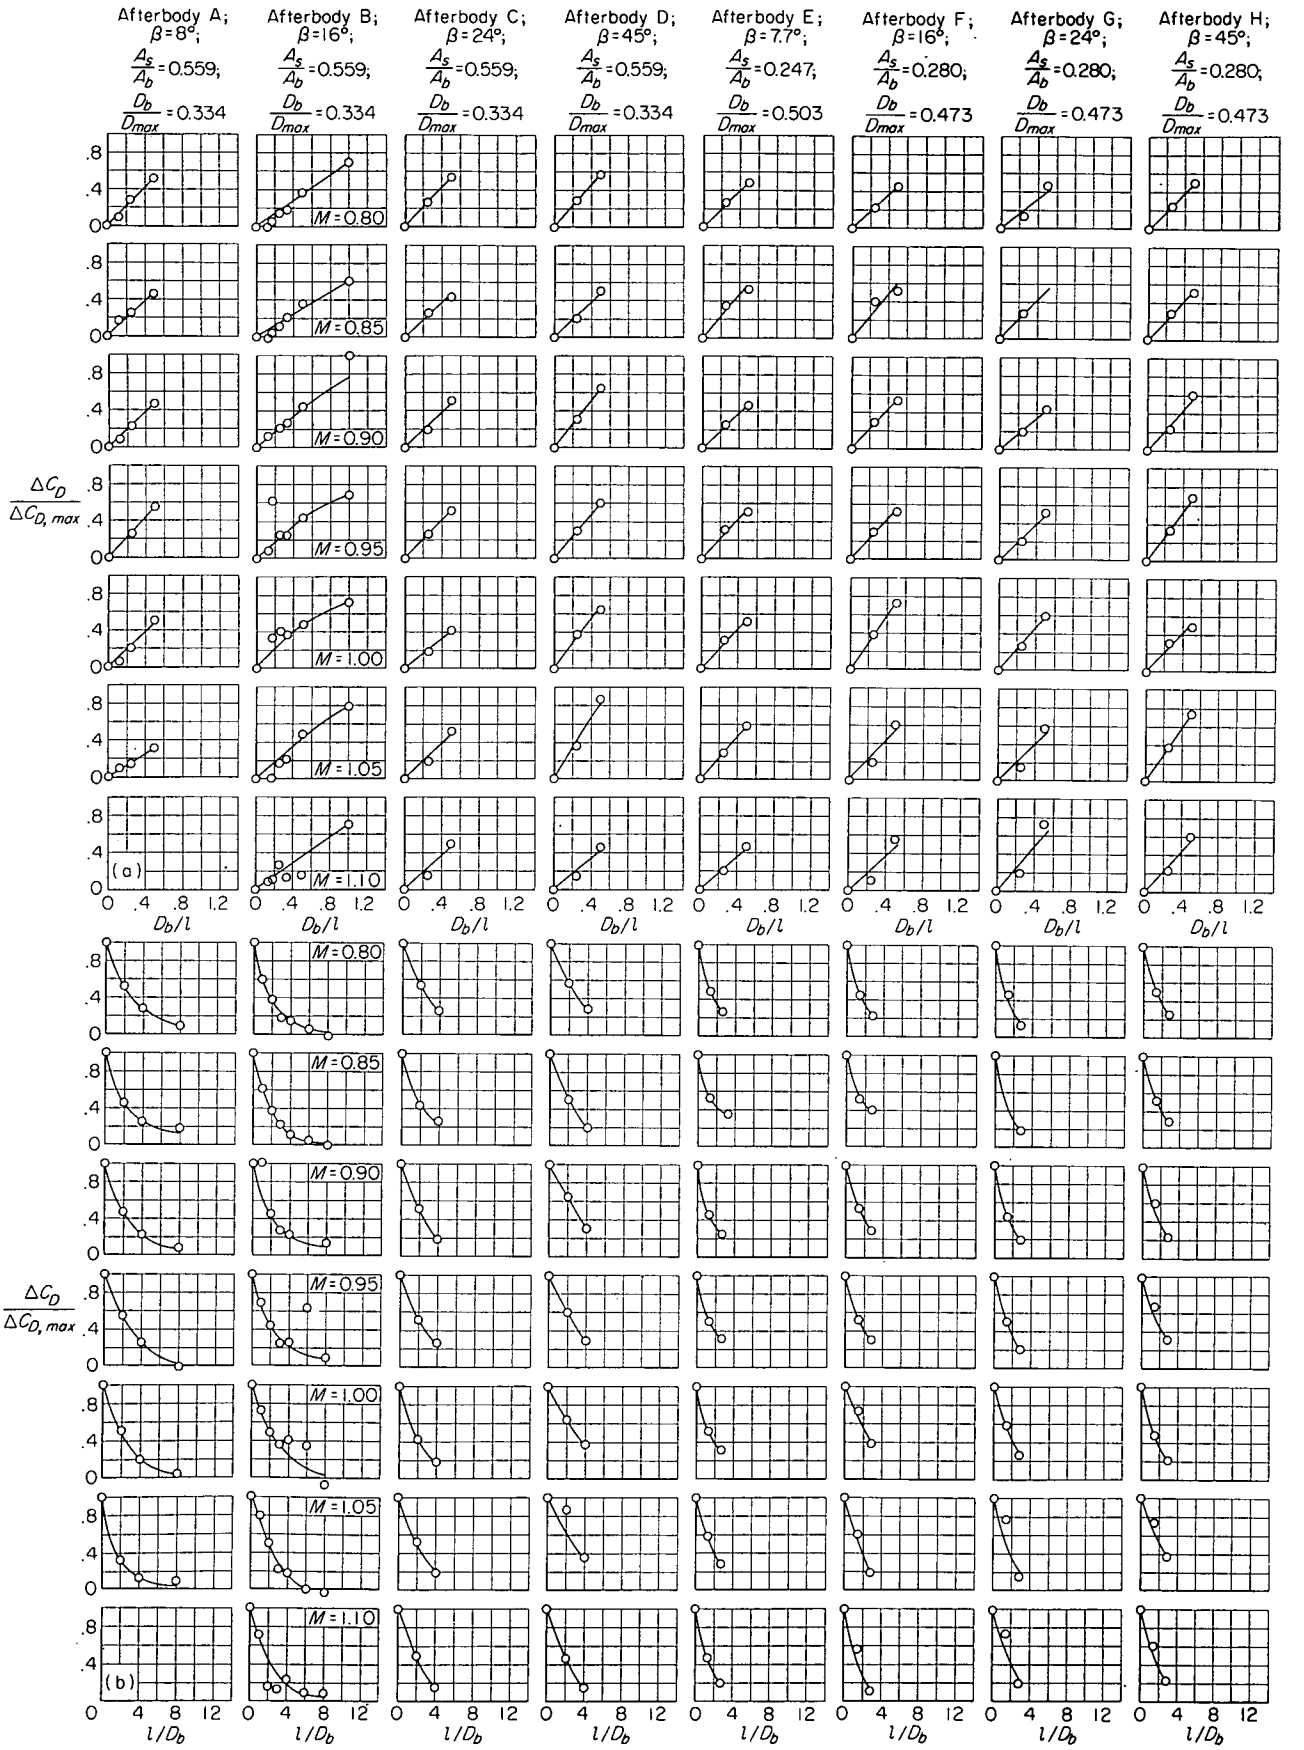
Inasmuch as the variation of C_D with sting angle is linear,

$$\Delta C_{D,max}=\theta\left(\frac{\partial C_{D,A}}{\partial\theta}\right) \tag{3}$$

where $\partial C_{D,A}/\partial\theta$ can be read from figure 11 for the correct value of M.

Substitution from equation (3) into equation (2) gives the drag correction

$$\Delta C_D=\theta\left(\frac{\Delta C_D}{\Delta C_{D,max}}\right)\left(\frac{\partial C_{D,A}}{\partial\theta}\right) \tag{4}$$



This relation will correct data for a sting with a conical section to data for a sting with only a cylindrical section.

In order to correct for the cylindrical-section diameter

$$\Delta C_D=\left(\frac{A_s}{A_b}\right)\left[\frac{\partial C_{D,A}}{\partial(A_s/A_b)}\right] \tag{5}$$

where $\frac{\partial C_{D,A}}{\partial(A_s/A_b)}$ can be read from figure 17. The complete sting correction then becomes

$$\Delta C_D=\theta\left(\frac{\Delta C_D}{\Delta C_{D,max}}\right)\left(\frac{\partial C_{D,A}}{\partial\theta}\right)+\left(\frac{A_s}{A_b}\right)\left[\frac{\partial C_{D,A}}{\partial(A_s/A_b)}\right] \tag{6}$$

FIGURE 16.—Concluded.

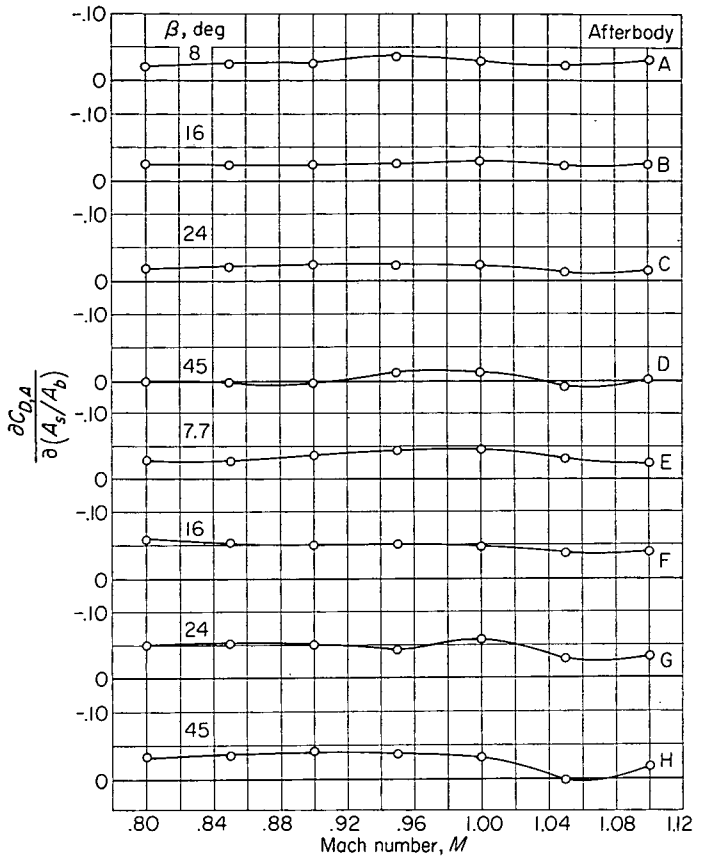

FIGURE 17.—Variation of sting-size effect with Mach number. $\frac{D_b}{l}=0$.

The correction thus obtained must be subtracted from the total-drag coefficient based on model frontal area. It should be noted that the value of ΔC_D will in all cases be negative and will result in a drag increase when data are corrected to the sting-off condition. It is estimated that the above method of obtaining sting corrections will give drag-coefficient increments generally within 0.03 of the values obtained by using the actual data points.

Corrections determined from the present results have been calculated for a model discussed in reference 5. In figure 18, the resulting corrections are compared with the corrections determined by the method described in reference 5. The model of reference 5 had $\beta=5.6°$, $D_b/D_{max}=0.416$, $\theta=4.2°$, $D_b/l=\infty$, and $A_s/A_b=0.85$. Afterbody E was chosen as most closely approximating the model. The model was tested in a closed-throat tunnel. The sting corrections in reference 5 were determined by using decreasing sting sizes and extrapolating the zero sting size. Figure 18 indicates good agreement between the present results and reference 5 for all configurations below a Mach number of 0.9. Above this speed, indications are that sting corrections are more sensitive to changes in tail configurations.

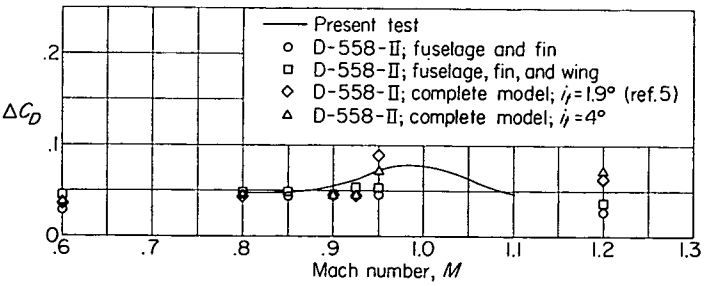

FIGURE 18.—Comparison of sting corrections from present test with corrections obtained in reference 5.

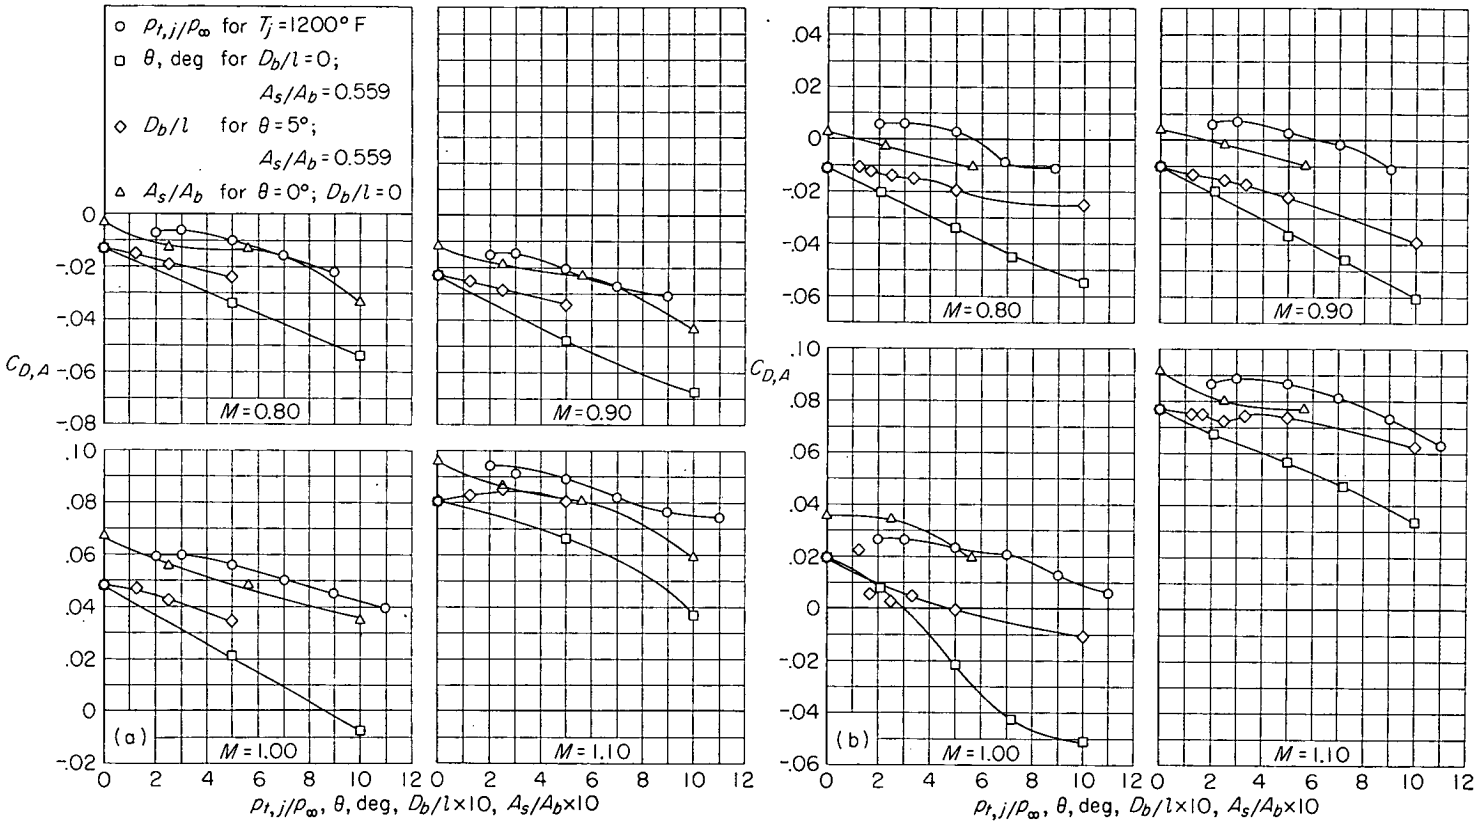

A direct comparison with the sting effects of references 4 and 6 could not be made since none of the afterbodies of this report approximate the configurations of references 4 and 6. However, it is worthy of note that the sting effects in references 4 and 6 are considerably larger than any of this test. This difference is a result of the configurations of references 4 and 6 having larger values of D_b/D_{max} (0.737 and 1.00, respectively).

SIMULATION OF JET EFFECTS WITH A STING

Jet effects studies were made on each afterbody including tests on a sting which had the shape of a free sonic jet expanding from the rear of the bodies. The sting shape was determined by measurements of a schlieren photograph of a jet at a total-pressure ratio of 5 and a temperature of 1,200° F. This sting having the same size and shape as the free jet always produced higher afterbody pressures than the jet. This result was as might be expected, since the sting could produce the solid-body effect but not the aspirating effect of the jet.

There is, however, a possibility of simulating jet effects with a sting of a different shape than that of the free jet. In figure 19 is shown the variation of afterbody pressure drag coefficient with the sting parameters of this investigation and with jet total-pressure ratio for a sonic free jet exhausting at 1,200° F.

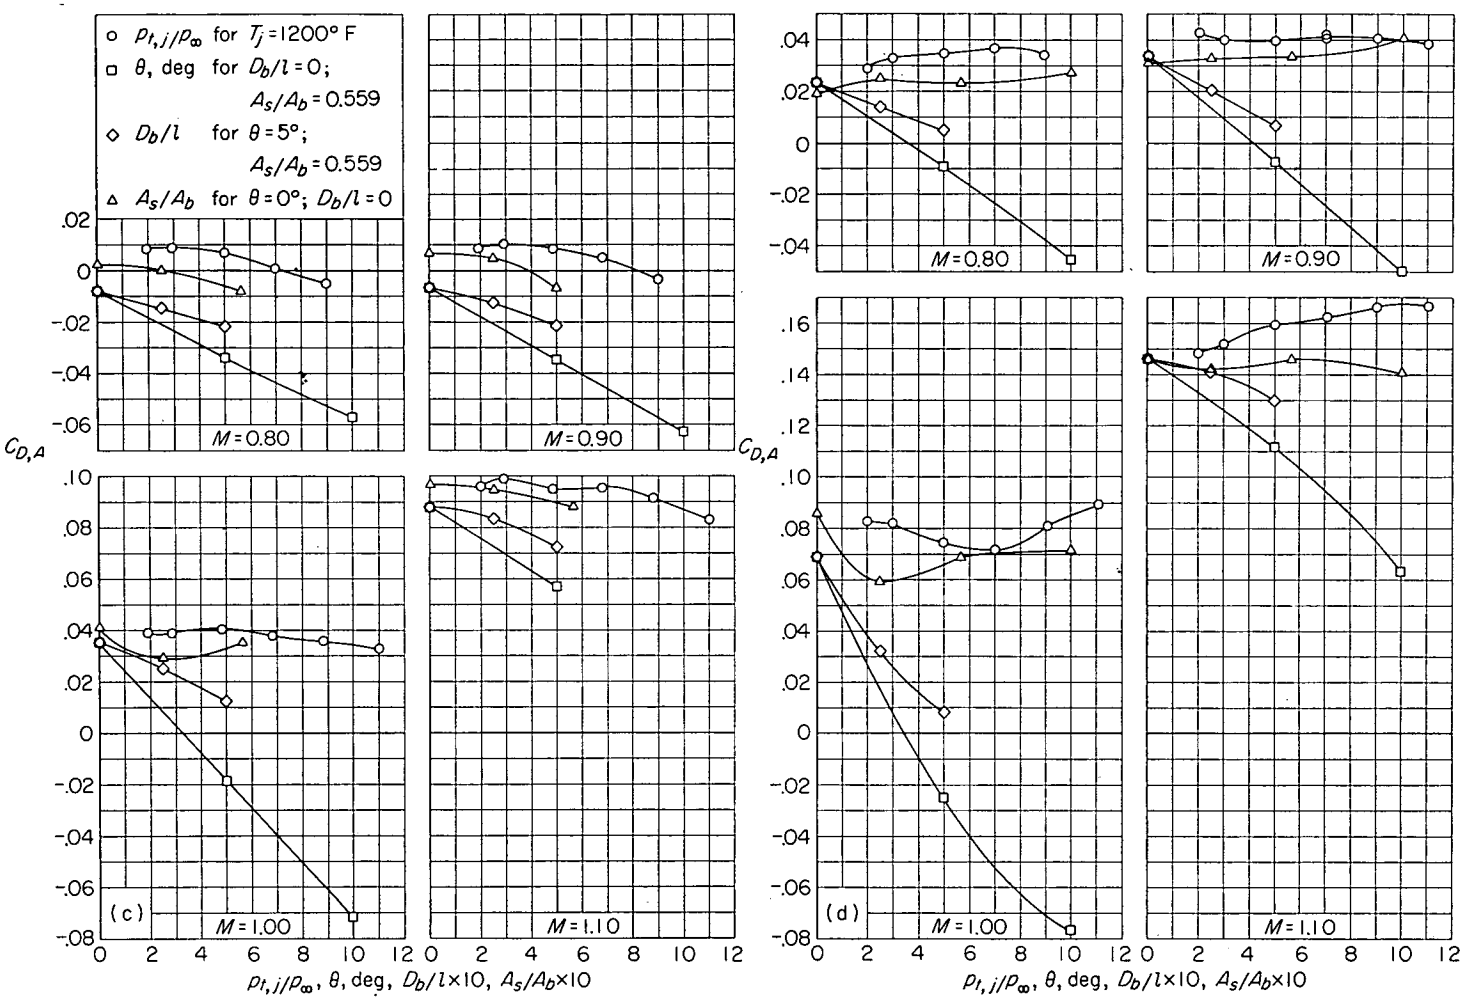

Figure 19 indicates that for the gradually contoured afterbodies a practical sting shape can be made which will produce the same drag as the jet at a given pressure ratio. As the afterbody shape becomes more blunt, the aspiration effect of the jet becomes increasingly predominant on the larger wake behind the blunt rear end, and it becomes increasingly more difficult to simulate the jet effect with solid sting shapes. This simulation is impossible for afterbodies D and H for reasonable jet-pressure ratios. Because of the small-diameter sting required, jet simulation is impractical for afterbody G. Afterbodies F and E would probably show agreement between sting and jet data at pressure ratios above those presented since for the higher jet pressure ratios, the free jet size would increase and cause higher pressures rearward of the base.

FIGURE 19.—Concluded.

CONCLUSIONS

From an investigation to determine the effects of sting-support on several body shapes, the following conclusions have been drawn:

1. The presence of a sting in general causes a drag reduction.

2. Increasing sting cone angle, decreasing sting cylindrical length ahead of the sting cone, and in general increasing sting diameter causes a drag reduction.

3. Sting-cone-angle effect increases with increasing boattail angle.

4. Approximate sting interference corrections can be made on models with afterbodies and sting supports similar in scale and geometry to those reported, provided the Reynolds number is of the same order of magnitude and the boundary layer ahead of the model base is turbulent.

5. For gradually contoured afterbodies, a sting can be made which will duplicate jet effects, but for blunt afterbodies no solid sting shape will produce the same effect as the jet.

REPORT 1354

EFFECT OF CHORD SIZE ON WEIGHT AND COOLING CHARACTERISTICS OF AIR-COOLED TURBINE BLADES[1]

By Jack B. Esgar, Eugene F. Schum, and Arthur N. Curren

SUMMARY

An analysis has been made to determine the effect of chord size on the weight and cooling characteristics of shell-supported, air-cooled gas-turbine blades. In uncooled turbines with solid blades, the general practice has been to design turbines with high aspect ratio (small blade chord) to achieve substantial turbine weight reduction. With air-cooled blades, this study shows that turbine blade weight is affected to a much smaller degree by the size of the blade chord.

The heat-transfer analysis shows that considerable saving in coolant flow is possible by utilizing a smaller number of large-chord blades rather than a larger number of small-chord blades with constant blade solidity. Generally, turbines with a blade chord of only 1 inch require about twice as much coolant as turbines with 3-inch-chord blades for a turbine-inlet temperature of 2500° R. As the blade chord is reduced below 1 inch, as it might be in small-diameter engines, the coolant-flow requirements increase very rapidly. The coolant flow required for a blade with ½-inch chord may be more than twice that required for a 1-inch-chord blade. In addition to the high coolant flows necessary, the small-chord blades are often unable to pass the required coolant flow at the pressure levels encountered in engine operation. Although this investigation was conducted specifically on corrugated-insert blades, the trends of the results are believed to be general. The study shows that, in air-cooled-turbine design, efforts should be made to use blades with as large a chord as appears feasible with regard to disk stress and aerodynamics.

INTRODUCTION

Turbine blade chord is an important consideration in the design of uncooled turbines, primarily because of its effect on turbine weight. This investigation was conducted to determine how blade chord affects the weight and cooling characteristics of air-cooled turbines. In general, the number of blades in a turbine can vary considerably without significantly affecting the turbine performance as long as the blade solidity (ratio of chord to pitch) is maintained constant. For solid uncooled turbine blades, the total airfoil weight is inversely proportional to the number of blades in the turbine (directly proportional to chord) for constant solidity. Since aerodynamic performance is only slightly affected but weight is significantly affected by the number of blades, it has been common practice among manufacturers of uncooled turbines to use a large number of short-chord high-aspect-ratio blades in their turbines. With the introduction of cooling into the turbine, some of the old rules are no longer valid, and a new look is required to determine optimum blade sizes.

In order to permit increases in turbine-inlet temperature on the order of 500° to 1000° R, it is necessary to extend coolant passages well into the blade leading and trailing edges. The trailing-edge coolant passages usually cause a thickening of the trailing edge and increased gas-passage blockage for each blade. This gas-passage blockage results in an aerodynamic performance loss. The required trailing-edge thickness for air-cooled blades is almost independent of blade size. A method of reducing the total gas blockage for the turbine is to reduce the number of blades and increase the chord to maintain solidity. As a result, the optimum number of blades with respect to aerodynamic performance may therefore decrease as trailing-edge thickness is increased.

Other factors may also suggest the use of a smaller number of larger-chord blades in air-cooled turbines. It is easier to build the required internal surface area into larger blades, and the total coolant-passage flow area for the turbine is almost directly proportional to chord size (same as weight being proportional to chord for solid uncooled blades), so that, for a given flow rate, pressure losses should be smaller when the chord is increased. In addition, total airfoil weight for blades with a portion of the interior hollowed out is no longer directly proportional to the chord for constant solidity. If the airfoils were thin hollow shells, the total airfoil weight for constant-solidity turbines would almost be independent of chord size.

In order to obtain a better understanding of the effects of chord size on air-cooled turbine blade weight, cooling effectiveness, and cooling-air pressure losses, an analytical study was made of these effects for corrugated-insert blades with chords varying from ½ to 3½ inches. In these studies two-stage turbine engines were considered, with turbine diameters varying from 15 to 35 inches, so that the turbine blade aspect ratios varied from approximately 1 to 4 for the range of chords considered. Required coolant flow and pressure losses were calculated for an engine with a sea-level compressor pressure ratio of 10 flying at a Mach number of 2.0 at 50,000 feet. While these results may not be completely general, the trends should be indicative of the effect of turbine blade chord size for a wide range of application.

ANALYSIS AND PROCEDURE

AIRFOIL WEIGHT AND SURFACE AREAS

The internal surface area per unit length of span of air-cooled turbine blades depends upon the aerodynamic profile of the blade, the blade chord, and the shell thickness, as well as the type of internal configuration. As the blade chord is varied, it generally is not possible to scale the blade directly to make the ratio of internal to external surface area remain constant. There are several reasons for this. First, there are minimum practical dimensions with regard to strength and fabrication. It is possible to vary shell thickness somewhat, but there are minimum thicknesses that depend on impact loads that the shell must withstand from foreign objects in the gas stream such as sand and carbon flakes. Minimum thicknesses of both the shell and internal configuration are determined by structural rigidity and by the effect of braze penetration for configurations that rely on brazing. In addition, the individual coolant-passage size can be reduced only so far and then the cooling-air pressure losses may become exorbitant or the passages may become plugged by brazing during fabrication or by small particles of foreign matter in the cooling air. For these reasons, both large and small blades may have an internal configuration where each passage has the same dimensions.

A type of air-cooled turbine blade that offers considerable potentiality for permitting substantial increases in turbine-inlet temperature with moderate cooling-airflow requirements is the corrugated-insert blade such as shown in figure 1(a). In this type of blade, corrugations of uniform amplitude are brazed to the inside surfaces of the blade shell. The best corrugation geometry is generally one that provides a maximum of surface area within pressure-drop limitations. This best corrugation is usually independent of blade chord as long as it can be placed inside the blade cavity, but the relative chordwise length of this corrugation is very much dependent upon the blade chord, as illustrated in figure 1

(a) Typical corrugated-insert blade.
(b) Effect of placing corrugation in small-chord blade.

FIGURE 1.—Effect of blade chord on air-cooled blade inside heat-transfer surface area.

for two blades of the same profile but with different chord lengths.

The ratio of internal to external surface area gives an indication of blade-cooling effectiveness. A practical method of determining how chord size affects the internal surface area is to make layouts of each blade to be investigated. This method was used in this report by using an assumed outside blade profile at the mean section shown in figure 1, where the maximum blade thickness is approximately 15 percent of the chord. The coolant passage was assumed to be uniform from root to tip. The outside profile changed slightly to permit taper in the blade shell. These assumptions result in a slight approximation, because in actual practice the blade profile will change along the blade span more than considered herein, but it is possible with proper design to maintain internal surface area approximately constant from root to tip. In all cases it was assumed that metal corrugations and the sheet-metal island in the center of the blade were of uniform thickness along the span. The corrugations were assumed to be 0.005 inch thick, and the island sheet metal 0.010 inch thick. The pitch of the corrugations was assumed to be 0.050 inch, and the amplitude was varied from 0.030 to 0.070 inch. This range of internal geometries has been found to have effective heat-transfer characteristics from a study of corrugations by the method of reference 1. The chordwise length of the corrugations in each blade size being known from layouts, the surface area and the cross-sectional area were calculated from relations given in reference 1. The blade shell, including leading- and trailing-edge portions where there were no corrugations, was also included in these calculations. The blade weight was calculated from the cross-sectional area using a metal density of 0.3 pound per cubic inch.

For a linear variation in metal cross-sectional area from root to tip of turbine blades, an expression for the centrifugal-stress distribution in the blades can be derived in the following manner. The cross-sectional-area distribution along the span can be expressed by

$$\frac{A-A_x}{A_t-A_x}=\frac{r-r_x}{r_t-r_x} \tag{1}$$

or

$$A=A_x\left[1-\frac{r-r_x}{r_t-r_x}\left(1-\frac{A_t}{A_x}\right)\right] \tag{2}$$

where r and A are variables. The stress is obtained from

$$\sigma_x=\frac{\mathscr{F}_x}{A_x}=\int_{r_x}^{r_t}\frac{r\omega^2}{A_x}\,dM \tag{3}$$

where

$$dM=\frac{12\Gamma A\,dr}{g} \tag{4}$$

and the constant 12 is a conversion from feet to inches. Combining equations (2) to (4) and integrating give the following expression:

$$\sigma_x=\frac{12\omega^2r_t^2\Gamma}{g}\left\{\frac{1}{2}\left[1-\left(\frac{r_x}{r_t}\right)^2\right]-\frac{1}{3}\frac{1-\left(\frac{r_x}{r_t}\right)^3}{1-\frac{r_x}{r_t}}\left(1-\frac{A_t}{A_x}\right)+\frac{1}{2}\left[\frac{r_x}{r_t}+\left(\frac{r_x}{r_t}\right)^2\right]\left(1-\frac{A_t}{A_x}\right)\right\} \tag{5}$$

If it is noted that $U_t=\omega r$ and if terms are collected, equation (5) can be written

$$\sigma_x=\frac{12U_t^2\Gamma}{g}\left\{\frac{1}{2}\left[1-\left(\frac{r_x}{r_t}\right)^2\right]-\frac{1}{6}\left[2-\frac{r_x}{r_t}-\left(\frac{r_x}{r_t}\right)^2\right]\left(1-\frac{A_t}{A_x}\right)\right\} \tag{5a}$$

By letting $r_x=r_h$ and $A_x=A_h$ in equation (5a), the centrifugal stress at the blade root can be calculated; and by multiplying both sides of equation (5a) by $(1200/U_t)^2$ an equivalent root stress can be obtained. The resulting values of equivalent root stress $\sigma(1200/U_t)^2$ are then, of course, the actual stresses for a tip speed of 1200 feet per second, which is a representative turbine speed. The stress values are presented in this manner so that they can be quickly converted to the stress that would result for any other tip speed of interest.

TABLE I.—TEMPERATURES, PRESSURES, AND OTHER CONDITIONS USED IN ANALYSIS

Assigned conditions:	
Engine compressor pressure ratio	10 at sea-level-static conditions; 6.3 at flight conditions
Flight altitude, ft	50, 000
Flight Mach number	2. 0
Turbine-inlet temp., °R	2500
Ram recovery pressure ratio	0. 87
Compressor adiabatic efficiency	0. 85
Turbine adiabatic efficiency	0. 85
Relative Mach number of gas entering turbine	0. 6
Mach number of gas at turbine exit	0. 5
Max. centrifugal turbine blade root stress for taper factor of 0.7, psi	30, 000
Second-turbine-stage hub-tip radius ratio	0. 6
Turbine blade stress-ratio factor	1.0 (except fig. 11)
Turbine blade solidity at mean section (both stages)	1. 5
Calculated conditions:	
First-turbine-stage hub-tip radius ratio	0. 73
Turbine tip speed (same for both stages), ft/sec	1095
Compressor-discharge temp. (blade root cooling-air temp. for most calculations), °R	1247
Compressor-discharge total pressure, lb/sq ft	10, 420
Static gas pressure at blade tip, lb/sq ft	7340 (first-stage rotor); 4000 (second-stage rotor)
Effective gas temperature, °R	2390 (first-stage rotor); 2048 (second-stage rotor)
Constant K_4 in gas-to-blade heat-transfer coefficient, eq. (13)	0.721 (first-stage rotor); 0.467 (second-stage rotor)

TURBINE DESIGN

In order to make this analysis representative of conditions that might be encountered in cooled turbojet engines, a two-stage turbine was designed for an engine with a sea-level-static compressor pressure ratio of 10. The engine design point was taken for a flight Mach number of 2.0 at 50,000 feet. Heat-transfer calculations were also made for these conditions. The turbine was designed according to the methods in reference 2, and temperature and pressure conditions at various stations through the engine were calculated by means of reference 3. The assigned conditions and the resulting calculated conditions are listed in table I. The compressor pressure ratio of 6.3 at a flight Mach number of 2.0 would result from constant-mechanical-speed operation for an arbitrarily assumed compressor.

The assigned turbine conditions result in a conservative turbine design. In a conservative turbine there is considerable freedom in the choice of a blade profile. An assumed profile was used in this investigation that is believed to be typical of profiles that may be encountered in air-cooled engines. For the sake of simplicity, the same profile was used for both the first and second stages and for all chord lengths. The profile is shown in figure 1.

In order to investigate a representative range of engines, turbine diameters of 15, 25, and 35 inches were considered, with a corresponding size change in the rest of the engine. The turbine design was the same for all diameters, but of course the blade size varied with the diameter.

BLADE COOLANT-FLOW REQUIREMENTS

The coolant-flow requirements for air-cooled turbine blades depend on the gas-to-blade heat-transfer coefficients, the blade temperature, the gas temperature, the coolant temperature at the blade base, and the coolant-passage geometry. In this analysis all these factors except the gas temperature vary for one reason or another. The calculation methods include each of these effects.

Gas-to-blade heat-transfer coefficient.—The average Nusselt number Nu, from which the average gas-to-blade heat-transfer coefficient h_o is obtained, can be found from the following correlation equation (ref. 4):

$$Nu=\overline{F}(Re)^{z}(Pr)^{1/3} \tag{6}$$

The reference length in the Nusselt and Reynolds numbers is l_o/π, and $\overline{F}$ and z are functions of transition ratio and Euler number of the blade.

The Reynolds number in equation (6) may be written as

$$Re=\left(\frac{w_g\sqrt{T'_g}}{A_{fl,g}P'_g}\right)_T\left(\frac{P'_g}{\sqrt{T'_g}}\right)_T\left(\frac{t_g}{t_b}\right)\left(\frac{l_o/\pi}{\mu_{g,b}g}\right) \tag{7}$$

By combining equations (6) and (7), the gas-to-blade heat-transfer coefficient can be expressed by

$$h_o=\frac{\overline{F}k_{g,b}}{\left(\frac{l_o}{\pi}\right)^{1-z}}\left[\left(\frac{w_g\sqrt{T'_g}}{A_{fl,g}P'_g}\right)_T\left(\frac{P'_g}{\sqrt{T'_g}}\right)_T\left(\frac{t_g}{t_b}\right)\left(\frac{1}{\mu_{g,b}g}\right)\right]^{z}Pr^{1/3} \tag{8}$$

The term $w_g\sqrt{T'_g}/A_{fl,g}P'_g$ is a function of gas Mach number and is essentially constant for Mach numbers between 0.7 and 1.0 (max. variation is about 9 percent). A Mach number of 0.7 is probably representative for most turbine designs; consequently, $w_g\sqrt{T'_g}/A_{fl,g}P'_g$ was evaluated from reference 5 for that Mach number. For this investigation variations in gas pressure (due to altitude) and gas temperature were not considered. The gas fluid properties $\mu_{g,b}$, $k_{g,b}$, and Pr can be written as a function of the blade temperature:

$$k_{g,b}=K_1t_b^{0.85} \tag{9}$$

$$\mu_{g,b}=K_2t_b^{0.7} \tag{10}$$

$$Pr\approx K_3 \tag{11}$$

The perimeter of the blade used in this analysis is $2.34(c)$. The perimeter can then be expressed in terms of the turbine tip diameter and the blade aspect ratio and hub-tip radius ratio as follows:

$$l_o=2.34\left(\frac{D_T}{2\mathscr{A}}\right)\left(1-\frac{r_h}{r_t}\right)_T \tag{12}$$

Substitution of equations (9) to (12) into equation (8) results in

$$h_o=\frac{K_4}{t_b^{1.7z-0.85}}\left(\frac{\mathscr{A}}{D_T}\right)^{1-z} \tag{13}$$

where K_4 is a grouping of all the constant terms in equations (8) to (12).

In reference 6, ten blade profiles were analyzed, including both impulse and reaction blades. An average value of z for these ten blades is 0.70. Using the value of z for rotor blades, equation (13) becomes

$$h_o=\frac{K_4}{t_b^{0.34}}\left(\frac{\mathscr{A}}{D_T}\right)^{0.3} \tag{14}$$

Equations (13) and (14) can also be written

$$h_o=\frac{K_5}{t_b^{1.7z-0.85}c^{1-z}}=\frac{K_5}{t_b^{0.34}c^{0.3}} \tag{15}$$

In this investigation K_4 was evaluated for each turbine stage; and then the variations in h_o with turbine diameter, blade aspect ratio, and blade temperature were calculated by use of equation (14). The turbine blade temperature t_b varies along the span because of heating of the cooling air.

Blade-to-coolant heat-transfer coefficient.—The boundary-layer flow inside air-cooled blades may be laminar, turbulent, or in transition. In laminar flow the heat-transfer correlation equation depends on the coolant-passage aspect ratio α (ref. 7). For turbulent flow the Nusselt number can be written

$$\frac{Nu}{Re}=\frac{0.0199}{Re^{0.2}} \tag{16}$$

for a constant Prandtl number of 0.7 (ref. 8). In the transition region there is considerable uncertainty as to what the heat-transfer rates may be. In this analysis it was assumed that Nu/Re was a constant in this transition region and at the same value that results from turbulent flow for a Reynolds number of 8000. This transition region was assumed to extend down to a Reynolds number that would also result in the same Nu/Re in laminar flow. These heat-transfer correlations are represented graphically in figure 2 and mathematically in table II(a). In this manner the Reynolds number at which the flow changes from laminar to transition varies slightly with coolant-passage aspect ratio. The fluid properties of the coolant were based on the film temperature.

For finned coolant passages an effective heat-transfer coefficient h_f is required. The equation for evaluating h_f is given in reference 9 as

$$h_f=\frac{h_i}{m+\tau}\left(\frac{2\tanh\phi L}{\phi}+m\right) \tag{17}$$

The effective coefficient is related to the inside coefficient by a function of the metal thermal conductivity and the ratio of the inside wetted perimeter to the outside perimeter. For the limiting case with infinite thermal conductivity, equation (17) becomes

$$\begin{aligned} h_f&=\frac{h_i}{m+\tau}(2L+m) \\ &=h_i\frac{l_i}{l_o} \end{aligned} \tag{18}$$

Equation (17) is evaluated for corrugated surfaces in reference 1 for corrugations having the same chordwise length as the outside surface that is exposed to the gas stream. In corrugated-insert blades it generally is not possible to extend the corrugations around the entire inside periphery of the blade. At the leading and trailing edges there are usually areas where there is not room to place the corrugations. For this reason, an evaluation of an entire turbine blade using the value of h_f for a corrugated surface gives an optimistic answer. In this analysis it was assumed that the ratio of the effective coefficient for the entire blade to that for a corrugated surface was the same as the ratio of the inside and outside wetted perimeters for the entire blade to that for the corrugated surface, which is expressed in equation form as

$$\frac{(h_f)_b}{(h_f)_c}=\frac{\left(\frac{l_i}{l_o}\right)_b}{\left(\frac{l_i}{l_o}\right)_c} \tag{19}$$

where $(h_f)_c$ is evaluated from reference 1 for the geometry used in the blade. This relation assumes that conduction effects are the same for the entire blade as they are for the corrugations.

Spanwise blade temperature distribution.—The local blade temperature $t_{b,x}$ can be obtained from the following heat balance:

$$\frac{q}{S}=h_o(t_{g,e}-t_{b,x})=(h_f)_b(t_{b,x}-T'_{a,x}) \tag{20}$$

where $T'_{a,x}$ is the total cooling-air temperature relative to the blade at distance x from the blade root. This temperature is approximately equal to the effective air temperature at this

TABLE II.—EXPRESSIONS FOR BLADE COOLANT-PASSAGE NUSSELT NUMBER AND FRICTION COEFFICIENT

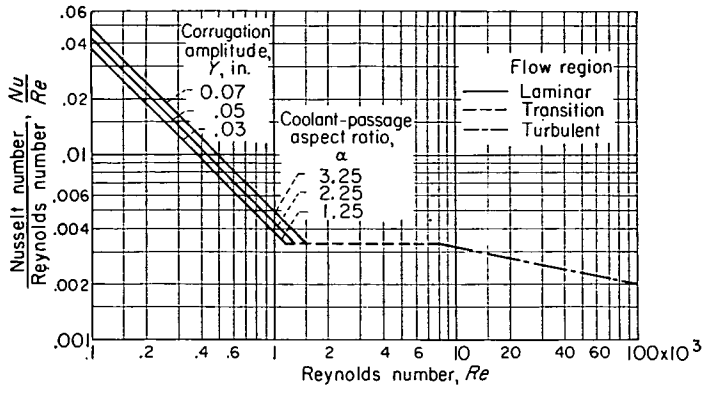

FIGURE 2.—Heat-transfer correlations for air-cooled-blade coolant passages.

point for subsonic Mach numbers. In this analysis the blade span was divided into ten equal increments, and a stepwise calculation procedure was used to calculate the temperature at each increment. To obtain the coolant-air temperature rise in each increment, the following heat balance was written:

$$q+w_aE=h_o l_o \Delta x(t_{g,e}-t_{b,x})+w_aE=w_a c_{p,a}\Delta T'_a \tag{21}$$

where the pumping work E done on the cooling air over the increment Δx is

$$E=\frac{\omega^2 r_x \Delta x}{gJ} \tag{22}$$

Combining equations (21) and (22) results in

$$\Delta T'_a=\frac{h_o l_o \Delta x}{w_a c_{p,a}}(t_{g,e}-t_{b,x})+\frac{\omega^2 r_x \Delta x}{gJc_{p,a}} \tag{23}$$

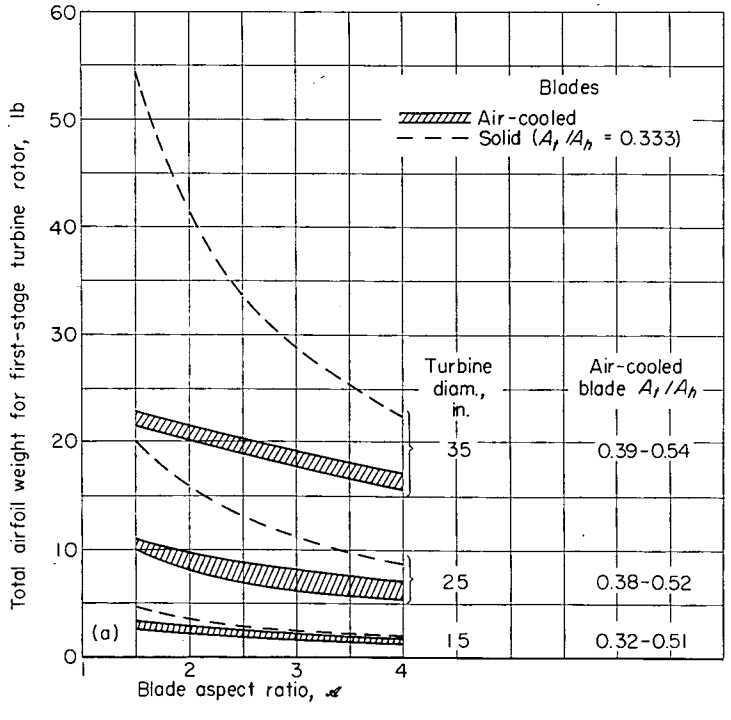
The blade temperature used to evaluate film temperature and fluid properties and to calculate T'_a at each increment was that temperature calculated in the previous increment. The spanwise temperature variations in the blade are generally small enough that this approximation has little or no effect on the final results.

Required cooling airflow.—The allowable blade temperature distribution for turbine blades depends on the spanwise blade stress distribution, the stress-rupture properties of the blade material, and the stress-ratio factor, as discussed in reference 10. The required cooling airflow is that which results in a curve of calculated blade temperature against blade span that is tangent to a curve of allowable blade temperature. This cooling airflow was found by an iterative procedure. A maximum difference of 2° between the calculated and allowable blade temperature was permitted at the blade critical section (spanwise position where difference in calculated and allowable temperature is smallest) in determining the required cooling airflow.

BLADE PRESSURE LOSSES

The cooling-air pressure change through the turbine blades was calculated by the method of reference 5 by using the required cooling airflow from the calculations described previously. The blade was divided into five equal increments for these calculations. The friction coefficients used were the same as those that can be read from figure 3 of reference 1, using the same values of coolant-passage aspect ratio α as shown in figure 2 of this report, except that in the transition region the friction coefficient was assumed to be independent of Reynolds number in exactly the same manner as Nu/Re was assumed to be independent of transition Reynolds number in figure 2. Equations for the friction coefficient are given in table II(b) in terms of $4C_{fr}$ for convenience in the use of the calculation procedure of reference 5.

The cooling-air pressure at the blade base was assumed to be 90 percent of the compressor-discharge pressure, which allowed for duct losses and some losses in velocity head. It was assumed that, if the calculated coolant static pressure at the blade tip was equal to or greater than the static gas pressure at the blade tip and if the Mach number at the tip was subsonic, then the blade was satisfactory with respect to loss. The static gas pressure at the blade tip was calculated from the turbine velocity diagram that was required to drive the compressor at the assumed flight conditions.



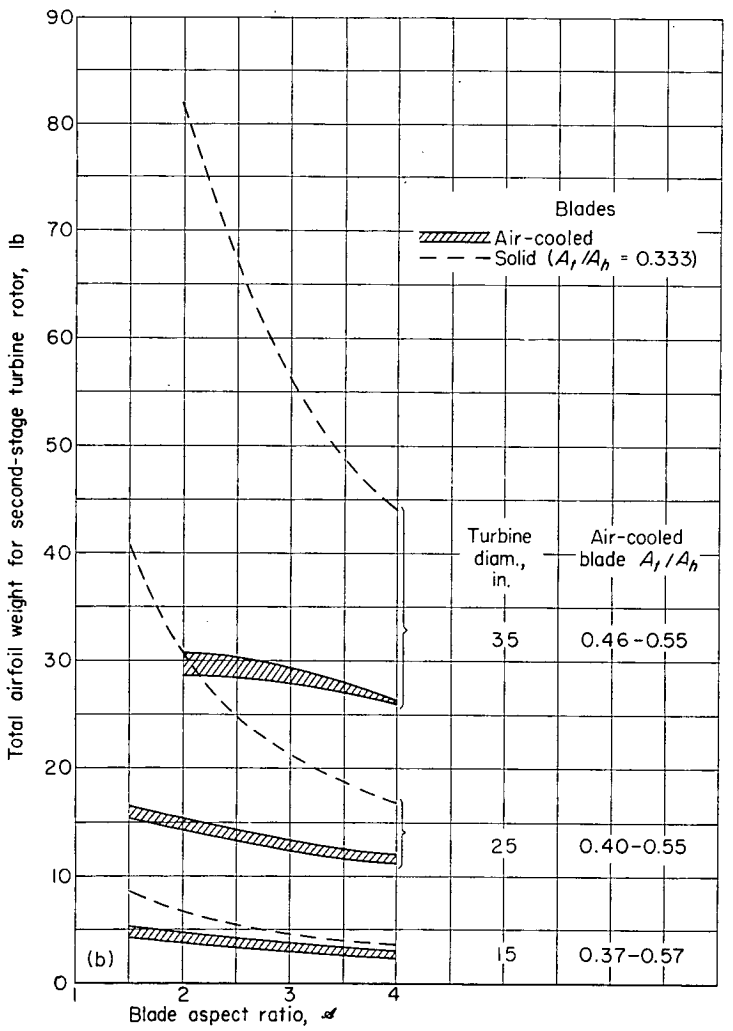
CALCULATION PROCEDURE

The entire calculation procedure for this analysis was set up in equation form, including the pressure-loss calculations and the relation between temperature and the 100-hour stress-rupture properties of A–286 alloy, the turbine blade material assumed for this analysis. The calculations were then made by an IBM 650 Magnetic Drum Data Processing Machine. Temperatures, pressures, and other conditions used in this analysis are listed in table I.

RESULTS AND DISCUSSION

AIRFOIL WEIGHT, STRESS, AND AREAS

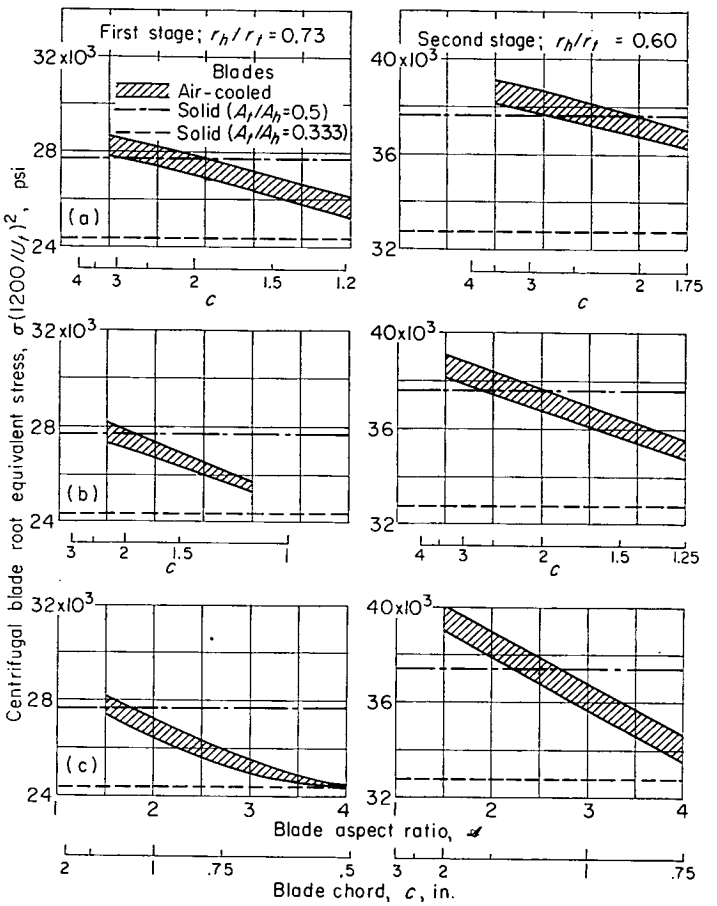
Weight.—The total airfoil weights of all the rotor blades in a turbine stage are plotted against blade aspect ratio in figure 3 for both the first and second stages of the turbines for turbine diameters of 15, 25, and 35 inches. Although the



(a) First stage. Hub-tip radius ratio, 0.73.

FIGURE 3.—Variation of turbine blade airfoil weight with turbine diameter and blade aspect ratio.

analysis presented in this report is a study of the effects of blade chord on weight and cooling characteristics of air-cooled blades, it is more convenient to plot most of the results of the analysis against blade aspect ratio, because the range of aspect ratio is common to turbines of different diameters, while the range of chord size varies considerably for different diameter turbines.



The weight of the air-cooled blades is represented by a shaded band. This band covers the range of weight values for the corrugation configurations considered herein. For turbine diameters of 25 and 35 inches, corrugation amplitudes of 0.03, 0.05, and 0.07 inch were considered, with an outside-shell thickness tapering from 0.045 inch at the root to 0.015 inch at the tip. For the 15-inch-diameter turbine, corrugation amplitudes of 0.03 and 0.05 inch were considered, with an outside-shell thickness tapering from 0.030 to 0.010 inch. Also shown in the figure are weights of solid uncooled blades having the same cross-sectional area at the root section of the blade and an aerodynamic taper of 3 to 1 from root to tip.

Two important conclusions may be drawn from figure 3. First, air-cooled blades are considerably lighter than solid blades having the same root profile, particularly for large

(b) Second stage. Hub-tip radius ratio, 0.60.

FIGURE 3.—Concluded. Variation of turbine blade airfoil weight with turbine diameter and blade aspect ratio.

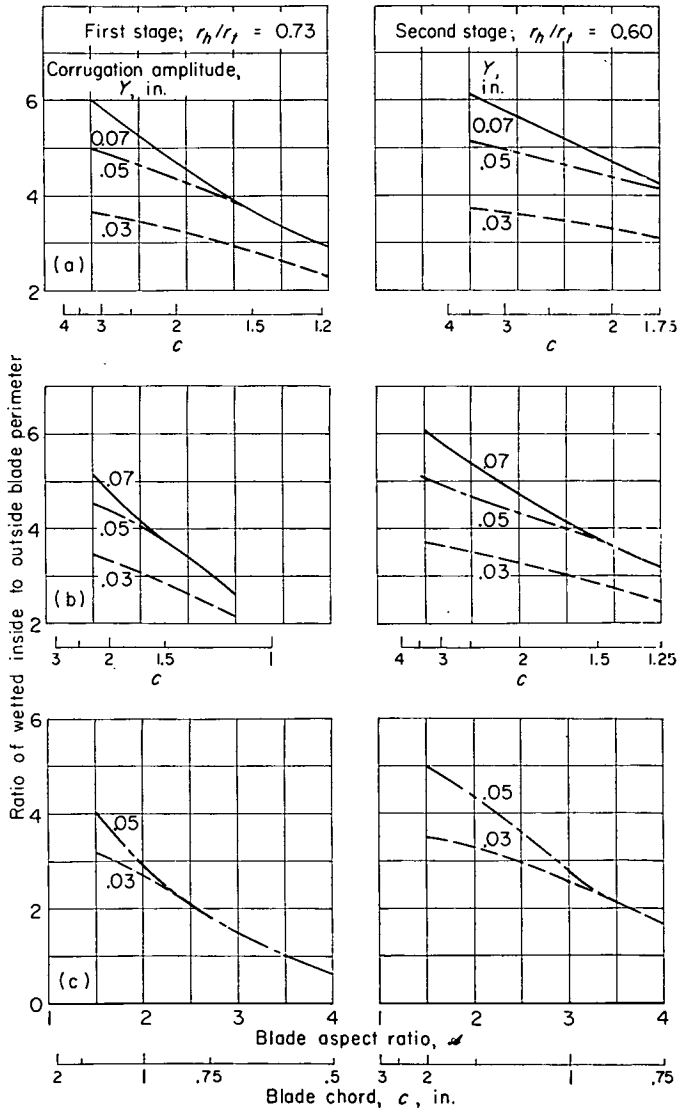
FIGURE 4.—Air-cooled-turbine blade root stresses.

turbine diameters; and second, as aspect ratio (or chord) is varied, the total blade weight for the turbine is affected to a much smaller degree for air-cooled blades than for solid blades. Air-cooled blades of very low aspect ratio can be used, and the total turbine blade weight will still be lighter than with solid blades of high aspect ratio.

Airfoil weight does not show the entire picture with regard to turbine weight, however. The use of low-aspect-ratio blades requires alterations in the turbine disk design to support the longer chords. Generally, the longer chords will probably result in an increase in disk weight, so that the total turbine weight will increase with chord more than indicated in figure 3. Some types of disk structure, such as multiple disk wheels, may make it possible to increase chord with little or no increase in disk weight. An evaluation of disk weight, however, is beyond the scope of this report. A rather complete design study is required before representative variations in disk weight with blade chord can be made.

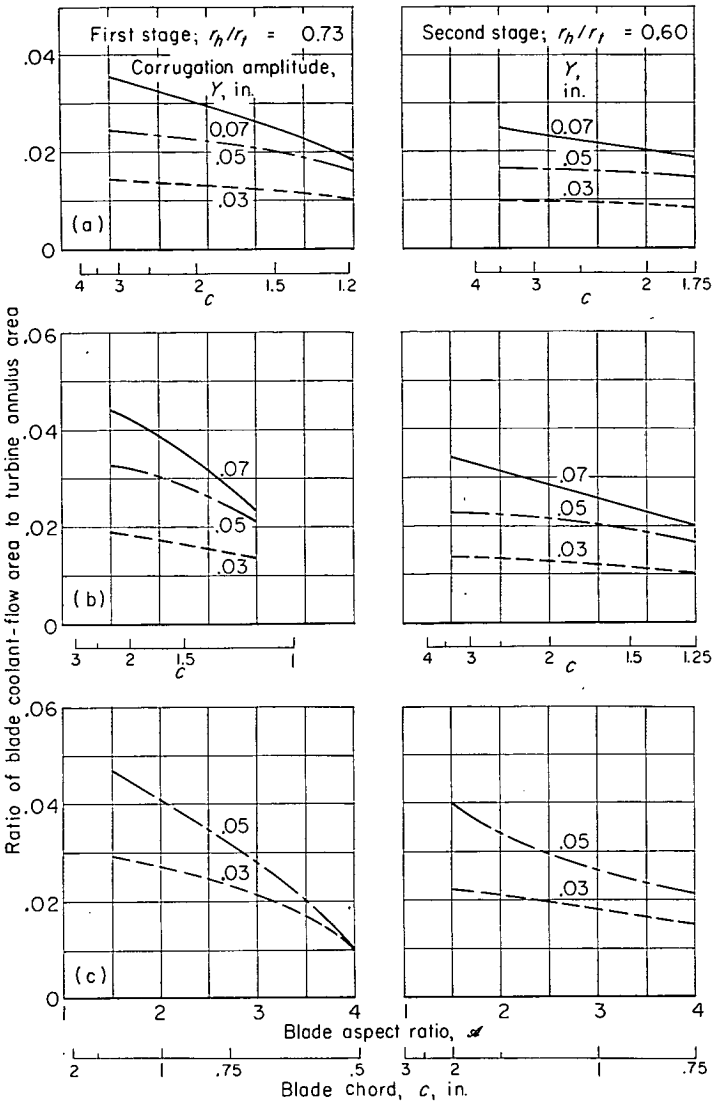
For constant-solidity turbines the total airfoil weight of solid blades varies inversely as the blade aspect ratio to the first power. (The individual blade weight varies inversely as the square of the aspect ratio.) In the study of air-cooled blades included herein, it was found that the total blade airfoil weight for the turbine varied inversely as the aspect ratio to a power varying between 0.1 and 0.65, depending on the turbine diameter. In general, the lower exponents ac-



company the large turbines (larger physical size of blades). For the 35-inch turbine the exponent was found to be about 0.1 for the second stage and about 0.3 for the first stage. For the 15-inch turbine the exponent was about 0.5 for the second stage and 0.65 for the first stage. The reason for this is obvious: With the smaller blades the shell and corrugations occupy a much larger portion of the cross-sectional area (the proportion of flow area decreases) than with the larger blades, so that the small blades more nearly approach the weight variation that occurs with solid blades.

Stress.—From the root and tip cross-sectional areas that were determined for each blade configuration, the centrifugal root equivalent stress was calculated. The results are plotted against both blade aspect ratio and chord in figure 4. Subsequent figures are plotted in a similar manner. The stress values are presented as shaded bands, and they cover the same range of variables as discussed in connection with figure 3. For reference, root stresses are also shown for solid blades with tip-to-root area ratios of 0.5 and 0.333. The area ratios for the air-cooled blades vary with blade size. The shells of all the blades have an area ratio of 0.333, but the sheet metal making up the corrugations and islands in the blades is untapered. More corrugations can be installed in the larger-chord blades (low aspect ratio), which will help the heat-transfer characteristics; but the addition of this untapered sheet metal results in higher area ratios and thus higher root stresses.

Figure 4 shows that, generally, the centrifugal root stresses of corrugated-insert air-cooled blades will be of the same order of magnitude as those for solid blades with tip-to-root area ratios varying from 0.5 to 0.333. With low hub-tip radius ratios (on the order of 0.60 shown for the second stage) and for blade aspect ratios below 2.5 or 3, the air-cooled-blade stresses are likely to be higher than those for solid blades with an area ratio of 0.5. Figure 4 also compares tip-to-root cross-sectional-area ratios for air-cooled blades for various coolant-passage configurations, blade aspect ratios, and hub-tip radius ratios; however, a comparison based on root stress is probably of more general interest.



Inside heat-transfer surface area.—The amount of surface area that can be placed inside air-cooled turbine blades relative to the blade outside surface area affects the efficiency of blade-cooling. The ratio of the wetted perimeter on the inside of the blade to the outside perimeter is plotted in figure 5 as a function of blade chord and aspect ratio, turbine diameter, and corrugation amplitude Y. The ratio of perimeters can vary by as much as 7 to 1 as the blade chord is varied from about 1.5 to 0.5 inch (aspect ratio varying from 1.5 to 4) for the 15-inch-diameter turbine. For the larger turbine engines and the corresponding larger chords, the ratio of perimeters varies about 2 to 1 for the same range of aspect ratio. If it were possible to scale blade coolant passages geometrically, the ratio of inside to outside surface area would remain constant as chord is varied. As mentioned previously, this is not practical for turbine blades. The two sketches in figure 1 illustrate the problem involved when the blade chord is shortened and the same corrugation geometry is used for both blade sizes. The smaller sketch shows that it may not even be possible to attach separate corrugations to the portions of the shell on both the suction and pressure surfaces of the blade. It is obvious that the small blade is impractical as shown. A different internal configuration is required, possibly one in which the corrugation amplitude changes along the chord so that the corrugations will contact both shell surfaces. The sketch is shown here only to illustrate some of the problems involved in trying to obtain large internal surface areas in short-chord blades.

Figure 5 shows that in all cases the ratio of heat-transfer surface on the inside of blades to that on the outside can be increased substantially by increasing blade chord (reducing aspect ratio). For very small turbine blades with chords on the order of 0.5 inch, the inside surface area becomes less than the outside surface area. This condition makes cooling the turbine blades extremely difficult.

FIGURE 6.—Effect of turbine blade size on coolant-passage flow area.

The corrugation amplitude also affects the amount of surface on the inside of the blade for a fixed corrugation pitch. It should be noted, however, that, with respect to area, frequently a corrugation of 0.07-inch amplitude is little or no better than one of 0.05-inch amplitude. The conduction path is longer with the larger amplitude, and the inside heat-transfer coefficients will be lower for a given mass velocity for the large corrugations, so that the extra heat-transfer surface area with the 0.07-inch-amplitude corrugations does not necessarily result in a blade that requires the smallest quantity of coolant flow. The large amplitude may be advantageous, however, because of large flow area and consequent smaller pressure losses, as is discussed subsequently.

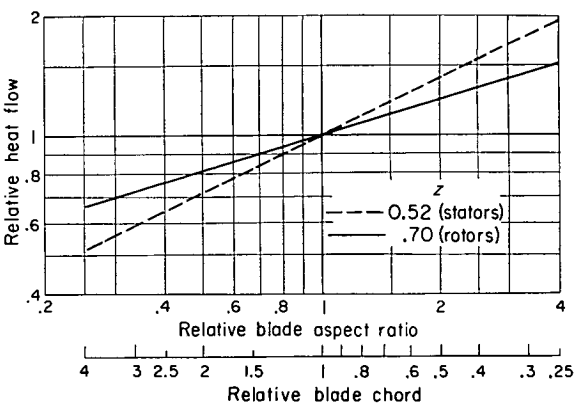
Coolant-flow area.—The ratio of the total coolant-flow area in the blades to the gas-flow area in the turbine annulus gives an indication of the quantity of compressor air that can be bled for turbine cooling for a reasonable pressure drop through the blades; or, conversely, it gives an indication of the pressure losses that will be encountered in the blades for a given coolant-flow ratio. The ratio of blade coolant-flow area to turbine annulus area is plotted in figure 6 as a function of blade chord and aspect ratio, turbine diameter, and corrugation amplitude. The trends here are similar to those for heat-transfer surface area. As the chord is decreased, the coolant-flow area is reduced, which may result in pressure-loss difficulties. It will be noted, however, that large-amplitude corrugations are almost always an advantage as far as coolant-flow area is concerned.

BLADE COOLANT-FLOW REQUIREMENTS

Heat-flow rates.—The quantity of heat that must be removed from a turbine blade by the cooling air is a function of the gas-to-blade heat-transfer coefficient, the temperature difference between the gas and the blade, and the surface area. The temperature difference between gas and blade is essentially independent of blade chord, since allowable blade temperature is determined by blade stress level (affected only slightly by blade chord) and the stress-rupture properties of the blade material. Also, for constant-solidity turbines the total blade surface area is constant. Consequently, the heat-flow rate into the blade is almost solely a function of the gas-to-blade heat-transfer coefficient h_o. Equation (15) shows that h_o varies inversely as the blade chord to the $1-z$ power.

It is evident, then, that increasing blade chord (or reducing blade aspect ratio) will reduce the cooling loads in blades. This effect is shown on a relative basis in figure 7. As stated previously, it appears that a representative value of z for rotor blades is 0.70. In reference 11 a value of z of 0.52 is given for a reaction-type blade that might be suitable for stators. The curves in figure 7 were obtained with these values of z. The figure shows that doubling the blade chord will reduce the heat-flow rate about 19 percent for rotor blades and about 28 percent for stator blades.

Required coolant-flow rates.—The combined effects of the areas shown in figures 5 and 6 and the variations in heat flow illustrated in figure 7 on the coolant flow required to cool blades for the turbines considered in this analysis are



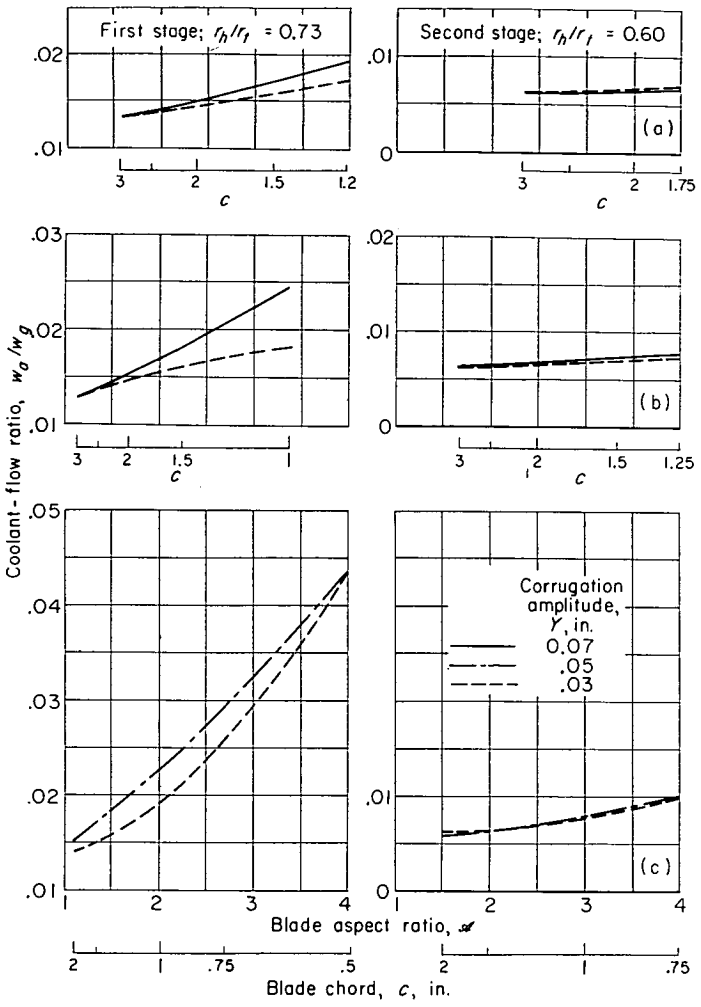


FIGURE 7.—Effect of turbine blade size on heat flow to blade.

(b) Turbine diameter, 25 inches.
(c) Turbine diameter, 15 inches.

FIGURE 8.—Effect of turbine blade size on coolant-flow requirements.

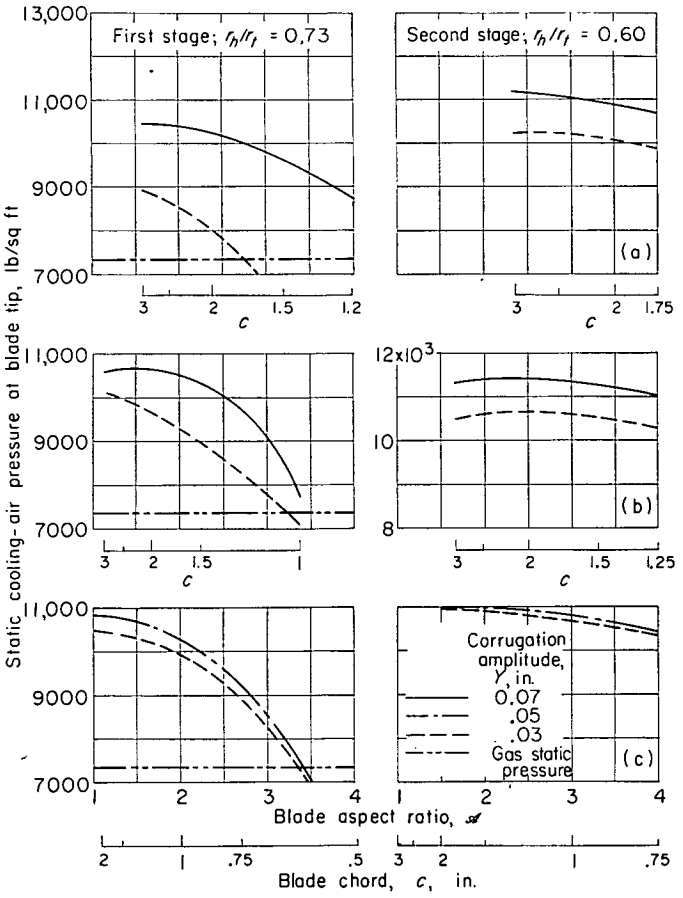
shown in figure 8, where the ratio of coolant flow to turbine gas flow is plotted against blade chord and aspect ratio. The figure shows that, invariably, as the blade chord is decreased (increased aspect ratio) the total quantity of air required for turbine cooling increases for a given corrugation configuration in the coolant passage. The reasons for this are, of course, obvious from the discussion of previous figures. However, in some cases the variations in required flow rate with blade chord and aspect ratio are quite large, particularly for small turbines, where the chord may become quite small. The analysis shows that the flow required for blades with 1-inch chord is generally about twice that required for blades with 3-inch chord. By further reducing the chord to 0.5 inch, the required coolant flow may become over twice that for blades with a 1-inch chord.

Figure 8 also shows the effect of corrugation amplitude on required cooling-airflow rate. Generally, the effect of amplitude is much smaller than the effect of blade chord on required coolant flow, particularly for the second stage of the turbines. In the second stage the gas temperature is reduced relative to that of the first stage, so that the cooling load is less severe and smaller variations due to either chord size or corrugation amplitude would be expected. Because of the small effect of corrugation amplitude on cooling-airflow requirements, the required flow for 0.05-inch corrugations is not shown for the 25- and 35-inch-diameter turbines. A few calculations were made, which showed that the flow required for a corrugation of 0.05 inch was intermediate between that required for the 0.07- and 0.03-inch corrugations.

The inside heat-transfer surface area can usually be increased by increasing the amplitude of the corrugations (fig. 5). Large surface area is usually desirable to improve cooling effectiveness, but it will be noted in figure 8 that slightly less cooling air is required with the smaller corrugation amplitude. The larger surface area of the large corrugations is more than offset by the reduced hydraulic diameter (which increases the heat-transfer coefficient) of the small corrugations.

The effect of corrugation geometry on required cooling airflow appears to have a different trend for the 15-inch-diameter turbine than for the other two diameters. For the larger-diameter turbines the difference in required cooling airflows for the 0.07- and 0.03-inch-amplitude corrugations increases with increasing aspect ratio (decreasing chord); but for the 15-inch turbine the required flows are the same for different amplitudes for an aspect ratio of 4. This effect can be explained by the fact that, for a turbine blade with 0.5-inch chord, it was not possible to place any corrugations inside the coolant cavity. For this reason the blade with 0.5-inch chord has the same flow area and same heat-transfer area for the blades represented by both the dashed and the dash-dot lines. The blade was actually a plain hollow blade.

With respect to heat transfer, figure 8 shows that there is generally considerably freedom in the choice of the corrugation amplitude, but pressure losses within the turbine blades should also be considered. Figure 8 gives no indication of the supply pressure required to force the cooling air through the blades. It is possible that under some conditions the pressure available from the engine compressor may be insufficient.



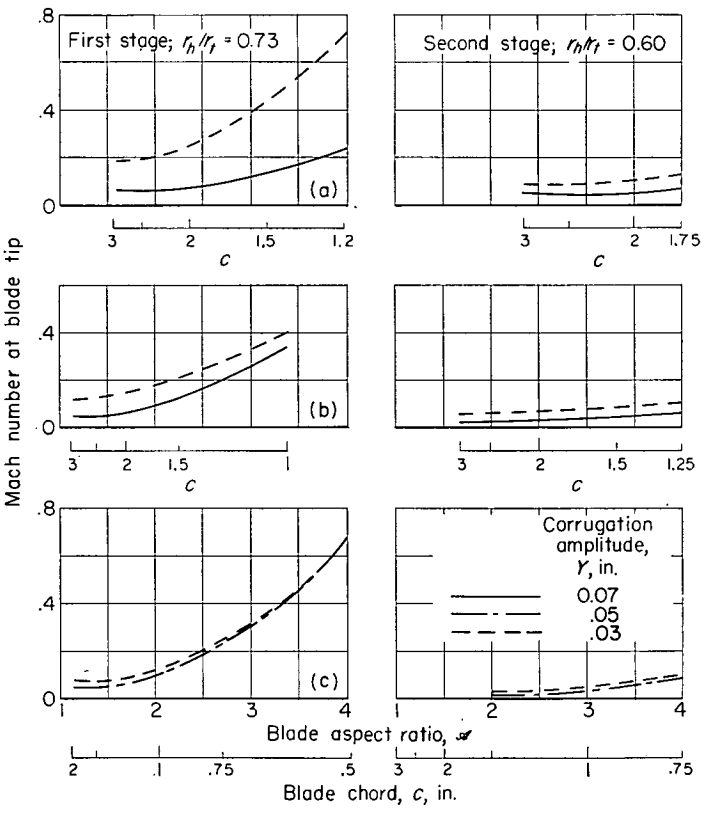
BLADE PRESSURE LOSSES

Coolant pressure at blade tip.—In order to force coolant through air-cooled turbine blades that discharge the cooling air at the blade tip, it is necessary that the static pressure of the coolant at the tip be at least as high as the static pressure of the gas at the tip. In this analysis coolant pressure losses were calculated for an inlet supply pressure that was as high as is considered feasible with the use of compressor bleed, in order to determine whether it would be possible to force the required flow through the blade. This supply pressure was 90 percent of compressor-discharge total pressure, since it seems likely that at least a 10-percent loss in pressure will result from loss of velocity head and duct losses. The cooling-

air temperature was assumed to be at compressor-discharge temperature. The static pressure of the cooling air at the blade tip is shown in figure 9 for these conditions of inlet pressure and temperature and for the flow rates shown in figure 8. The static gas pressure at the blade tip is also shown for the first stage of the turbine. For the second stage the static gas pressure is not shown, because it is much below the scale on the curves (4000 lb/sq ft, table I).

For all cases shown except one, the static cooling-air pressure at the blade tip in the first stage can become less than the static gas pressure as the blade chord is decreased. This pressure limitation very definitely limits the minimum blade chord that can be tolerated. There appear to be no pressure limitations in the second stage of the turbine.

Figure 9 shows that it may be advantageous to use large-amplitude corrugations in turbine blades to reduce pressure losses, even though the cooling-airflow requirements are somewhat higher (fig. 8). It can be observed from figure 9 that under some conditions it is possible to have a coolant pressure rise through the blades. The supply total pressure to the blades was approximately 9400 pounds per square foot; yet for many cases the tip static pressure is considerably higher than the supply total pressure. This pressure rise is a result of the pumping due to rotation.



(a) Turbine diameter, 35 inches.
(b) Turbine diameter, 25 inches.
(c) Turbine diameter, 15 inches.

FIGURE 9.—Effect of turbine blade size on static cooling-air pressure at blade tip.

Coolant Mach number at blade tip.—Relatively low coolant-passage Mach numbers are generally desirable. High Mach numbers in themselves are not necessarily a disadvantage; but they cause static-pressure losses, and the blades may choke and make it impossible to increase the coolant-flow rate without increasing the coolant density. A high coolant-passage Mach number gives little margin for error in the design. For instance, if the Mach number is 0.7, the flow rate can only be increased about 9 percent for a constant total pressure and temperature before choking will occur. The coolant Mach numbers at the blade tip are shown in figure 10 for the same pressures and flows obtained from figures 8 and 9. Comparison of figures 9 and 10 shows that, when the tip Mach number approaches a value of about 0.4, the static-pressure losses in the blade may become excessive. Figure 10 gives further indication of flow difficulties that can be encountered with small-chord blades.

GENERALITY OF RESULTS

The results of this analysis are presented for specific engine conditions. Therefore, the values of blade aspect ratio or blade chord at which cooling may become difficult cannot be considered to be general. By changing the turbine blade material, the coolant temperature, the turbine-inlet temperature, the turbine stress level, the blade stress-ratio factor, or other design conditions, cooling limitations may

(a) Turbine diameter, 35 inches.
(b) Turbine diameter, 25 inches.
(c) Turbine diameter, 15 inches.

FIGURE 10.—Effect of turbine blade size on cooling-air Mach number at blade tip.

be met at entirely different conditions from those encountered in this analysis. For example, the cooling-airflow requirements were calculated for the 35-inch-diameter turbine for a chord of 2 inches and a coolant-passage amplitude for three different stress-ratio factors (ratio of design stress to average centrifugal stress). As the stress-ratio factor is increased, the blade is designed for a higher stress level; and consequently it must operate at a lower temperature. As a result, the coolant-flow requirements increase with increasing stress-ratio factor. Figure 11 shows the effect of stress-ratio factor on cooling airflow, tip Mach number, and coolant pressure at the tip. A similar effect would result from varying the blade material. A material capable of withstanding high temperatures might have the trend exhibited for a stress-ratio factor of 1, while a material that could not withstand such high temperatures would exhibit the trends shown for a higher stress-ratio factor. As would be expected, the required coolant flow and tip Mach number increase and tip static pressure decreases with an increase in stress-ratio factor; but there are no great changes that would indicate that the trends of figures previously presented would vary greatly if a different set of conditions were chosen for the calculations. Stress-ratio factor would, of course, have a much larger effect for a blade chord that resulted in higher tip Mach numbers and lower tip static pressures.

Figure 12 shows how coolant-flow requirements, Mach number, and tip pressure can be affected by the coolant temperature. Most of the calculations for this analysis were made with a coolant temperature of 1247° R, which corresponds to the temperature at the discharge of the compressor. By use of an aftercooling device, it may be possible to reduce the cooling-air temperature. In figure 12 curves are shown for cooling-air supply temperatures of 1247° and 1000° R for the first stage of the 35-inch-diameter turbine. A reduction in cooling-air temperature naturally reduces the quantity of air required for blade-cooling. The cooling-airflow reduction shown in figure 12 varies between about 20 and 25 percent over the range of blade chords investigated. At low coolant Mach numbers the Mach number reduction due to reducing cooling-air temperature is about the same order of magnitude as the reduction in cooling airflow. This effect on static pressure at the blade tip is quite small. For a blade chord of 1 inch, however, there is a large difference in tip Mach numbers owing to the cooling-air temperature effect; but, as can be seen from the shape of the curves, reducing the cooling-air temperature does not allow a significant reduction in permissible blade chord. The results shown in figure 12 are similar to those shown in figure 11, in that the conclusions that can be drawn from this study do not appear to be affected significantly by the value of cooling-air temperature used in the analysis.

It is not within the scope of this report to investigate the effects of turbine blade chord for all combinations of engine conditions. It is believed, however, that enough conditions were investigated to point out trends and to indicate that the use of small-chord blades can become a problem in air-cooled engines. Other blade configurations may possibly create less of a problem than corrugated blades for small chords, but even with those configurations similar trends would be expected. As turbine-inlet temperature is increased above 2500° R, the problems will become more severe than presented herein because of the higher coolant flows that will be required. It can be concluded from this study that in the design of air-cooled turbines it is generally

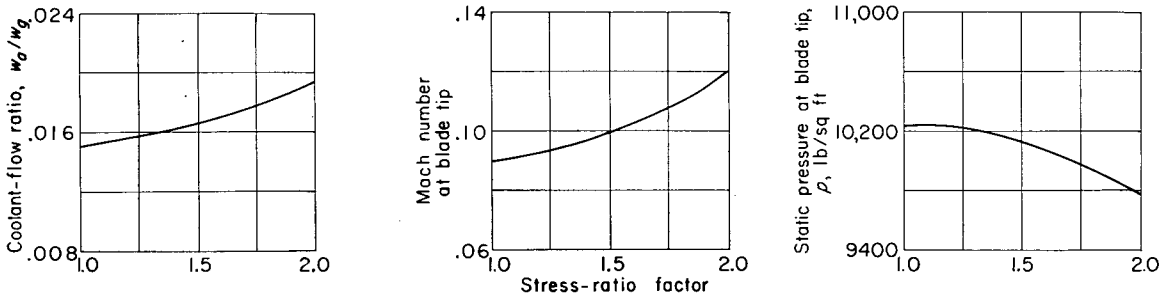


FIGURE 11.—Effect of stress-ratio factor on cooling and pressure-drop characteristics of turbine blades. First stage of 35-inch-diameter turbine; chord, 2 inches; corrugation amplitude, 0.07 inch.

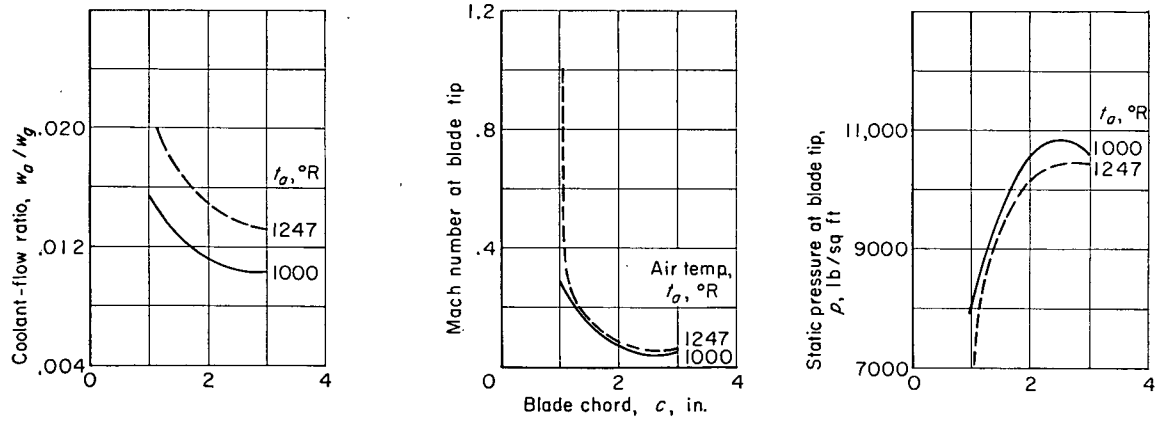

FIGURE 12.—Effect of cooling-air temperature on cooling and pressure-drop characteristics of turbine blades. First stage of 35-inch-diameter turbine; corrugation amplitude, 0.07 inch.

desirable to utilize blades with as large a chord as appears feasible from considerations of disk stress and aerodynamics.

SUMMARY OF RESULTS

The results of this investigation of the effects of chord size on weight and cooling characteristics of air-cooled turbine blades can be summarized as follows:

1. Air-cooled-turbine blade weight is affected to a much smaller degree by the size of the blade chord than is the weight of solid uncooled blades.

2. When solidity is maintained constant, the heat-transfer surface and the flow area in the coolant passage of air-cooled blades are considerably larger relative to the surface and flow area on the gas side of the blades with large-chord blades than with small-chord blades. As a result, cooling large-chord blades should be easier.

3. Heat-transfer and pressure-drop analyses show that small-chord blades require a larger total amount of cooling air for the turbine and have higher pressure losses than larger-chord blades. Cooling airflow for turbines with 1-inch-chord blades is generally about twice that required for turbines with 3-inch-chord blades. By further reducing the chord to 0.5 inch, the required cooling airflow may become more than twice that for blades with 1-inch chord.

4. Cooling-air pressure losses increase as blade chord is reduced, and it may often be impossible to pass the cooling airflow required at the pressure levels available from compressor bleed to cool blades with small chords.

5. The exact blade chords at which it may no longer be feasible to cool air-cooled blades depend upon the assumptions and conditions of the analysis, but the trends indicated in this report are probably general for other engines, other blade configurations, and other engine conditions.

REPORT 1355

A THEORETICAL AND EXPERIMENTAL STUDY OF PLANING SURFACES INCLUDING EFFECTS OF CROSS SECTION AND PLAN FORM [1]

By CHARLES L. SHUFORD, Jr.

SUMMARY

A summary is given of the background and present status of the pure-planing theory for rectangular flat plates and V-bottom surfaces. The equations reviewed are compared with experiment. In order to extend the range of available planing data, the principal planing characteristics for models having sharp chines have been obtained for a rectangular flat and two V-bottom surfaces having constant angles of dead rise of 20° and 40°. Planing data were also obtained for flat-plate surfaces with very slightly rounded chines for which decreased lift and drag coefficients are obtained.

A revision of the theory presented in NACA Technical Note 3233 is presented for the rectangular flat plate. The revised theory bases the aerodynamic suction effects on the total lift rather than solely on the linear component. Also a crossflow drag coefficient which is dependent on the shape of the chines was found from experiment to be constant for a given immersed cross section; however, for surfaces, such as those having horizontal chine flare or vertical chine strips, the crossflow drag coefficient is constant only for the chine-immersed condition. The theory is extended to include triangular flat plates planing with base forward and V-shaped prismatic surfaces having a constant angle of dead rise, horizontal chine flare, or vertical chine strips. A method is also presented for estimating the center of pressure for surfaces having either rectangular or triangular plan form. The results calculated by the proposed theory have been correlated only with the data considered to be pure planing; however, for conditions not considered pure planing, a method is given for estimating the effects of buoyancy. The agreement between the results calculated by the proposed theory and the experimental data is, in general, good for calculations of pure-planing lift and center-of-pressure location for flat plate, V-bottom, and related planing surfaces.

INTRODUCTION

Recent developments in water-based aircraft have resulted in configurations utilizing planing surfaces operating at angles of trim, length-beam ratio, and Froude number beyond those for which most of the available planing theories were correlated with experimental data. In reference 1 a preliminary review of these theories for a pure-planing rectangular flat plate was made to determine whether available planing theories were adequate in estimating the planing lift in these extended ranges. In addition to this review, a modification and addition to existing theory which is useful in predicting the lift and center of pressure for pure-planing rectangular flat plates was presented.

The review in reference 1 indicated there were no data available in the extended ranges of combined high trim and high length-beam ratios; consequently, the principal planing characteristics for models having sharp chines have been obtained in these extended ranges for a rectangular flat and two V-bottom surfaces. It was also noted in reference 1 that there was a difference in the lift coefficients obtained from various experimental investigations; therefore, data have been obtained for rectangular flat-plate surfaces having very slightly rounded chines to determine the influence of slight differences in construction at the point of flow separation on the lift coefficient.

The review of existing theories and data has been extended to include those applicable to V-bottom surfaces. The theory presented in reference 1 for estimating the lift and center-of-pressure location of a pure-planing rectangular flat plate has been revised and extended to include triangular flat plates planing with base forward and V-shaped prismatic surfaces having a constant angle of dead rise, horizontal chine flare, or vertical chine strips. Since water-based aircraft operate at low Froude numbers as well as high Froude numbers, an approximate method has also been presented for estimating the effect of buoyancy on lift coefficient.

REVIEW OF EXISTING PLANING-LIFT THEORY

In reference 1 the pure-planing lift equations for rectangular flat plates presented in references 2 to 11 were reviewed and compared with experiment. In addition to lift theories for rectangular flat plates, the present review considers V-shaped surfaces having a constant angle of dead rise and V-shaped surfaces having horizontal chine flare.

Since publication of reference 1, Farshing (ref. 12) presented a cubic equation for the lift on rectangular flat plates derived from a consideration of deflected mass and based on an effective angle of attack. The equation has the form

$$C_L^3+[(2.292-1.571A)\tau-2.379-A]C_L^2+$$
$$[2A+4+(6.283A-4.584)\tau]C_L-6.283A\tau=0 \quad (1)$$

However, the lift coefficient obtained from equation (1) was multiplied by an empirical factor to get better agreement with experimental data; thus,

$$C_{L,S}=C_L\xi \quad (2)$$

where

$$\xi=1.359-\tanh\left(\frac{1+A}{8A}\right) \qquad (2^\circ \leqq \tau \leqq 18^\circ) \quad (3)$$

$$\xi=1.359-\tanh\left(\frac{1+A}{8A}\right)+\left(\frac{\tau-18^\circ}{90.53}\right)\tanh\frac{1}{A^2} \qquad (18^\circ \leqq \tau \leqq 30^\circ) \quad (4)$$

and τ is measured in degrees.

P. R. Crewe of Sanders-Roe Ltd. (British) in correspondence with the Langley Laboratory proposed an equation for rectangular flat plates and a V-shaped surface having a basic angle of dead rise of 20° and horizontal chine flare that had a linear term with a form analogous to airfoil lifting-surface theory. This equation, based on the data of Kapryan and Weinstein (ref. 13), is

$$C_{L,S}=\sin\tau\cos\tau\left[\frac{8}{\pi}\frac{1}{1+\sqrt{1+\left(\frac{2}{A}\right)^2}}\left(1-\frac{\beta_{basic}}{\pi}\right)+2\sin\tau-B\sin^2\tau\right] \quad (5)$$

where

$B=2.67$ $(A<2.0)$

$B=3.0$ $(A>2.0)$

and β_{basic} is the basic angle of dead rise in radians for a model having horizontal chine flare.

In reference 14, Korvin-Kroukovsky, Savitsky, and Lehman proposed an equation for rectangular flat plates and V-shaped surfaces having a constant angle of dead rise that was derived primarily on the basis of the data of Sottorf (ref. 15) and Sambraus (ref. 16). This formula can be written as

$$C_{L,S}=0.012(57.3\tau)^{1.1}A^{0.5}-0.0065(57.3\beta)A\left[\frac{0.012(57.3\tau)^{1.1}}{A^{0.5}}\right]^{0.6} \quad (6)$$

Locke (ref. 17) proposed that the lift characteristics of rectangular flat plates and V-shaped surfaces having a constant angle of dead rise can be presented by a power function of the form

$$C_{L,S}=0.5\left(1-\frac{2\beta}{\pi}\right)K\tau^{\eta} \tag{7}$$

where K and η depend only on aspect ratio and are obtained from curves given in reference 17.

Schnitzer (ref. 18) presented an equation for rectangular flat plates and V-shaped surfaces which was derived from a consideration of two-dimensional deflected mass and was modified for three-dimensional flow by Pabst's empirical aspect-ratio correction factor (ref. 19) and Bobyleff's flow coefficients presented in reference 20. The equation can be written in the form:

$$C_{L,S}=A\phi\cos^2\tau\sin\tau\left\{\frac{\pi}{4}\left[\left(\frac{\pi}{2\beta}-1\right)\tan\beta\right]^2+B\left(\frac{l_k}{b}\tan\tau-\frac{\tan\beta}{2}\right)\right\} \tag{8}$$

The term ϕ, which is dependent on aspect ratio, and the term B, which is dependent on angle of dead rise, are given in references 19 and 20, respectively. For the case of a flat-plate planing surface, equation (8) reduces to

$$C_{L,S}=\phi\left(\frac{\pi^3 A}{16}\sin\tau\cos^2\tau+0.88\sin^2\tau\cos\tau\right) \tag{9}$$

In reference 21, Brown presented empirical equations based on deflected-mass considerations for rectangular flat plates and V-shaped surfaces having a constant angle of dead rise. The equations for a flat plate can be written in the form:

$$C_{L,S}=\frac{2\pi}{\cot\frac{\tau}{2}+\pi+\left(2\cot\frac{\tau}{2}-\pi\right)\frac{l_m}{b}} \qquad (l_m\leqq b) \tag{10}$$

and

$$C_{L,S}=(1.67\sin\tau+0.09)\sin\tau\cos\tau\left(1-\frac{b}{l_m}\right)+\frac{2\pi}{3\cot\frac{\tau}{2}}\frac{b}{l_m} \qquad (l_m\geqq b) \tag{11}$$

For a surface having a constant angle of dead rise,

$$C_{L,S}=3.6\frac{l_k}{b}\cot^2\beta\sin^3\tau(1-\sin\tau)\cos\tau \qquad (l_k\leqq l_{k,cr}) \tag{12}$$

and

$$C_{L,S}=\left[1.67\left(1-\frac{2\beta}{\pi}\right)\sin\tau+0.09\right]\sin\tau\cos\tau\left(1-\frac{l_{k,cr}}{l_k}\right)+0.9\frac{b}{l_k}\sin\tau(1-\sin\tau)\cos^3\tau \qquad (l_k\geqq l_{k,cr}) \tag{13}$$

where

$$l_{k,cr}=\frac{b}{2}\cot\tau\tan\beta \tag{14}$$

which is defined as the critical keel wetted length. For surfaces having a constant angle of dead rise and a transverse step, the critical keel wetted length is defined as the keel wetted length at which the stillwater line passes through the rearmost point of the chine. For the flat plate the value of the critical keel wetted length was assumed, after analysis of experimental data, to be equal to the beam.

PROPOSED THEORY

LIFT

In reference 1 an equation for the lift on a rectangular flat plate was developed from a consideration of linear and nonlinear components of lift (an approach generally used in low-aspect-ratio and slender-body airfoil theory). In the present report this equation is revised and extended to include V-bottom surfaces. The equation is divided into three parts: (1) a reasonably accurate approximation to the linear components of lift is made; (2) a method for calculating the crossflow effects is presented; and (3) an estimation of the aerodynamic leading-edge suction is made.

Linear term.—The linear term is determined in reference 1 from a consideration of the lifting-line theory and is given by

$$C_{L,1}=\frac{0.5\pi A\tau}{1+A} \tag{15}$$

This relation gives the linear component of lift on a pure-planing flat plate.

In references 3 and 18, a dead-rise function was determined from a consideration of an iterative solution made by Wagner (ref. 2) for the impact force on a V-bottom surface immersing with a constant vertical velocity. The dead-rise function can be written

$$K(\beta)=\left(1-\frac{2\beta}{\pi}\right)^2\left(\frac{\tan\beta}{\beta}\right)^2$$

This dead-rise function (developed for application to equations derived from virtual mass concepts) does not correlate well with experiment when applied to equation (15) for angles of dead rise above approximately 25°. Therefore, another dead-rise function $1-\sin\beta_e$ which correlates well with experiment up to angles of dead rise of 50° is used; thus,

$$C_{L,2}=\frac{0.5\pi A\tau}{1+A}(1-\sin\beta_e) \tag{16}$$

This expression is for the linear component of lift on rectangular flat and V-bottom planing surfaces. A comparison of the dead-rise function $1-\sin\beta_e$ with the dead-rise function based on Wagner's solution is given in figure 1.

Crossflow effects.—For a simple theoretical consideration of the crossflow effects, the velocity component perpendicular to the surface of a flat plate is assumed to be of the magnitude $V\sin\tau$. The flow is projected into components

526597—60——25

perpendicular to and parallel to the planing surface, and the drag force associated with the flow perpendicular to the planing surface is calculated. The normal force on a flat plate, therefore, is

$$N=C_{D,c}\frac{\rho}{2}S(V\sin\tau)^2$$

Then

$$C_{L,3}=C_{D,c}\sin^2\tau\cos\tau \tag{17}$$

is a lift coefficient due to crossflow effects, and is proportional to $\sin^2\tau$. This relation is the concept presented for airfoils by Betz in reference 22. The crossflow drag coefficient $C_{D,c}$ used in this elementary derivation of the crossflow term was assumed in reference 1 to be one-half the value $C_{D,c}=2$ generally used for aerodynamic surfaces. The value of $C_{D,c}$ is known to vary with the shape of the cross section and to be sensitive to local shape at the edges. Since the theoretical determination of these effects is very difficult and the simple cases which have been solved have not correlated with experiment, the analysis of suitable experiments will generally provide the easiest and most accurate method of determining $C_{D,c}$.

For the case of the V-bottom the theoretical effect of dead rise is given by Bobyleff in reference 20 for a bent lamina, the section of which consists of two equal straight lines forming an angle. Bobyleff's flow coefficient, which can be approximated by $\cos\beta_e$ (see fig. 2), represents the ratio of the resultant pressure on a V-bottom to that experienced by a flat plate of the same beam in normal flow; thus,

$$C_{L,4}=(C_{D,c})_{\beta_e=0}\sin^2\tau\cos\tau\cos\beta_e \tag{18}$$

which is the crossflow component of lift.

Suction component of lift.—An airfoil has a suction component of lift due to the large negative pressures produced by the flow around the leading edge of the airfoil; however, for a planing surface where there is no flow around the leading edge, this suction does not appear. In the strictest sense the suction component of lift should be based only on the linear term (see ref. 1); however, comparison of experiment with theory indicates that better agreement is obtained if the suction component of lift is based on $C_{L,2}+C_{L,4}$. Therefore, the lift is less than that predicted by equations (16) and (18) by an amount

$$C_{L,5}=(C_{L,2}+C_{L,4})\sin^2\tau \tag{19}$$

Total lift.—The total lift on pure-planing surfaces can be obtained from the sum of the linear component of lift (eq. (16)) and the crossflow effects (eq. (18)) minus the suction component of lift (eq. (19)); thus, by combining terms

$$\left.\begin{aligned} C_{L,S}&=\left[\frac{0.5\pi A\tau}{1+A}\cos^2\tau\,(1-\sin\beta_e)\right]+\\ &\quad[(C_{D,c})_{\beta_e=0}\cos^3\tau\sin^2\tau\cos\beta_e]\\ C_{L,S}&=C_{L,6}+C_{L,7}\end{aligned}\right\} \tag{20}$$

where

$$C_{L,6}=\frac{0.5\pi A\tau}{1+A}\cos^2\tau\,(1-\sin\beta_e) \tag{21}$$

and

$$C_{L,7}=(C_{D,c})_{\beta_e=0}\cos^3\tau\sin^2\tau\cos\beta_e \tag{22}$$

For equation (20) to predict adequately the lift on triangular surfaces planing with base forward, it has been necessary to define the aspect ratio as the ratio of maximum beam to overall length; that is, $A_t=b/l$.

APPLICATION OF LIFT THEORY

In order to use equation (20) to predict the lift of planing surfaces, only the determination of the proper value of $C_{D,c}$ is required. Values of $C_{D,c}$ for various chine configurations for which experimental data are available are presented in figure 3. For a given model $C_{D,c}$ did not vary with trim or length-beam ratio. Also it can be seen that, as long as the angle of dead rise was constant for the entire beam, $C_{D,c}$ did not vary with the angle of dead rise.

Rectangular flat and V-bottom surfaces having a constant angle of dead rise.—The crossflow drag coefficient for the sharp-chine models was determined from tests (from ref. 23 and data presented in the present report) to be 4/3. This value is two-thirds the value given for a two-dimensional flat-plate airfoil; thus, from equation (20)

$$C_{L,S}=\frac{0.5\pi A\tau}{1+A}\cos^2\tau(1-\sin\beta_e)+\frac{4}{3}\sin^2\tau\cos^3\tau\cos\beta_e \tag{23}$$

The relative magnitudes of the total lift (eq. (23)), the total lift before removal of lift due to leading-edge suction $\left(\text{eq. (16) plus eq. (18) with } C_{D,c}=\frac{4}{3}\right)$, and the crossflow term $\left(\text{eq. (22) with } C_{D,c}=\frac{4}{3}\right)$ is shown in figure 4 for surfaces having angles of dead rise of 0°, 20°, and 40°.

Horizontal chine flare.—The total lift on a pure-planing V-shaped prismatic surface with horizontal chine flare similar to the models shown in figure 5 can be determined from equation (20). The crossflow drag coefficients $C_{D,c}$ determined from data presented in references 13, 24, and 25 are given in figure 3.

Vertical chine strips.—The total lift on a pure-planing V-shaped prismatic surface with vertical chine strips similar to the models shown in figure 6 can be determined from equation (20). The crossflow drag coefficients determined from the data presented in references 25 and 26 are given in figure 3.

Triangular flat plate.—The total lift on a pure-planing triangular flat plate planing with base forward can be estimated from equation (23) if the aspect ratio is defined as the ratio of the maximum beam to the overall length or $A_t=b/l$; thus,

$$C_{L,S}=\frac{0.5\pi A_t\tau}{1+A_t}\cos^2\tau+\frac{4}{3}\cos^3\tau\sin^2\tau \tag{24}$$

CENTER OF PRESSURE

The center of pressure on a planing surface may be determined from the lift coefficients given by equations (21) and (22) and by estimating the location of the center of pressure of these two components of the total lift coefficient for a given planing-surface plan form.

Rectangular plan form.—The center of pressure of the component of lift given by equation (21) is assumed to be located at seven-eighths of the mean wetted length from the trailing edge of the planing surface. This location is between the three-quarter-chord position generally assumed in lifting-line theory and the position obtained from the prediction of no lift behind the section maximum width for low-aspect-ratio airfoils (ref. 27).

The center of pressure for the lift due to crossflow effects is generally assumed to be located at the center of the area in airfoil theory. Therefore, the center of pressure for the component of lift given by equation (22) is assumed to be located at the center of the mean wetted length; thus,

$$\left(\frac{l_{cp}}{l_m}\right)_{calc}=\frac{\frac{7}{8}C_{L,6}+\frac{1}{2}C_{L,7}}{C_{L,S}} \tag{25}$$

where $C_{L,6}$ is given by equation (21), $C_{L,7}$ is given by equation (22), and $C_{L,S}$ is given by equation (20).

Triangular plan form.—The center of pressure of the component of lift given by the first term on the right-hand side of equation (24) is assumed to be located at the mean of the heavy spray line which is approximately the section of maximum wetted width.

The center of pressure for the component of lift given by the second term on the right-hand side of equation (24) (that is, the crossflow term) is assumed to be at approximately the center of the wetted area; thus,

$$\left(\frac{l_{cp}}{l_m}\right)_{calc}=\frac{C_{L,8}+\frac{2}{3}C_{L,9}}{C_{L,S}} \tag{26}$$

and is the center-of-pressure location for triangular flat plates planing with base forward. The value of $C_{L,S}$ is determined from equation (24) where $C_{L,8}$ and $C_{L,9}$ are given by the first and second terms on the right-hand side of equation (24), respectively.

COMPARISON OF PROPOSED AND PREVIOUS PLANING FORMULAS

A comparison of the values of lift coefficient (plotted against trim for constant length-beam ratio) calculated from the proposed theory (eq. (20)) and from previous summarized planing formulas is given in figures 7 to 10 and an index to the comparison is given in the following table:

Configuration	Equation (20)* compared with planing formulas presented in—		Lift coefficient values presented in figure—
	Reference	Equation	
Rectangular flat plate	4, 5, 6, and 7	----------	7(a)
	8, 9, and 10	----------	7(b)
	----------	(7), (9), (10), and (11)	7(c)
	----------	(2), (5), and (6)	7(d)
	1	----------	7(e)
	11	----------	**
V-shaped surface having a constant angle of dead rise of 20°	----------	(6) and (7)	8(a)
	----------	(8), (12), and (13)	8(b)
V-shaped surface having a constant angle of dead rise of 40°	----------	(6) and (7)	9(a)
	----------	(8), (12), and (13)	9(b)
V-shaped surface having an angle of dead rise of 20° and horizontal chine flare (β_s=16°)	----------	(5)***	10

*Value of $C_{D,c}$ of $\frac{4}{3}$ (see eq. (23)) used unless otherwise noted.

**Lift coefficients were not plotted since the results depended on the airfoil data used.

***Value of $C_{D,c}$ of 1.59 used in equation (20).

In figure 11 the values of lift coefficient (plotted against mean-wetted-length—beam ratio for constant trim) calculated from the proposed theory (eq. (23)) and planing formulas as presented in references 14, 17, 18, and 21 are compared with the data of the present report (see tables I(a), II, and III) and references 23 and 28 for models having angles of dead rise of 0° (fig. 11(a)), 20° (fig. 11(b)), and 40° (fig. 11(c)). Only the theories that apply to both flat-plate and V-shaped surfaces have been compared in figure 11.

It can be seen from figures 11 (a) to 11(c) that none of the planing formulas presented in references 14, 17, 18, and 21 are adequate for estimating the lift coefficients for either flat-plate or V-bottom planing surfaces, whereas the lift coefficients calculated from the equation proposed in the present report (eq. (23)) agree very well with experiment. The equation presented in reference 12 (eq. (2)), however, gives a good approximation of the lift coefficient for a flat plate. (See fig. 7(d).)

EXPERIMENTAL INVESTIGATION

DESCRIPTION OF MODELS

The models used for this investigation had a beam of 4 inches and a length of 36 inches. The models shown in figure 12 for a flat plate and surfaces having angles of dead rise of 20° and 40° were constructed of brass and are the same models investigated in references 23 and 28. Additional flat-plate models that had sharp chines, 1/64-inch-radius chines, and 1/16-inch-radius chines were constructed of plastic. (See fig. 13.) The model with the 1/64-inch-radius chines was made by rounding the chines on the sharp-chine model after the tests with the sharp-chine model had been completed. The plastic models were backed with a 1/2-inch reinforcing steel plate.

APPARATUS AND PROCEDURES

The experimental investigation was made with the main towing carriage in Langley tank no. 2 and existing strain-gage balances which independently measured the lift, drag, and moment. The lift and drag were measured with the balances capable of measuring: (1) 600 pounds of lift and 250 pounds of drag, and (2) 1,000 pounds of lift and 600 pounds of drag. The moment was measured about an arbitrary point above the model. The tests were made with the wind and spray shield installed, as shown in figure 14, unless otherwise indicated.

The wetted areas were determined from underwater photographs made with a 70-millimeter camera mounted in a waterproof box located at the bottom of the tank. The camera and high-speed flash lamps were set off by the action of the carriage interrupting a photoelectric beam. The wetted length was obtained from markings on the bottom of the models. In order to assure a very smooth bottom, the markings on the brass models were erased except in the region of the heavy spray line. (See fig. 15.) The plastic models had markings each 1/2 inch for the full length of the models.

The force measurements were made at constant speeds for fixed angles of trim. The change in trim due to structural deflection caused by the lift and drag forces on the model was obtained during the calibration of the balances and the trim of the model was adjusted accordingly before each run. Slight adjustments to lift and resistance to correct the data

to the desired trim were made after completion of tests for the cases where the forces or center-of-pressure location were different from the values used to estimate the trim due to structural deflection. The change in trim due to structural deflection did not exceed 0.2° for most conditions although in a few cases changes up to 0.6° occurred.

The aerodynamic forces on the model and towing gear were found to be negligible when the wind screen was used. The aerodynamic tares were subtracted from the data when the wind screen was not used.

The accuracy of the quantities measured are believed to be within the following limits:

Lift, lb	±5.0
Resistance, lb	±3.0
Trimming moment, ft-lb	±3.0
Wetted length, ft	±0.01
Trim, deg	±0.15
Speed, ft/sec	±0.20

The forces were converted to coefficient form by using a measured value of density of 1.942 slugs/cu ft. The kinematic viscosity measured during the tests varied from 1.53×10^{-5} sq ft/sec to 1.80×10^{-5} sq ft/sec.

RESULTS AND DISCUSSION

GENERAL

The lift coefficient, resistance coefficient, ratio of wetted length to beam, ratio of center-of-pressure location to mean wetted length, speed coefficient, and kinematic viscosity are presented at given trims in tables I to III for all models. The lift and drag coefficients are expressed both in terms of the square of the beam and in terms of principal wetted area.

Sharp chines.—The lift coefficients and center-of-pressure location for the sharp-chine models are considered in the section "Comparison of Theory and Experiment for Lift."

The resistance data for the sharp-chine brass models having constant angles of dead rise of 0°, 20°, and 40° are presented in figure 16 as plots of the variation of drag coefficient $C_{D,S}$ and induced drag coefficient $C_{D,i}$ (which is equal to $C_{L,S}\tan\tau$) with mean-wetted-length—beam ratios for given trims. The difference between the solid and dashed lines represents the friction drag. (Since the data were obtained for speeds above the critical speed of wave propagation for the 6-foot-deep tank, there is no wave drag due to transverse waves included; however, there may be some drag due to spray or other causes included in this difference.) At high trims and low length-beam ratios the induced drag exceeds the total drag and indicates an apparent negative friction force. (This result was previously reported in ref. 23.) The volume of forward spray is large at high trims and appears to have a high forward velocity with respect to the model. The relative velocity of the model in the region of forward spray therefore is effectively reversed (see fig. 17) so that the friction drag due to this spray acts in a direction opposite to that of the drag in the principal wetted area and thereby reduces the total drag. Therefore, at low length-beam ratios where the friction drag is small, this negative friction drag due to forward spray may cause a negative friction force at high trims.

The variation of $\frac{l_k-l_c}{b}$ with trim for the models having sharp chines and constant angles of dead rise of 0°, 20°, and 40° is given in figure 18. At a trim of 12°, the value of $\frac{l_k-l_c}{b}$ is approximately constant for all length-beam ratios for the models having constant angles of dead rise of 0°, 20°, or 40°. At high trims, however, the values of $\frac{l_k-l_c}{b}$ for the flat-plate model increase with increase in length-beam ratio, are approximately constant for a given trim for a model having a constant angle of dead rise of 20°, and decrease with an increase in length-beam ratio for a model having a constant angle of dead rise of 40°. The value of $\frac{l_k-l_c}{b}$ for the flat-plate model decreases with increase in trim at low length-beam ratios and increases with increase in trim at high length-beam ratios; however, the value of $\frac{l_k-l_c}{b}$ decreases with increase in trim for all length-beam ratios for the models having constant angles of dead rise of 20° and 40°.

Wind screen and spray shield.—The lift coefficient for the flat-plate model with wind screen and spray shield removed (aerodynamic tares subtracted) was approximately the same as the lift coefficient obtained when the wind screen and spray shield were used. (See fig. 19.) At a trim of 12° the drag coefficient for the flat-plate model with the wind screen removed was approximately the same as the drag coefficient obtained with the wind screen installed (see fig. 20); however, for a trim of 18° the drag coefficient of the flat plate with the wind screen removed was less than that obtained when the wind screen was used even before the aerodynamic tares were subtracted. The value of the difference is in the wrong direction to be explained by the aerodynamic tares. (The aerodynamic tares subtracted were less than the difference in fig. 20.) The variation of the center-of-pressure location with mean length-beam ratio on the flat-plate model was approximately the same for data taken with and without the wind screen and spray shield installed. (See fig. 21.)

Speed.—The effect of speed at high trims (24°) is shown in figures 22 to 24. The variation of lift coefficient, drag coefficient, and center-of-pressure location is approximately the same for speeds of 30 and 60 feet per second for 4-inch-beam prismatic models having constant angles of dead rise of 0°, 20°, and 40°; therefore, there was apparently no speed effect for this range of speeds.

Rounded chines.—The effect of $\frac{1}{64}$-inch-radius and $\frac{1}{16}$-inch-radius chines on the lift coefficient, drag coefficient, center-of-pressure location, skin-friction coefficient, and lift-drag ratio of a 4-inch-beam rectangular flat plate is shown in figures 25 to 29. Rounding the sharp chines of the flat-plate model to radii of $\frac{1}{64}$ inch and $\frac{1}{16}$ inch resulted in a decrease in lift and drag coefficients; however, the center-of-pressure location, skin-friction coefficients, and lift-drag ratios remained approximately the same. A decrease in lift of approximately 5 and 9 percent resulted from rounding the sharp chines to a radii of $\frac{1}{64}$ inch and $\frac{1}{16}$ inch, respectively. (See fig. 25.) A decrease in lift for a small rounding of the chines was also observed by Perry (ref. 29).

The variation of skin-friction coefficient with Reynolds

number for a trim of 8° is presented in figure 28 for a flat-plate model having sharp chines and 1/16-inch-radius chines. The agreement between the data and the Schoenherr turbulent-flow line indicates that, at low trims and high Reynolds numbers, the drag can be calculated with reasonable accuracy from

$$C_{D,S}=C_f+C_{L,S}\tan\tau \tag{27}$$

where C_f is determined from the Schoenherr turbulent flow line. (See ref. 30.) The lift-drag ratios at high trims are influenced little by the chine condition; however, at low trims (8°) the lift-drag ratios for the sharp-chine models are slightly higher than those for models having rounded chines. (See fig. 29.)

Pure planing.—The experimental data were considered as pure planing if the lift coefficient due to buoyancy based on the total wedge-shaped volumetric displacement of the planing surface $C_{L,Vol}$ did not exceed a given value. The lift coefficient due to buoyancy was calculated from the wedge-shaped volumetric displacement of the planing surface below the level water surface given by

$$C_{L,Vol}=\frac{l_m}{b}\frac{1}{2C_V{}^2}\sin 2\tau \tag{28}$$

for rectangular flat plates and

$$C_{L,Vol}=\frac{1}{(l_k+l_c)\,C_V{}^2}\left[\frac{l_c{}^2}{b}\sin 2\tau+\frac{1}{3}(2l_c+l_k)\tan\beta\right] \tag{29}$$

for rectangular surfaces having dead rise and

$$C_{L,Vol}=\frac{l}{b}\frac{1}{3C_V{}^2}\sin 2\tau \tag{30}$$

for triangular flat plates with straight leading edge and pointed trailing edge.

The allowable lift coefficient due to buoyancy $C_{L,Vol}$, as determined from equations (28) to (30), was arbitrarily selected as 0.01 at a trim of 16°. The maximum allowable lift coefficient due to buoyancy $C_{L,Vol}$ for other trims was determined by drawing a straight line from zero trim (and zero lift coefficient due to buoyancy $C_{L,Vol}$) through the value 0.01 at a trim of 16° on a curve of the variation of lift coefficient with trim. For the flat-plate data the maximum allowable lift coefficient due to buoyancy $C_{L,Vol}$ selected by this method at a trim of 2° varied from 16 percent of the predicted lift coefficient at a length-beam ratio of 8 to 3.3 percent of predicted lift coefficient (eq. (23)) at a length-beam ratio of ½. These values decreased with increasing trim so that at 30° they would vary from 6.6 percent at a length-beam ratio of 8 to 3.0 percent at a length-beam ratio of ½. The permissible lift coefficient for surfaces having dead rise is, in general, a slightly greater percentage of the predicted lift coefficient than the values given for the rectangular flat plate.

Buoyancy.—The experimental lift coefficients given in reference 31 less the lift coefficients calculated from equation (20) with $C_{D,c}=1.15$ plotted against the lift coefficient due to buoyancy $C_{L,Vol}$ calculated from equation (28) are plotted in figure 30. Since equation (20) with $C_{D,c}=1.15$ is approximately the pure-planing lift for the model investigated in reference 31 (see fig. 32 (c)), the subtraction of this value from the experimental lift coefficients should indicate the amount of lift due to buoyancy present in the data. Only values of the difference between the experimental lift coefficient and the calculated lift coefficient greater than 0.01 are considered since, for small differences between experimental and calculated values, this method is not considered to be sufficiently accurate to determine the lift coefficient due to buoyancy present in the experimental data; however, this method should give reasonably accurate indications of the lift coefficient due to buoyancy present in the experimental data for the cases where the lift coefficient due to buoyancy is large. Figure 30 shows that the magnitude of the lift coefficient due to buoyancy for different speeds is approximately one-half the lift due to buoyancy based on the total wedge-shaped volumetric displacement computed by equation (28); therefore, a rough empirical approximation of the increase in lift coefficient due to buoyancy can be calculated with reasonable accuracy from

$$C_{L,B}\approx\frac{1}{2}C_{L,Vol}\qquad(\tau\geqq 8°;\ C_V\geqq 3) \tag{31}$$

where $C_{L,Vol}$ is given in equations (28) to (30). For low trims (4°) a lift coefficient due to buoyancy greater than that given by equation (31) is required to account for the additional lift coefficient due to buoyancy as indicated by the flagged symbols in figure 30.

COMPARISON OF THEORY AND EXPERIMENT

Lift.—Only the experimental data indicated as pure planing by the method discussed in the preceding section are considered for the comparison with theory. Also, the data considered are only for the chine-immersed condition. The theory is applicable to the non-chine-immersed condition; however, for surfaces having other than a constant angle of dead rise such as those having horizontal chine flare or vertical chine strips, the shape of the cross section varies, and, therefore, the crossflow drag coefficient would not be the same value as that determined for the chine-immersed condition. The values were calculated from the proposed theory as if there were no non-chine-immersed conditions. For the non-chine-immersed condition, the lift coefficient for a surface having a constant angle of dead rise is approximately the value determined at the instant of chine immersion and is a constant for a given trim and angle of dead rise. (The length-beam ratio is approximately a constant value for all non-chine-immersed conditions for a given trim and angle of dead rise.)

In order to simplify the comparison, the data are summarized in the following table:

Configuration	Description of model used	Data to be compared— Equation of present paper—	Data to be compared— Experimental data of reference—	Data presented in figure—	Remarks
Rectangular flat plate	4-inch-beam brass model	(23)	----------	31 (a)	Agreement good except at trims above approximately 30° at large length-beam ratios
	Sharp chine plastic model		----------	31 (b)	
	4-inch-beam brass model		23	31 (c)	Agreement good
	Various models		12, 32, 31, 33, 34, 16, 15, and 25	31 (d) to 31 (k)	Agreement good; some differences with wooden models
	4-inch-beam plastic model with 1/16-inch-radius chines and 1/64-inch-radius chines	(20)	Present paper	32 (a) and 32 (b)	$C_{D,c}$ reduced to 1.15 and 1.20
	Wooden model (same model used in both ref. 31 and 35)		31, 32, and 35	32 (c) to 32 (e)	Models used in reference data had either slightly rounded or roughened chines and reduced values of $C_{D,c}$ resulted. In case of reference 35 the chines had greater chine radius or roughness as a result of wear in use; further reduction in $C_{D,c}$ resulted.
Basic V-surface	With angle of dead rise of 20°	(23)	28 and 25	33	Agreement good except for trims above approximately 30°
	With angle of dead rise of 40°		28 and 25	34	
	With angle of dead rise of 50°		36	35	Agreement good for length-beam ratios above 3.0; below this value the experimental data failed to show the usual increase in C_L as l_m/b decreased. Similar effect slightly evident in fig. 34 (b) for $\beta=40°$.
V-surface with horizontal chine flare	With an effective angle of dead rise of 16°	(20) ($C_{D,c}$ value from fig. 3)	13 and 25	36	Agreement good
	With an effective angle of dead rise of 32°47′		24 and 25	37	Agreement good
V-surface with vertical chine strip	With an effective angle of dead rise of 15°33′	(20) ($C_{D,c}$ value from fig. 3)	26	38	Agreement good
	With an effective angle of dead rise of 31°59′		26	39	Agreement good
Triangular flat plate (base forward)	Wooden surfaces (see fig. 40)	(24)	31 and unpublished tank no. 2 data	41	Agreement good up to trims of 16°. Values lower than those at trim of 20°; chines may be slightly rounded since they are made of wood.

Some of the experimental data that were obtained with wooden models (for example, see ref. 31) were lower than the values predicted by the proposed theory; this difference is thought to be due to the influence of the local shape at the edges (slightly rounded or roughened chines).

The effects of Reynolds number, scale, and nonuniform chine radii on $C_{D,c}$ have not been determined because of the limited data available.

The lift on various pure-planing surfaces with rectangular or triangular plan forms similar to those considered can be estimated by changing the value of the crossflow drag coefficient $C_{D,c}$ for a given configuration. Values of the crossflow drag coefficient should be determined from tests; however, reasonably accurate approximations that are satisfactory for engineering calculations can probably be made (see fig. 3) that will approximate the pure-planing lift for surfaces similar to those considered herein.

For planing surfaces that vary considerably from those considered herein, only data for a given angle of trim and aspect ratio (for a given effective angle of dead rise) are required to determine the value of $C_{D,c}$ from equation (20). (The experimental values of lift coefficient, trim, aspect ratio, and effective angle of dead rise are substituted into equation (20), which is then solved for the value of $C_{D,c}$.) Since the value of $C_{D,c}$ is a constant for a given planing-surface cross section, the lift coefficient for wide ranges of trim and aspect ratio can then be estimated. If values of $C_{D,c}$ are obtained for two or more effective angles of dead rise for a given type of planing surface, the value of $C_{D,c}$ for similar surfaces having a different effective angle of dead rise can be estimated by interpolation. Therefore, in order to calculate the lift coefficient from equation (20) for wide ranges of trim, length-beam ratio, and effective angle of dead rise for a given family of planing surfaces, only a very few test points are required.

Center-of-pressure location.—A comparison of theory and experiment for the center of pressure is given in the following table:

Configuration	Description of model used	Data to be compared— Equation of present paper [a]	Data to be compared— Experimental data of reference—	Data presented in figure—	Remarks
Rectangular flat plate	4-inch-beam brass model	(25)	23, 31, and 25	42	Good agreement
Basic V-surface	With angle of dead rise of 20°	(25)	25 and 28	43	Good agreement
	With angle of dead rise of 40°	(25)	25 and 28	44	Good agreement
	With angle of dead rise of 50°	(25)	36	45	Good agreement
V-surface with horizontal chine flare	With an effective angle of dead rise of 16°	(25)	13 and 25	46	Good agreement
	With an effective angle of dead rise of 32°47′	(25)	24 and 25	47	Good agreement
V-surface with vertical chine strips	With an effective angle of dead rise of 15°33′	(25)	26	48	Good agreement
	With an effective angle of dead rise of 31°59′	(25)	26	49	Good agreement
Triangular plan form	Wooden surfaces (see fig. 40)	(26)	31 and unpublished tank no. 2 data	50	Good agreement

[a] The values of $C_{D,c}$ for equation (25) were determined from figure 3.

CONCLUDING REMARKS

The principal planing characteristics for models have been obtained in extended ranges of trim and length-beam ratio for a rectangular flat plate and two V-bottom surfaces; therefore, force approximations for water-based aircraft can be made in these extended ranges with more confidence. The data obtained for rectangular-flat-plate surfaces having very slightly rounded chines indicated that slight differences in construction at the point of flow separation can result in decreased lift and drag coefficients obtained for a given flat-plate configuration; however, the center-of-pressure location, skin-friction coefficients, and lift-drag ratios remained approximately the same for the trims tested (8° to 18°). These data showed that slight differences in construction at the point of flow separation were probably the reason for the differences in experimental data obtained for a given configuration by various experimenters.

The proposed theory appears to predict with engineering accuracy the lift and center-of-pressure location of rectangular flat plates, triangular flat plates planing with base forward, and V-shaped surfaces having a constant angle of dead rise, horizontal chine flare, or vertical chine strips. A reasonably accurate approximation can probably be made for the crossflow drag coefficient of a given model that will result in satisfactory engineering calculations of lift and center of pressure for pure-planing surfaces similar to those considered in the present report. Also, the proposed theory (which can be applied to both the chine-immersed and the non-chine-immersed condition) together with the method for approximating the lift coefficient due to buoyancy gives a reasonably accurate method for estimating the lift characteristics of planing surfaces for a wide range of conditions.

REPORT 1356

INVESTIGATION OF SEPARATED FLOWS IN SUPERSONIC AND SUBSONIC STREAMS WITH EMPHASIS ON THE EFFECT OF TRANSITION [1]

By Dean R. Chapman, Donald M. Kuehn, and Howard K. Larson

SUMMARY

Experimental and theoretical research has been conducted on flow separation associated with steps, bases, compression corners, curved surfaces, shock-wave boundary-layer reflections, and configurations producing leading-edge separation. Results were obtained from pressure-distribution measurements, shadowgraph observations, high-speed motion pictures, and oil-film studies. The maximum scope of measurement encompassed Mach numbers between 0.4 and 3.6, and length Reynolds numbers between 4,000 and 5,000,000.

The principal variable controlling pressure distribution in the separated flows was found to be the location of transition relative to the reattachment and separation positions. Classification is made of each separated flow into one of three regimes: "pure laminar" with transition downstream of reattachment, "transitional" with transition between separation and reattachment, and "turbulent" with transition upstream of separation. By this means of classification it is possible to state rather general results regarding the steadiness of flow and the influence of Reynolds number within each regime.

For certain pure laminar separations a theory for calculating dead-air pressure is advanced which agrees well with subsonic and supersonic experiments. This theory involves no empirical information and provides an explanation of why transition location relative to reattachment is important. A simple analysis of the equations for interaction of boundary-layer and external flow near either laminar or turbulent separation indicates the pressure rise to vary as the square root of the wall shear stress at the beginning of interaction. Various experiments substantiate this variation for most test conditions. An incidental observation is that the stability of a separated laminar mixing layer increases markedly with an increase in Mach number. The possible significance of this observation is discussed.

INTRODUCTION

Flow separation often is considered as a scourge to many technical devices which depend upon the dynamics of fluids for successful operation, inasmuch as separation often limits the usefulness of these devices. For example, the maximum lift of an airfoil and the maximum compression ratio of a compressor are limited by the occurrence of separation. Separated regions can also occur near a deflected flap, around a spoiler control, in an overexpanded rocket nozzle, behind a blunt base, on the leeward side of an object inclined at large angle of attack, and near the impingement of a shock wave from one body upon the boundary layer of another. Such occurrences make flow separation a very common phenomenon warranting much research effort.

Of the numerous experimental results on separated flows, a few have proved to be applicable throughout the subsonic, transonic, and supersonic speed ranges. The first and most important result involves the phenomenon of boundary-layer transition. In 1914 Prandtl (ref. 1) demonstrated that the pronounced effects of flow separation on the low-speed drag of a bluff body, such as were observed earlier by Eiffel (ref. 2), are determined by the type of boundary-layer flow approaching the separation point; that is, whether it is laminar or turbulent. In the initial post-war years, a number of independent investigations (refs. 3, 4, 5, and 6) were conducted in transonic and supersonic wind tunnels which revealed similar marked effects on compressible flow fields when the boundary layer approaching separation was changed from laminar to turbulent. These experiments leave little doubt that separated flows with transition upstream of separation are fundamentally different from those with transition downstream.

From various experiments on separated flows, a second general result can be detected which may not have been evident at the time the various experiments were conducted, but which is perceptible now through the medium of hindsight coupled with the findings of more recent research. This second result concerns the importance of the location of transition within a separated layer relative to the position of laminar separation. Schiller and Linke (ref. 7) found that even under conditions where the boundary-layer flow remains laminar at separation, the pressure distribution about a circular cylinder depends significantly on how near transition is to the separation position. They observed that an increase in either Reynolds number or turbulence level moved transition upstream in the separated layer to a position closer to separation, and that such movement considerably affected the drag and pressure distribution. Closely related to these findings are some isolated observations that transition location often correlates with an abrupt pressure

[1] Supersedes NACA TN 3869 by Dean R. Chapman, Donald M. Kuehn, and Howard K. Larson, 1957.

Preceding Page Blank

rise when the separated layer is laminar. This correlation is found within "separation bubbles" on airfoils (ref. 8), and in many other cases, both at low speed and supersonic speed, as is discussed in detail later. Thus with a separated layer remaining laminar, a variation in Reynolds number changes the location of transition relative to the separation point and this varies the pressure rise associated with transition; the consequence is an effect of Reynolds number on pressure distribution which is especially pronounced in the separated flow behind a base. (See refs. 5 and 6.) An initial approach to the computation of such effects has been made by Crocco and Lees (ref. 9) who consider explicitly the movement of transition along a separated layer. The synoptic result of these various investigations is that the location of transition relative to separation is a variable generally important to separated flows wherein the boundary layer is laminar at separation.

In most previous experiments attention generally has been directed to the type of boundary-layer flow existing at separation and to the relative distance between transition and separation; less attention has been given to the type of boundary-layer flow existing at reattachment and to the relative distance between transition and reattachment. ("Reattachment" is taken herein to mean the localized zone wherein a separated layer either meets a surface or another separated layer.) At sufficiently low Reynolds numbers, a type of separation can exist where transition is downstream of the reattachment zone, or perhaps even nowhere in the flow field. In order to achieve this pure laminar [2] type of separation in a low-speed flow, however, the Reynolds number must be very low (e. g., the order of several thousand for a circular cylinder). In view of the unusually low Reynolds number required, and the fact that the reattachment position is not steady in a subsonic wake, it is understandable that conditions at reattachment previously have received relatively little emphasis in investigations of separated flow. An isolated example of pure laminar separation was observed by Liepmann and Fila (ref. 10) behind a small, half-cylinder, roughness element placed within a subsonic laminar boundary layer.

The present investigation, which is concerned in considerable part with flow conditions near reattachment, was conducted in three phases differing greatly in purpose and scope. Such division was not planned but was dictated by some rather surprising and encouraging results obtained during the initial phase of experimentation, coupled with some major revisions in the wind-tunnel facility made during the interval over which the research was conducted. The initial experiments (conducted in 1953) were concerned with the manner in which Reynolds number variation at supersonic speed affects the separated-flow region upstream of two-dimensional steps of various height. Comparison of the results of the initial experiments with those of other experiments revealed several intriguing similarities among various separated flows on presumably unrelated configurations. These similarities (discussed in detail later) suggested that the location of transition relative to reattachment might be just as fundamental to any separated flow as is the location of transition relative to separation. In order to explore this possibility, a second phase of experiments was conducted with a variety of model shapes rather than just a step. A third phase of experiments was conducted after modifications were made to the wind tunnel which enabled operation over an extended Mach number and Reynolds number range. Inasmuch as an ultimate hope was to improve the understanding of separated flows, it was thought mandatory to include measurements at subsonic as well as supersonic speeds as an integral part of the research. All measurements were made on two-dimensional models.

This report covers three subjects: (1) a general survey of the experimental results grouped according to whether transition is downstream of reattachment, between separation and reattachment, or upstream of separation; (2) a description and experimental test of a theory of the fundamental mechanism near reattachment which governs the dead-air pressure in a separated region (this theory is used to provide an explanation of why transition location relative to reattachment is of importance to separated flows); (3) a simple analysis and pertinent experiments on "free interaction" type flows wherein the boundary layer interacts freely with an external supersonic flow in the manner originally pictured by Oswatitsch and Wieghardt (ref. 11). A preliminary report presenting briefly some of the salient results of this investigation has been published as reference 12.

In the three-year interim over which the present experiments and theoretical research were conducted, various results of other studies appeared which benefited and influenced the course of this research. A thorough investigation of turbulent separation induced by steps and by interaction of oblique shock waves with the turbulent boundary layer on a wind-tunnel wall was published by Bogdonoff (ref. 13) and by Bogdonoff and Kepler (ref. 14). As a result it was deemed unnecessary to investigate turbulent separations for these two cases, except to provide incidental comparisons and checks with their data. Similarly, extensive results of Gadd, Holder, and Regan (ref. 15) became available for the case of shock-wave-induced separation. In these latter experiments, separated flows with transition downstream of reattachment were observed as were fully turbulent flows and flows with transition between separation and reattachment. The importance of transition location relative to reattachment is clearly recognized by Gadd, et al. More recently, the research of Korst, Page, and Childs (ref. 16) became available, in which nearly the same fundamental theoretical mechanism was employed in their calculations of base pressure for thin turbulent boundary layers as that mechanism described and experimentally tested herein for thin laminar boundary layers. Comparison of results from these various recent and independent researches is made later in the report.

[2] For reasons explained later, many flows commonly designated as "laminar" separations in previous investigations really are affected significantly by the presence of transition locally in the reattachment zone; such flows are referred to herein as "transitional" separations. Consequently, it is desirable for purposes of emphasis and contradistinction to use an unambiguous terminology, such as "pure laminar," for those flows which truly are unaffected by transition.

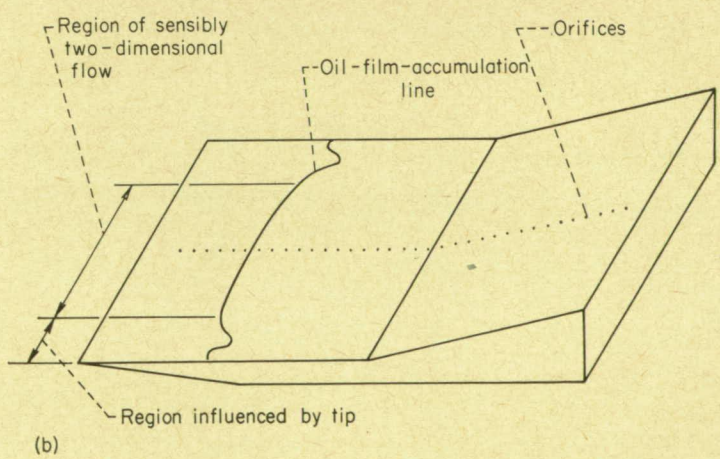
APPARATUS AND TEST METHODS

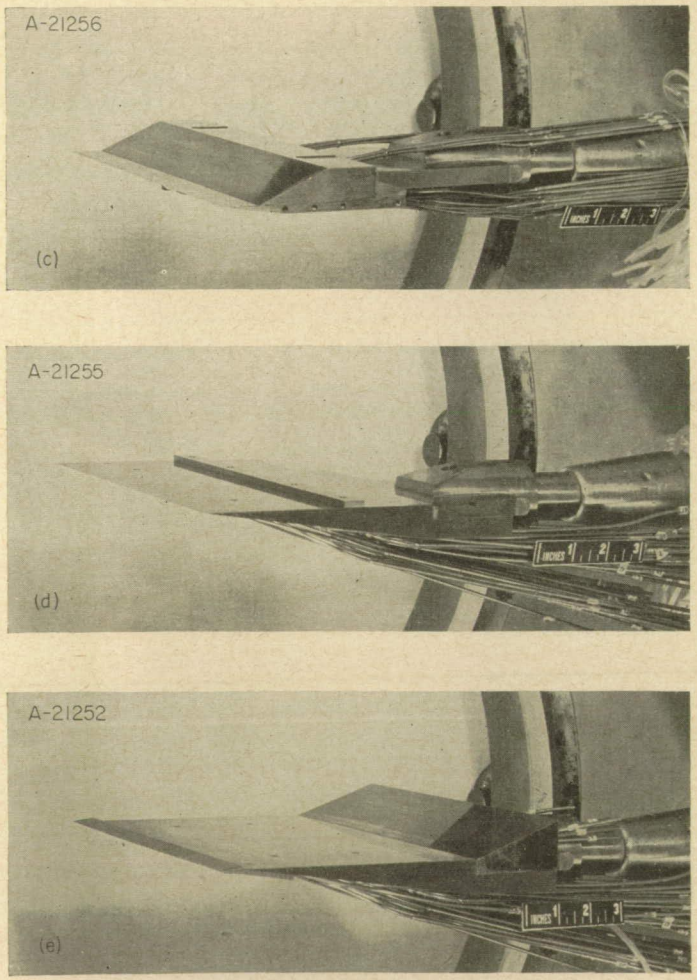


WIND TUNNEL

Experiments were conducted in the Ames 1- by 3-foot supersonic wind tunnel No. 1. This tunnel operates continuously with dry air over a range of reservoir pressures. For the initial portion of experiments, the range of tunnel pressures available was limited to between 2.5 and 30 pounds per square inch absolute, and the Mach number was limited to about 2.4. Revisions to the tunnel structure, flexible-plate nozzle, and drive motors were made in 1955 so that subsequent experiments could be made over the range of pressures between about 2 and 60 psia and at Mach numbers up to about 3.6. Subsonic speed control ($0.4 \leq M_\infty \leq 0.8$) was obtained by choking the flow downstream of the test section with the flexible, supersonic diffuser.

MODELS AND SUPPORTS

Several types of models with different supports and end plates were employed, each being designed to provide two-dimensional flow conditions. Pressure orifices were located at stations near the center span, and, in most cases, were spaced either 0.05 or 0.10 inch apart. The initial experiments were conducted on step models in an 8-inch-wide two-dimensional channel placed within the 1- by 3-foot test section (see ref. 17 for description of channel). Since use of the channel made model changes and observation rather cumbersome, subsequent experiments were conducted without the channel apparatus by mounting the 8-inch span models on a sting from the rear, and by attaching at both tips relatively small, transparent (lucite), end plates. The photograph in figure 1 (a) illustrates the latter method of

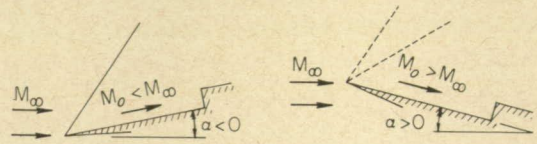


(a) Photograph showing oil-film accumulation taken during a run of model CC10°—2 with end plates.
(b) Sketch of typical oil-film-accumulation line.

FIGURE 1.—Typical model installations.

sting mounting. Since comparison of results obtained with the two methods of mounting showed no significant difference, all subsequent measurements were taken with this latter method of mounting. For those data presented, the flow over the center portion of the model was judged essentially two-dimensional according to three indications: (1) several pressure orifices located spanwise 2 inches off center revealed only small variations of static pressure; (2) the pattern formed by oil film on a model surface (see fig. 1 (b)) was normal to the flow direction over a sizable center portion of span; and (3) at all Mach numbers, changing from triangular-shaped to rectangular-shaped end plates had no effect on midspan pressure distribution, and at Mach numbers above about 2.3, even the removal of end plates had no effect. End plates often were not used at the higher Mach numbers, as this enabled better shadowgraphs to be obtained.

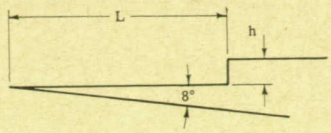
Photographs of several models mounted without end plates are presented in figures 1 (c), 1 (d), and 1 (e). The



(c) Model CC25°—2. (d) Model S–4. (e) Model CC25°—5 (trip 4).

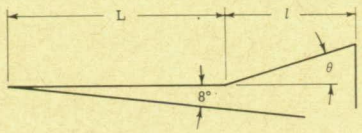
FIGURE 1.—Concluded.

geometry, dimensions, and designations of the various models are given in figure 2. Most of the models of figure 2 consist of a basic flat plate to which various wedges and steps were fastened to form additional models. This basic flat plate also was used for measurements of boundary-layer-transition Reynolds number to give an indication of wind-tunnel disturbance level. The leading-edge thickness of the flat plate was determined optically to be 0.005 inch. The leading-edge thickness of the other models (for which the surface contour is an integral part of the basic plate) is believed to be approximately the same.



TEST METHODS AND TECHNIQUES

Variation in Mach number.—The Mach number M_o approaching an interaction region was varied in several ways. At subsonic speed, the angle of attack was held fixed while adjustment of the diffuser minimum area provided variation in test-section Mach number M_∞. At supersonic speed, the angle of attack was changed to provide variation in M_o, as illustrated, and the flexible nozzle walls occasionally were repositioned to provide additional varia-



tion in M_∞. Only a few test-section Mach numbers were required to achieve variation in M_o from values near 1 to about 3.6, inasmuch as the angle of attack for some of the models could be varied by $\pm 16°$. Thus a given M_o could be obtained with either an expansion wave or a shock wave occurring at the model leading edge. It was found in most cases that for a given M_o both types of settings would yield the same pressure distribution over the center-span portion of the model. In several cases, though, detached bow waves at $\alpha > 0$ resulted from excessive flow deflection over the lower surface, and this caused transition to occur prematurely on the upper surface. Under such conditions, the pressure distribution in transitional-type separations differed from that obtained at the same M_o, but with an expansion wave at the leading edge. In some cases of laminar separation, small differences in the shape of pressure distribution—but not in the pressure rise to separation—were observed at the same M_o for the two types of settings. These small differences are attributed to known differences in tunnel-empty pressure distribution at the different nozzle settings.

Optical techniques.—One or more shadowgraphs were taken for each pressure distribution in order to determine the location of transition. Relatively long exposure times were used ($\frac{1}{25}$ to $\frac{1}{100}$ sec) since the mean position of transition was desired rather than an instantaneous position. In the first two phases of experimentation, film was placed next to a side window which intercepted near-parallel light passing through the test section. Polaroid-Land film was used. In the third phase of experimentation, the film was placed on a parallel-motion mechanism surrounded by light-proof bellows (see fig. 3). This enabled the distance from the model to the film to be adjusted in order to take advantage of focusing effects induced by the refraction of parallel light as it passes through the boundary layer (for an explanation of the focusing effects, see ref. 18). Comparison of figures 4 (b) with 4 (a) reveals the improvement achieved by increasing the distance between the film and

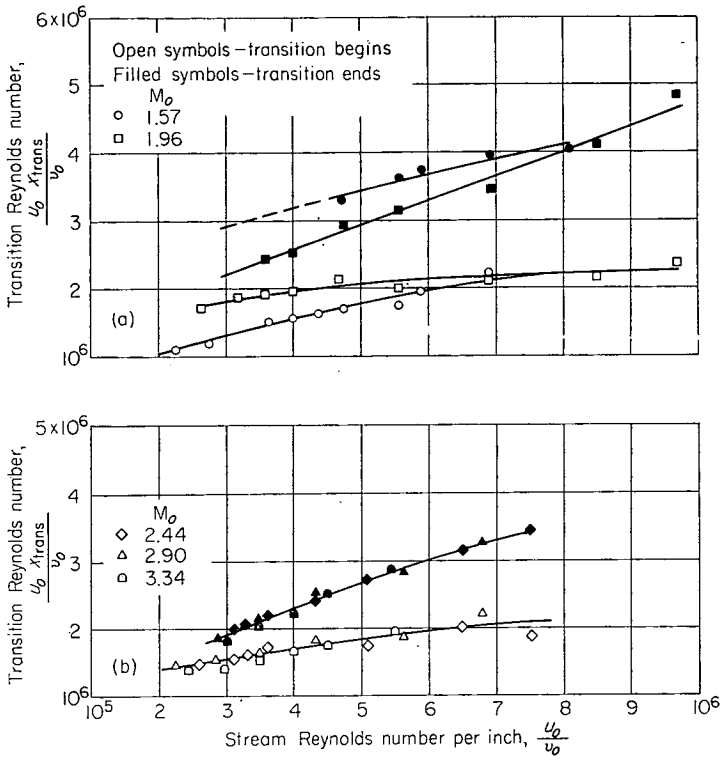
the flat-plate model. The white line, indicating the nature of boundary-layer flow, is displaced from the surface where it can be better observed. Comparison of figures 4 (d) with 4 (c) reveals the improvement achieved in visualizing the separated flow over a curved surface model by increasing the film-to-model distance.

High-speed motion pictures (Fastax) were taken of the shadowgraph field in order to ascertain the relative steadiness of various separated flows. The parallel light was of sufficient intensity to permit pictures of several thousand frames per second to be taken from the shadowgraph pattern cast on a ground-glass screen. Runs at various frame speeds up to 6000 frames per second showed that flow unsteadiness could be detected readily at speeds near 2000 frames per second.



Transition determination from shadowgraphs.—Two methods, depending upon tunnel pressure, were used to detect transition from the shadowgraphs. At low tunnel static pressures, with small film-to-model distances, transition location appeared as the "end" of the laminar (white) line on the shadowgraphs. At high tunnel static pressures, with small film-to-model distances, or at arbitrary pressure with large film-to-model distances, optical refraction effects are large, and a technique used by Pearcey (ref. 18) was employed to locate transition. Under these conditions the white laminar line appears displaced from the surface by a distance large compared to the boundary-layer thickness. For flow over a flat plate, the apparent displacement is nearly constant from the surface as long as the layer remains laminar, since the density profiles are nearly similar along the plate length. An example is illustrated in figure 5 (a).

(a) Transition beginning near rear of plate. $M_o=2.0$; $R_L=1.9\times10^6$.
(b) Transition region on plate. $M_o=2.9$; $R_L=2.3\times10^6$.
(c) Transition region on plate. $M_o=3.3$; $R_L=2.8\times10^6$.

FIGURE 5.—Shadowgraphs indicating type of boundary-layer flow and location of transition on the flat plate model.

When the Reynolds number is increased so that transition is completed on the plate, the white line converges to the surface in the transition region. Examples of this are illustrated in figures 5 (b) and 5 (c). The beginning of convergence represents the beginning of transition effects on the density profile and is taken as the beginning of transition itself. The end of convergence, where the white line practically meets the surface, represents the first position where the density profile has its maximum gradient close to the surface (compared to a laminar profile) and is taken as the end of transition. Under high refraction conditions, therefore, both the beginning and end of transition often could be ascertained approximately. As an example, the results of transition determinations by this method for the flow over a flat plate (leading-edge thickness 0.005 in.) are presented in figure 6. The method employed in determining

(a) Lower supersonic Mach number range.
(b) Higher supersonic Mach number range.

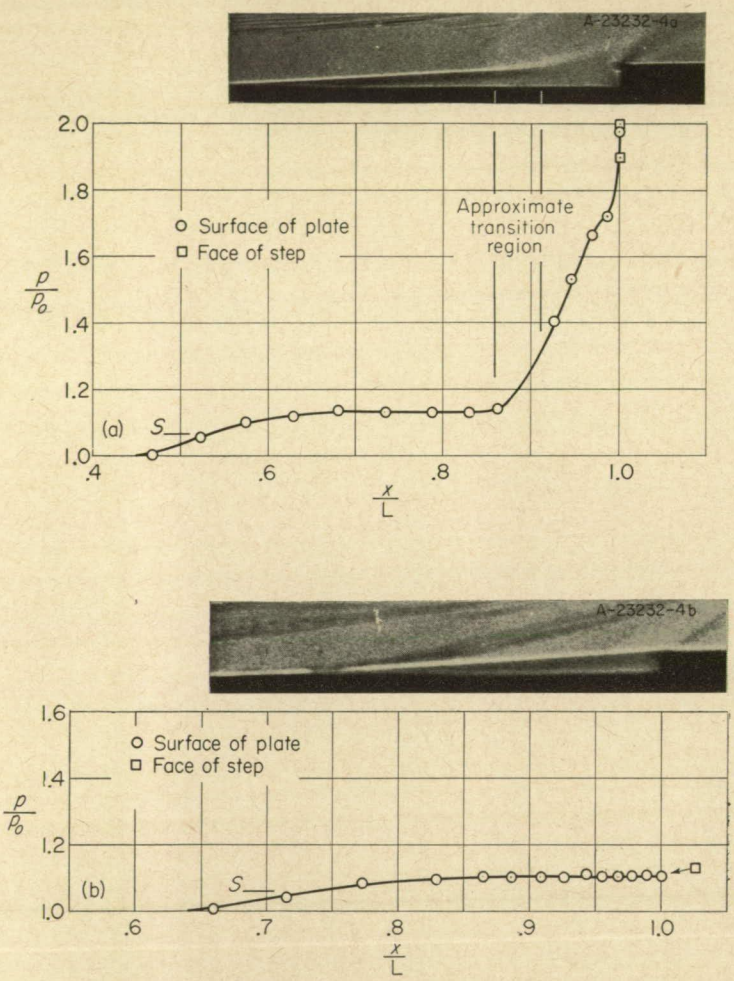
FIGURE 6.—Reynolds number of transition on a flat plate in the Ames 1- by 3-foot wind tunnel No. 1. (Leading edge approximately 0.005 in. thick.)

the beginning and end of transition for these data is illustrated in figure 5 (b). The transition Reynolds number is plotted as a function of the Reynolds number per unit length, inasmuch as this variable appears to be more significant than the Mach number. For example, at stream Mach numbers above 2.0, the curves for both beginning and end of transition are independent of Mach number when plotted in this fashion. These curves will be used later in comparison with other data.

Boundary-layer trips.—A common experience in supersonic wind-tunnel operation is that larger and more severe trips are required as the supersonic Mach number is increased. This trend is reported in detail by Winter, Scott-Wilson, and Davies (ref. 19) who find that the required wire diameter for tripping the boundary layer increases roughly exponentially with Mach number (an interpretation of this trend is given later as it involves a result from the present research). Moreover, merely placing a disturbance at some streamwise position on a model does not insure a fixed transition location. For example, in the present investigation, at Mach numbers near 3 the wire trips often did not effect transition until a short distance before the separation position. Under these conditions the effective origin of the turbulent layer varied with tunnel pressure in an unknown manner over the plate length between the wire and the separation position. Data obtained on the effects of Reynolds number variation are uncertain under such conditions.

In the course of experimentation various full-span boundary-layer trips were used depending primarily on the Mach number. At subsonic and moderate supersonic Mach numbers a 0.015-inch-diameter wire (trip 1) placed 0.13 inch from the leading edge, as sketched in figure 2 (c), was adequate to effect transition near the wire. At the higher supersonic Mach numbers a trip more severe than a small wire was needed. On several models tested in this higher Mach number range during the second phase of experiments, the upstream portion of the model plate was corrugated by sawtoothed machining (see trip 2 in fig. 2 (c)) and on one model a section of wire screen also was added (trip 3). During the third phase of research a "base trip," consisting of a small wedgelike attachment to the leading edge, was employed (see trip 4 in fig. 2 (c) and photograph in fig. 1 (e)). A pressure orifice was installed in this base in order to determine when the trip fixed transition. A plot of the base pressure as a function of tunnel pressure revealed the tunnel pressure above which transition was fixed near the trip.

Surface oil-film technique.—A useful technique employed in the course of research was an oil-film method for determining quantitatively the location of separation (and hence the pressure rise to a separation point). It is known that liquids coated on a surface will accumulate along a line of separation. The flow upstream of separation washes liquid downstream, whereas reverse flow downstream of separation washes liquid upstream. In order to make this technique quantitative and to minimize interference, very small amounts of liquid are required. To detect minute accumulations of liquid, light at glancing incidence was employed. This enabled an accumulation to be detected of height much smaller, for example, than the mouth of a pitot tube. Silicone oil (Dow Corning DC 200–10) was employed, sometimes mixed with regular hydrocarbon oil. Thin films of this oil were mobile yet would not evaporate even after four or five hours of continuous tunnel operation. It was found possible either to coat portions of a model before a run or to emit oil from an orifice during a run. The minute, threadlike lines of accumulation, which were observed readily, could not be photographed well during tunnel operation. For photographic purposes, the surface oil film for the model in figure 1 (a) (possibly not visible in half-tone reproduction) was allowed to accumulate in larger amounts than for most quantitative measurements. A typical accumulation pattern is sketched in figure 1 (b).



The oil-film technique for determining the separation point is believed to be more sensitive than the pitot-probe technique. Using a Stanton tube 0.005 inch high, for example, Gadd, et al., (ref. 15) could determine only roughly the laminar separation point and, hence, were unable to detect any Reynolds number dependence on the pressure rise to separation. As will be seen later, the oil-film technique readily enables the Reynolds number dependence to be determined as well as quantitative values of rather good accuracy for the pressure rise.

Extensive use of the oil-film technique revealed, under certain test conditions, an anomalous, double-accumulation pattern which was difficult to interpret. Some details of the research conducted to resolve this anomalous behavior are described in Appendix A.

RESULTS AND DISCUSSION PERTAINING TO RELATIVE TRANSITION LOCATION

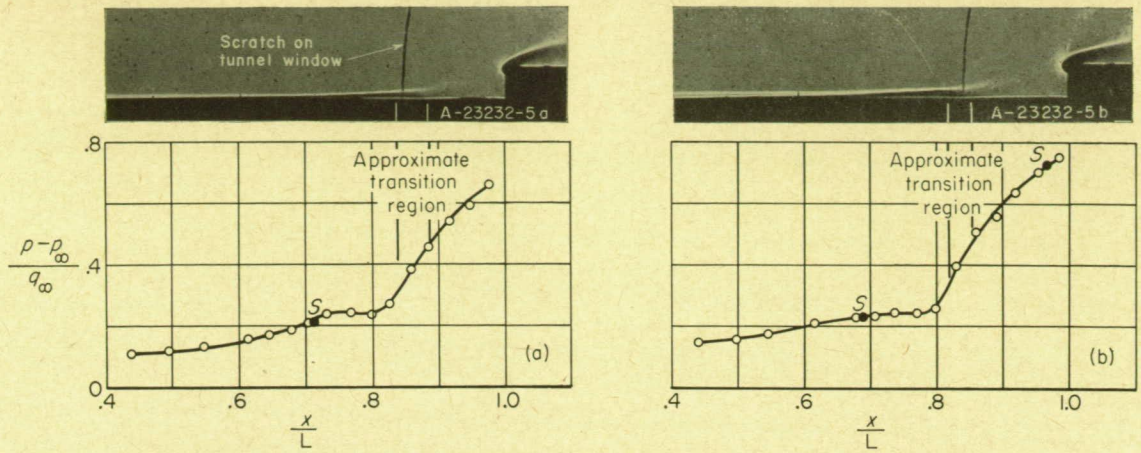
GENERAL SURVEY ILLUSTRATING DOMINANT IMPORTANCE OF RELATIVE TRANSITION LOCATION

Results of initial experiments.—As noted previously, the initial experiments were conducted on step models in a two-dimensional-channel apparatus; they clearly revealed the basic importance of transition location relative to a reattachment position. Transition location was found to correlate closely with an abrupt rise in pressure when transition was between separation and reattachment. A typical example of this is illustrated in figure 7 (a). The pressure distribution in this type of separation was affected markedly by variations in Reynolds number. In contradistinction, no abrupt rise in pressure was observed when transition was downstream of the reattachment point (step shoulder); figure 7 (b) represents a typical example of this. The step height in figure 7 (b) is smaller than that in figure 7 (a) and is sufficiently small so as not to bring about transition. The pressure distribution for this pure laminar type of separation was affected only slightly by variations in Reynolds number.

(a) Transition upstream of reattachment. S–7; $M_o=1.9$; $R_L=0.92\times10^6$.

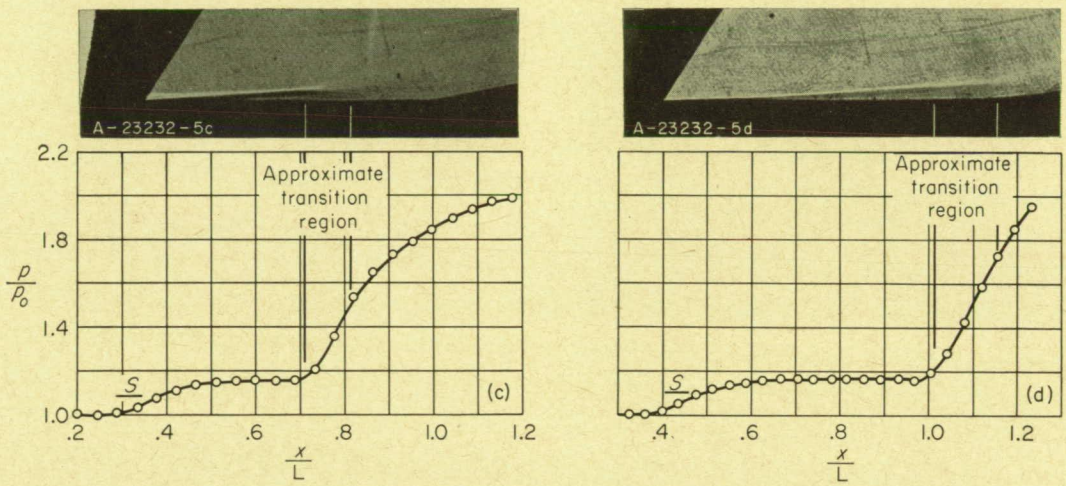
(b) Transition downstream of reattachment. S–8; $M_o=1.9$; $R_L=0.87\times10^6$.

FIGURE 7.—Typical results from two-dimensional channel illustrating importance of transition location relative to reattachment.



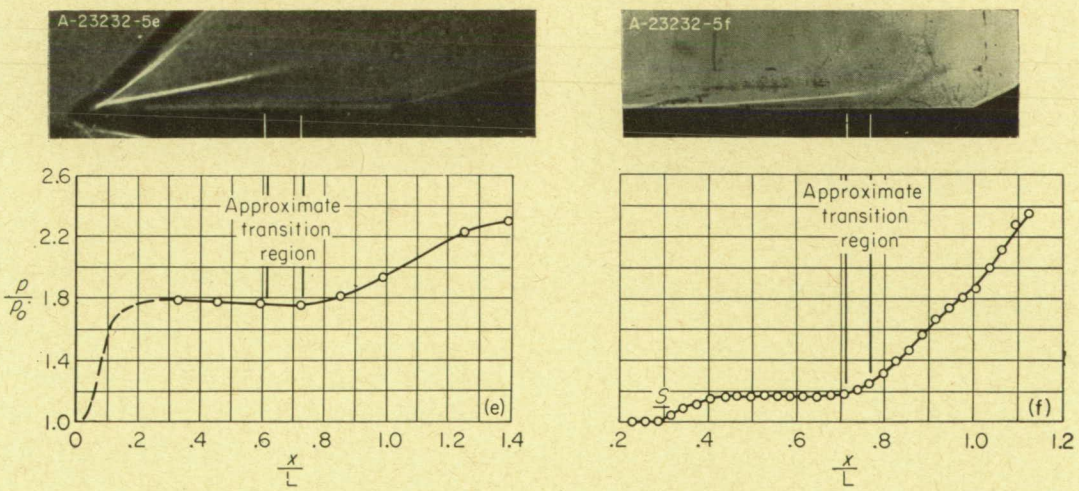
These contrasting characteristics show that the location of transition relative to reattachment is of critical importance at least to the separated flow ahead of a step.

The results of the initial experiments revealed some intriguing similarities between various results of experiments on separated flow from several other sources involving entirely different object shapes. The trend observed, of a slight influence of Reynolds number on pure laminar separations, was the same as the trend which could be interpreted from the base-pressure experiments of Reller and Hamaker (ref. 20). Also, the trend of large influences of Reynolds number for transitional separations was the same as that which could be interpreted from many previous measurements of base pressure. Crocco and Lees (ref. 9) make essentially this interpretation, only with reference to transition upstream of a "critical" location in the wake rather than upstream of reattachment. Consequently, it seemed possible that transition location relative to reattachment might be generally important to separated flows and that there might be some characteristics common to a variety of separated flows having the same relative transition location. The second phase of experiments was conducted with various model shapes in order to investigate this possibility. Some of the more salient results are surveyed below; they relate to the correlation between transition and abrupt pressure rise, to the relationship between type of pressure distribution and relative transition location, and to the effect of Reynolds number variation on separated flows.



Correlation between transition and occurrence of abrupt pressure rise.—Transition was determined from shadowgraphs in two different ways (described in the section APPARATUS AND TEST METHODS). Under conditions of low pressure and low optical refraction, the mean location of transition was taken as the end of the familiar white line adjacent to a surface. Altogether about 170 cases of this type were examined corresponding to different combinations of Mach number, Reynolds number, and model shape. Figure 7 (a) represents one example, and various others are shown in figure 8 [3] for subsonic as well as supersonic flow. The terminal location of the white line is near an abrupt pressure rise in each case. There is sufficiently close coincidence of the two locations to associate the location of transition with that of a rapid rise in pressure. Emphasis is placed on the fact that the correlation for subsonic flow (figs. 8 (a) and 8 (b)) is much the same as that for supersonic flow. This attests to the fundamental importance of transition for separated flows.

As explained previously, both the beginning and the end of transition could often be determined, when optical refraction was high, by the beginning and end of convergence of the white line toward a solid surface. Altogether, about 95 cases of this type were examined for various combinations of Mach number, Reynolds number, and model shape. Some typical examples are shown in figure 9. In most of these examples transition occurs in an adverse pressure gradient, and the streamwise extent of the transition region



[3] In these and other figures, a separation point determined from an oil film observation is represented by a filled symbol. Separation pressure rises determined from a correlation (presented later) of measurements on a variety of model shapes are represented by a short line.

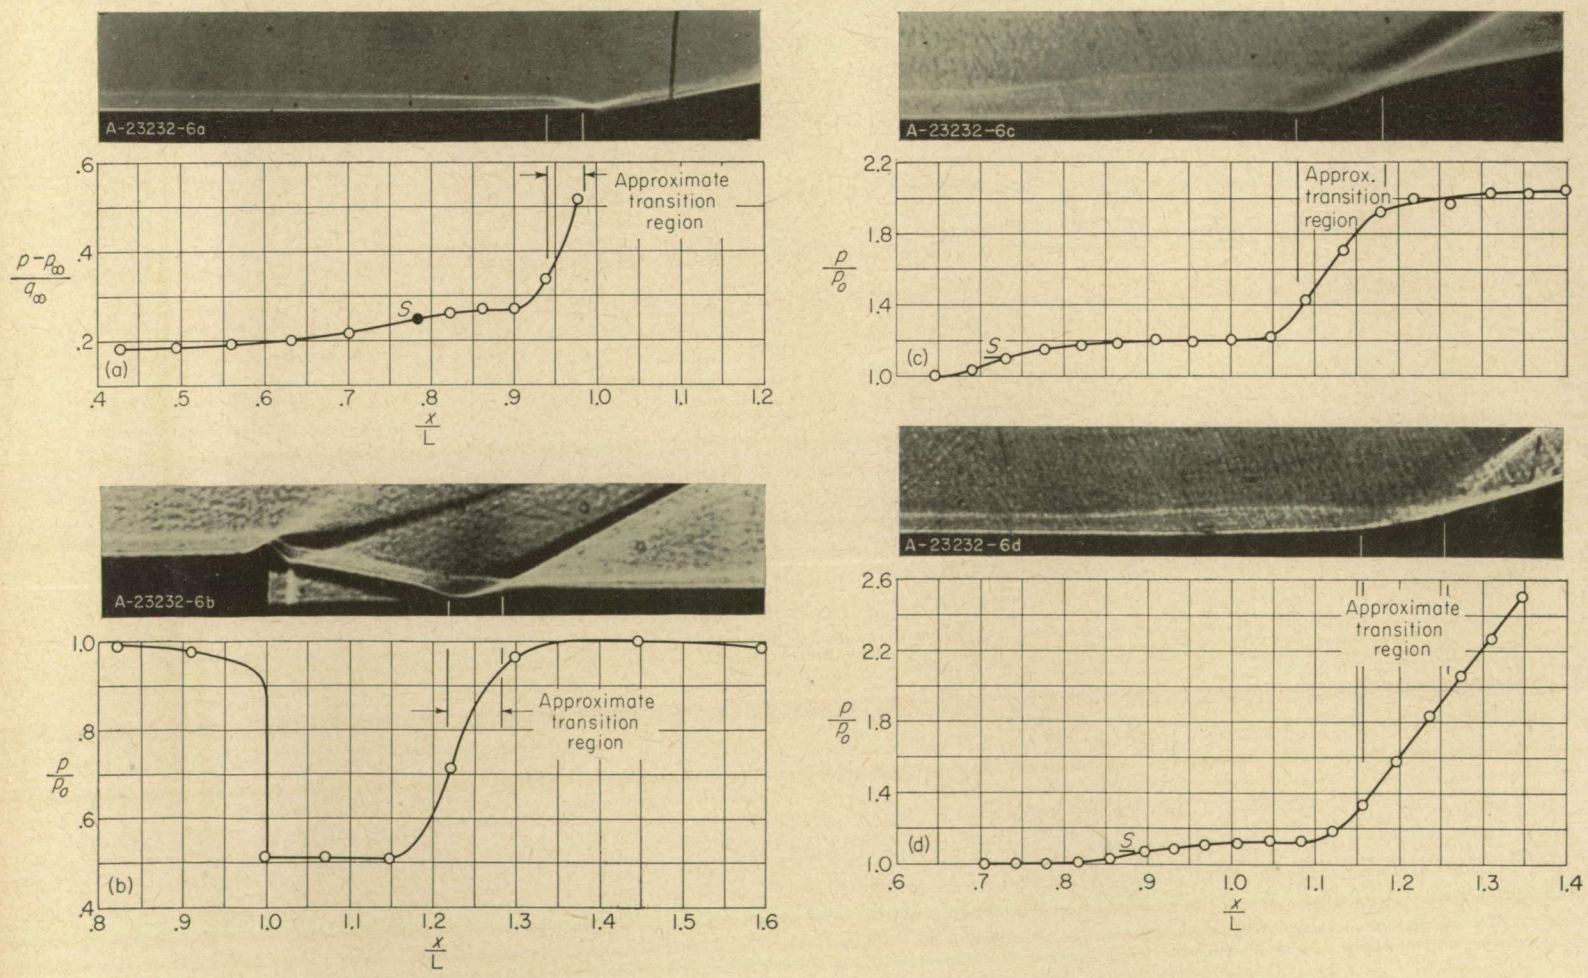
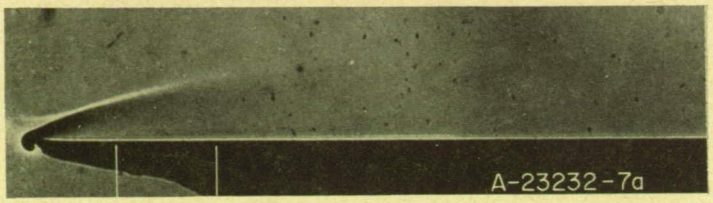
FIGURE 8.—Correlation of transition with abrupt pressure rise; low tunnel pressures.



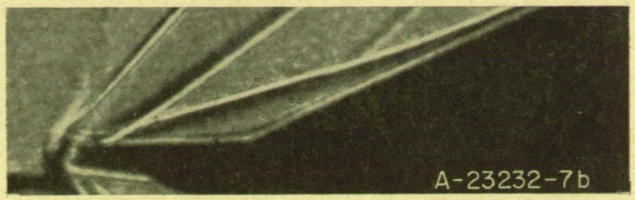
is much shorter than on a flat plate. In all cases the abrupt pressure rise occurs near the transition region, so that a marked pressure rise again is associated with transition.

It is interesting that, in subsonic flow over step models, separation bubbles often were observed on the flat surface well upstream of the step. An example is illustrated in figure 8 (b). In such cases, oil film accumulated at two streamwise locations; the upstream separation is that of a laminar layer and locates the upstream portion of the bubble; the downstream separation (not evident in shadowgraph) is that of a turbulent layer as it approaches the step. Turbulent reattachment presumably occurs somewhere between the two experimentally determined positions of separation.

The correlation of the location of transition with that of an abrupt pressure rise has been observed previously in many isolated cases. Experiments at low subsonic speeds conducted on circular cylinders, spheres, and airfoils, as reported by Fage (ref. 21), showed similar close correlation of transition location (determined by surface shear data from a Stanton tube) with an inflection point in pressure distribution which just preceded an abrupt pressure rise.[4] Analogous correlation also was noticed in transonic flow by Ackeret, Feldmann, and Rott (ref. 4), in supersonic shock-induced separations by Gadd, Holder, and Regan (ref. 15), and in subsonic separation bubbles on airfoils by Gault (ref. 8).



In spite of the many observations of correlation between transition location and abrupt pressure rise—as evidenced in figures 7 to 9 and in previous experiments—it is not necessary that transition in a separated layer be accompanied by a rapid pressure rise, or that abrupt rises in pressure necessarily indicate transition. If transition is far upstream of reattachment, and only slightly downstream of separation, then transition can occur in the mixing layer under conditions of nearly constant pressure. An example of this is shown in figure 10 (a) in which transition is com-



[4] In retrospect, it would be expected that for such correlation to have existed, transition would have occurred within a small "separation bubble" in these early experiments. This expectation was indicated by Bursnall and Loftin (ref. 22). Such bubbles have been observed frequently on airfoils but rarely on a sphere or circular cylinder. A direct confirmation of the existence, not often appreciated, of a small separation bubble on the upstream half of a circular cylinder in the supercritical Reynolds number range is reported by Gault (ref. 8) who used a liquid film to detect separation.

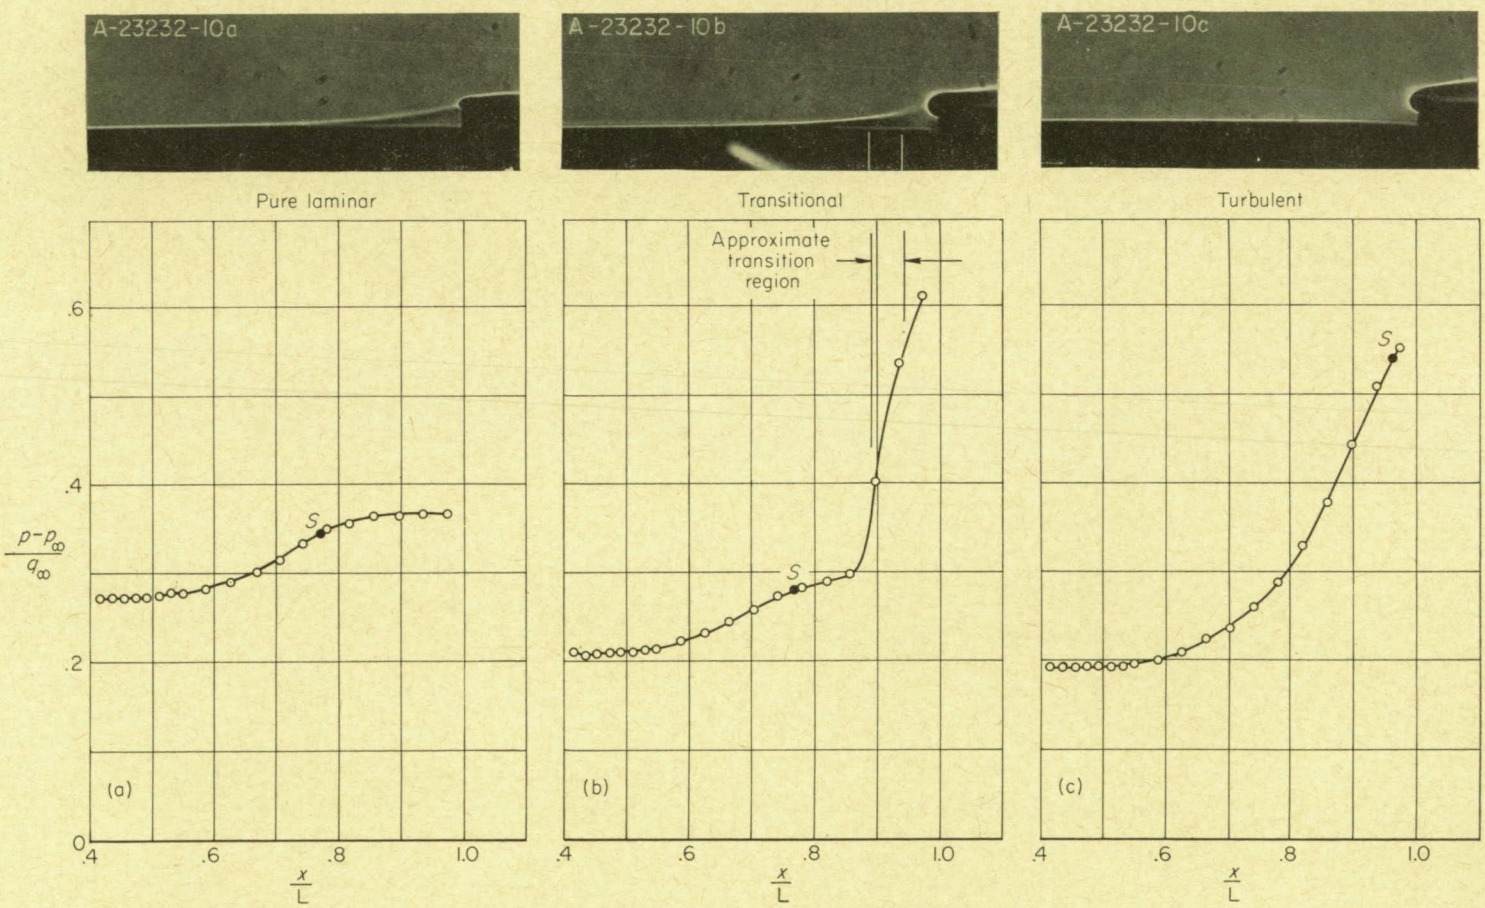
FIGURE 12.—The three regimes for a step; $M_o\approx3.5$.

pleted well upstream of reattachment and the pressure rise is brought about by a fully turbulent layer as it reattaches. If a reattaching layer is laminar and very thin, it also can bring about an apparent rapid rise in pressure and not be indicative of transition. An example of this is presented in figure 10 (b) for which transition is downstream of the field of view. (A theory for the pressure rise of a thin, pure laminar, reattaching layer is given later.) In view of these observations, the pertinent conclusions drawn from the close correlation often observed between transition and an abrupt pressure rise is as follows: Once transition is between separation and reattachment—and is relatively close to reattachment—there is an abrupt pressure rise associated with transition; hence, any change in a parameter which experience has shown to affect transition (such as Reynolds number, surface roughness, turbulence level, etc.) can also change pressure distribution directly through its change in the location and magnitude of the steep pressure rise.

Representative pressure distributions for the three regimes and results of high-speed motion picture studies.—As the importance of transition location relative to reattachment is now manifest, and the importance of transition location relative to separation has long been known, it is clear that distinction should be made for any given object shape between the three regimes of flow separation; "pure laminar" where transition is downstream of reattachment, "transitional" where transition is between reattachment and separation, and "turbulent" where transition is upstream of separation. Within the scope of this study, all three regimes were observed for most of the model shapes, as the following table illustrates:

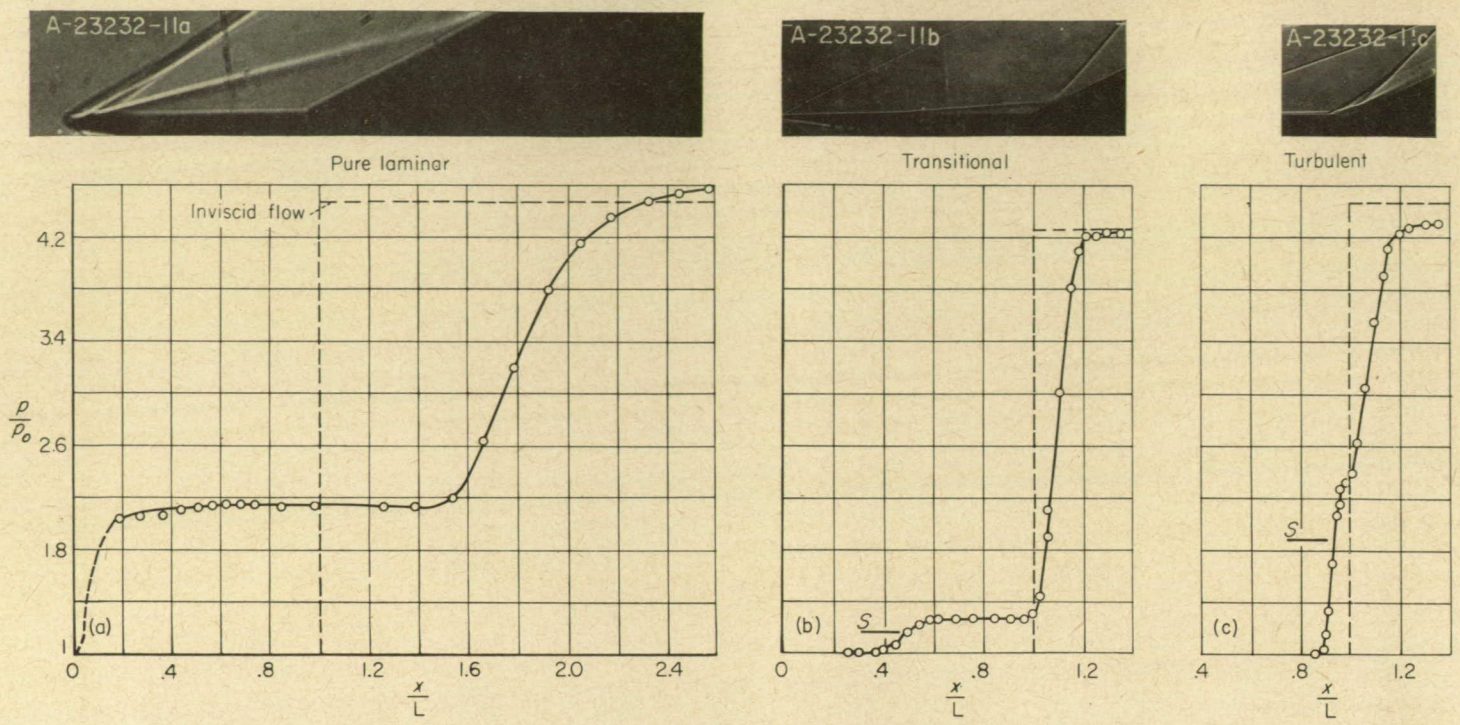
Regimes observed in present study			
Model	Pure laminar	Transitional	Turbulent
Step	$M>1$, $M<1$	$M>1$, $M<1$	$M>1$, $M<1$
Compression corner	$M>1$, $M<1$	$M>1$, $M<1$	$M>1$, $M<1$
Base	$M>1$	$M>1$	$M>1$
Curved surface	$M>1$	$M>1$	$M>1$
Oblique shock	$M>1$	$M>1$	
Leading-edge separation	$M>1$	$M>1$	



Studies were not conducted with the turbulent regime for leading-edge separation, or with the turbulent regime for oblique-shock-induced separation. Much data are available for this latter case in references 14 and 15.

Shadowgraphs and corresponding pressure distributions for the three regimes, at both supersonic and subsonic speeds, are illustrated in figures 11 through 17 for various models and various Mach numbers. Figure 11, which shows the

step in supersonic flow, reveals as well as any the basic differences between the three regimes. The pure laminar regime (fig. 11 (a)) has a plateau of nearly constant pressure representing a dead-air region. The separation-point pressure, p_s, and the plateau pressure, p_p, are of the order of 15 and 30 percent greater, respectively, than the pressure p_o just upstream of the separated region. For some step models, pressures were measured at a few points on the step face and were usually found—for the pure laminar regime—to be the same as the dead-air pressure (see fig. 7 (b) for example). In a few cases, a very small pressure rise was observed in the corner and on the step face. It is thought that there always is a small region near the step shoulder where pressures on the face locally are higher than the dead-air pressure, since a portion of the separated layer presumably must be brought to rest on the step face. If the separated layer at separation is thick, then the expected magnitude of pressure increase would be small, and if it is very thin, then the area over which the pressure increase would occur would be confined to a small area near the shoulder. This may explain why a significant pressure variation over the step face is not often measured. High-speed motion pictures (taken at $M_o=2.3$ with 2000 to 6000 frames per sec.) indicated the pure laminar separation over a step to be steady.



Most of these characteristics for pure laminar separation over a step differ from those for transitional separation illustrated in figure 11 (b). In the transitional regime the boundary layer is still laminar at separation so the pressure rise to separation remains about the same as for pure laminar separation, but the role of transition is to bring about much greater pressure rises before reattachment occurs at the step. Pressure variation on the step face, now easily measurable, amounts to the order of 0.1 p_o (see fig. 7 (a) for example). As Lange (ref. 23) has noticed previously, this variation implies that sizable subsonic velocities exist within the reverse flow region just upstream of the step. High-speed motion pictures indicated the flow to be unsteady in the region between transition and reattachment on the step. Such unsteadiness might be expected since transition itself is fundamentally a nonstationary phenomenon. In spite of this unsteadiness, the white line indicative of laminar flow appeared reasonably steady over most of its length whenever transition was relatively far from separation and relatively close to reattachment. At higher Reynolds number, though, where transition was close to separation, the angle of separation appeared unsteady in the motion pictures as did the flow downstream of transition.

These qualitative flow conditions again alter on passing

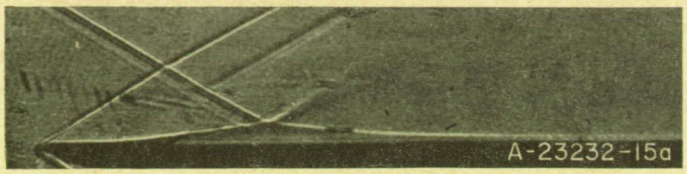
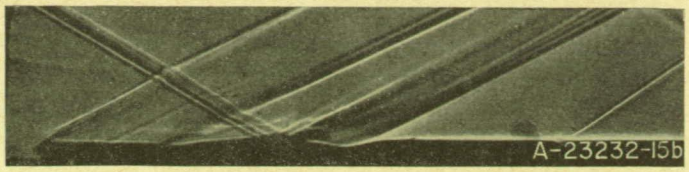
FIGURE 17.—The three regimes for a curved surface; $M_o=2.7$.

to the turbulent regime illustrated in figure 11 (c). The pressure rise to separation now is much larger (about five times larger), as should be expected. A plateau in pressure (characteristic of dead air) does not occur since the eddying motion of the turbulent layer energizes the air. Pressures on the step face were found to vary in much the same manner as for the transitional regime. The flow field observed in high-speed motion pictures was not perfectly steady like the laminar separation was, but, compared to the transitional separation, the turbulent separation was relatively steady. Shock waves occasionally appeared to move slightly but no appreciable movement of the separated layer could be detected. This degree of steadiness of turbulent separation upstream of a step appears much the same as that observed by Bogdonoff and Kepler (ref. 14).

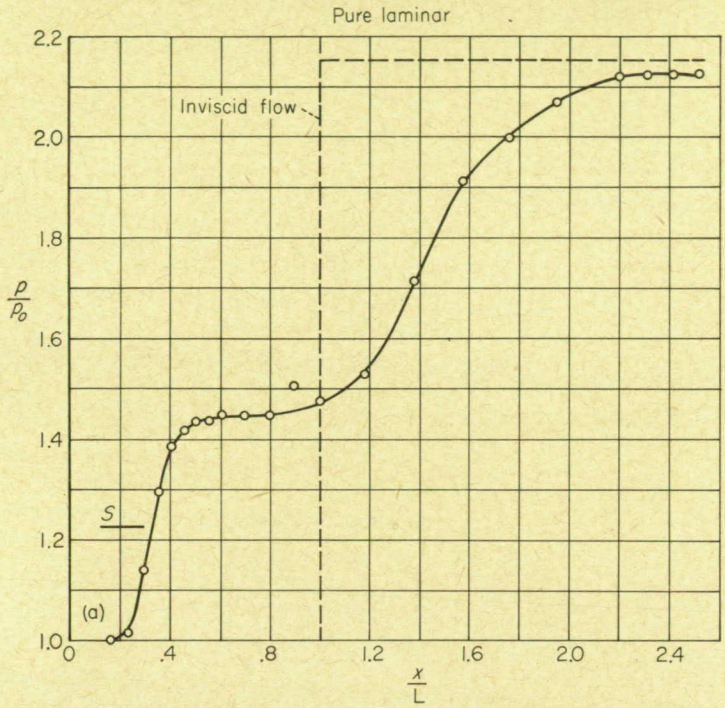
The data in figures 12 through 17 for steps, compression corners, bases, and curved surfaces show several similarities within a given regime to the characteristics just described for a step at $M_o=2.3$. It is emphasized that certain qualitative similarities exist irrespective of model shape or Mach number, or whether the flow is subsonic or supersonic (cf., e. g., figs. 11 and 13). Pure laminar separations ((a) portions of figs. 11 through 17) usually involve small pressure changes and relatively gradual pressure gradients. They are steady when observed in motion pictures at several thousand frames per second.[5] The transitional separations for the different configurations ((b) portions of figs. 11 to 17) involve severe pressure gradients near transition and usually were observed to be unsteady. The only transitional-type separation of those investigated which appeared steady was that over the base(e. g., fig. 16 (b)). The various turbulent separations (figs. 11 (c) to 17 (c)) are associated with abrupt pressure variation near both separation and reattachment. They were observed to be relatively steady flows except for the compression corners, which were rather unsteady in several cases at Mach numbers near shock detachment.



A general feature worth noting concerns the proximity of shock waves to the boundary layer in the various types of separated flow. For pure laminar separations the shock wave associated with separation, as well as the shock wave associated with reattachment on a flat surface, does not enter or originate within the boundary layer (see figs. 14 (a), 16 (a), and 18 (a)). The coalescence of compression wavelets into a shock wave occurs at a considerable distance from the boundary layer. In these cases, there obviously is no direct interaction of shock wave and boundary layer; there is, however, strong interaction of the supersonic external flow and the boundary layer. When pure laminar separation is induced by the reflection of an incident shock wave from a laminar boundary layer, the incident wave necessarily enters and locally interacts with the viscous layer near the station of impingement, but the shock waves formed near separation and reattachment do not originate within the viscous layer (see fig. 18 (a)). It is only after transition moves upstream of a reattachment position, thereby bringing about a steep pressure rise, that a shock wave originates partially within the boundary-layer flow near reattachment on a surface (see figs. 11 (b) through 18 (b)). Similarly, only after transition moves upstream of separation does a shock wave originate partially within the boundary-layer flow near separation.

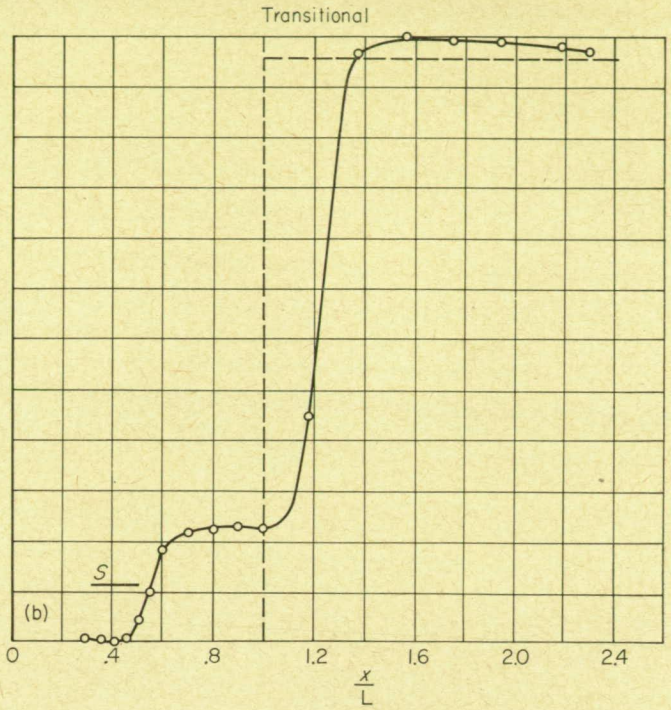


In the process of varying tunnel pressure, the conversion from transitional-type to turbulent-type separation often was observed to be irregular and unsteady. During such conversion, shadowgraphs were blurred since relatively long exposure times were used. The pressure distribution was not smooth since the various orifice-tube connections were not identical, and thus responded differently to the fluctuating pressure. An example illustrating these characteristics is shown in figure 19 (a) in comparison to an example of steady turbulent flow (fig. 19 (b)). Also, during such conversion between transitional and turbulent regimes, oil film did not accumulate along a threadlike line as it otherwise did. Instead, oil wandered irregularly over the plate in a jagged, random fashion. It is interesting, perhaps, to note that similar unsteady conversions have long been observed. In the fundamental paper on spheres by Prandtl (ref. 1) wherein smoke was used to determine the line of separation, the same type of unsteady flow with jagged separation line was observed during the conversion from the transitional regime to the turbulent regime. It is possible that certain of the unsteady flow phenomena sometimes found on various practical devices are intimately related to the unsteadiness found on these models of simple shape when conditions were such that the flow was on the verge of conversion between transitional-type and turbulent-type separation.



Representative Reynolds number effects for the three regimes.—As previously remarked, a variation in Reynolds number was found to have only a minor effect on pure laminar separations. This is illustrated in figure 20 (a). The ordinate is the pressure rise $|p'-p|$ across the reattachment region divided by the pressure p' just downstream of reattachment. The quantity p is measured at an arbitrary fixed point in the separated region. Some of the pure laminar separations are seen to be affected to a negligible extent by variation in Reynolds number. This is consistent with a theory to be developed shortly which indicates that the lack of dependence on Reynolds number is a characteristic of pure laminar separations for which the boundary-layer thickness at separation is zero or negligible. Other curves in figure 20 (a) show a small Reynolds number effect which amounts at the most to about a $\frac{1}{4}$-power variation. In these cases the boundary-layer thickness at separation is not negligible. Generally speaking, though, the pure laminar separations investigated are affected only to a small extent by variation in Reynolds number.

As might be anticipated, transitional-type separations behave differently than the pure laminar separations when subjected to variation in the Reynolds number. The effect of Reynolds number on various transitional-type separations is shown in figure 20 (b). Some of these flows are affected markedly by variation in Reynolds number. When such large variations were found, it was observed that transition was relatively near reattachment. For example, the lower Reynolds number portion of the filled-circle data points



[5] Obviously, not all pure laminar separations are steady in subsonic flow. It is well known that the separated flow behind a cylinder develops into an unsteady vortex trail even at Reynolds numbers near 100 where the separated flow is entirely laminar.

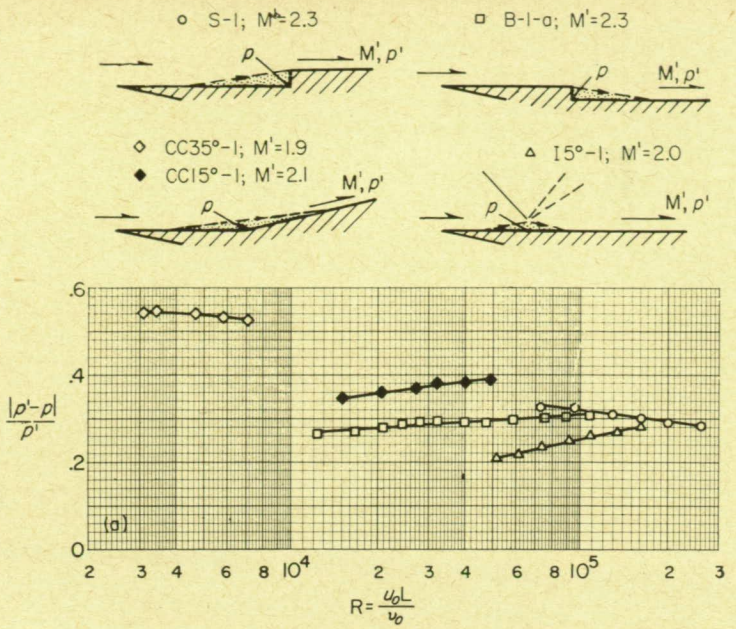
FIGURE 19.—Example of unsteady flow during conversion from transitional to turbulent flow.

shows large effects and corresponds to transition relatively near reattachment, whereas the higher Reynolds number portion corresponds to transition relatively near separation and shows much less effect. In most cases, a movement of transition upstream of reattachment (brought about by an increase in Reynolds number) increases the pressure rise through the reattachment region.

Turning now to turbulent flows for which transition is upstream of separation, the characteristic influence of Reynolds number again changes rather strikingly. The effect of the variation in Reynolds number on various turbulent separations is shown in figure 20 (c). For this type of separation, the effects of Reynolds number are either small or negligible.

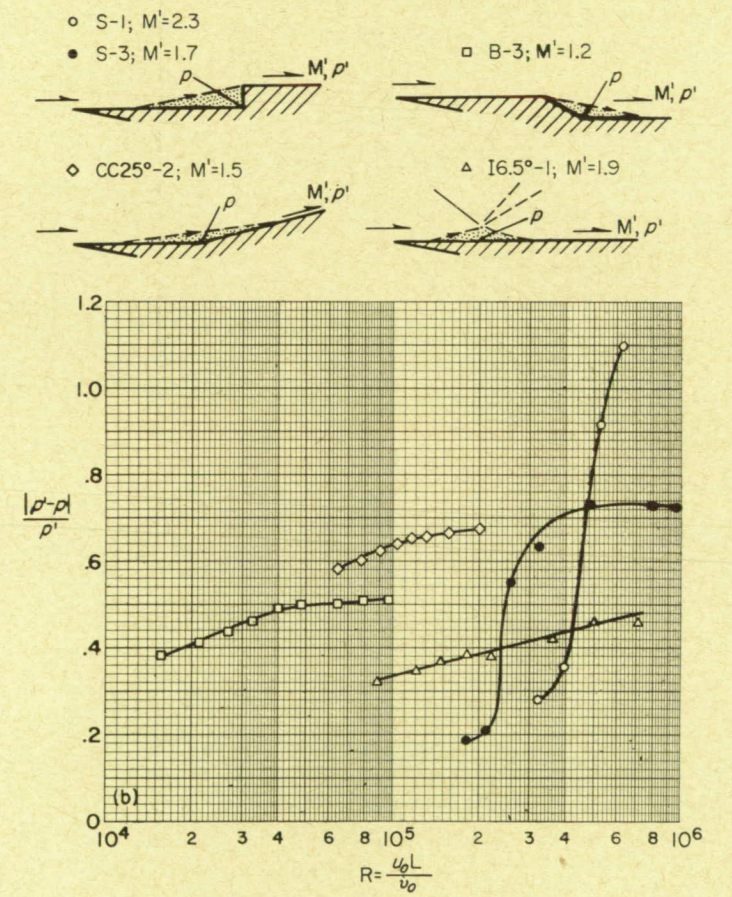
The typical effects of Reynolds number variation for the three separation regimes also can be clearly seen from complete pressure distributions. Some example pressure distributions for pure laminar separations over a compression corner at various Reynolds numbers are shown in figure 21 (a). These pressure distributions are only slightly affected by variation in Reynolds number, as would be anticipated from the trend illustrated in figure 20 (a). Some example pressure distributions for transitional separations over a curved surface at various Reynolds numbers are shown in figure 21 (b). These data show a large effect of variation in Reynolds number just as do the data in figure 20 (b). For example, the pressure drag coefficient of the curved surface would change by a factor of about 4 over the range of Reynolds numbers (0.16 to 0.81×10^6) represented. Also in agreement with the trend of figure 20 (b) for transitional separations, it is seen from figure 21 (b) that the changes in final pressure rise with Reynolds number are larger when transition is relatively near reattachment (Reynolds numbers from 0.16 to 0.36×10^6) than when transition is relatively near separation (Reynolds numbers from 0.36 to 0.81×10^6). Some example pressure distributions in turbulent separation at various Reynolds numbers are shown in figure 21 (c). As previously noted in figure 20 (c), the observed dependence on Reynolds number is small.

The characteristic influences of Reynolds number variation as illustrated for these different models also can be illustrated by a single model. A special model consisting of three bases in series was investigated on which all three separation regimes were found to occur simultaneously at 21 psia tunnel pressure, as may be deduced from study of figure 22. Although the results obtained with this special model are instructive, they do not reveal any new feature over and above those already illustrated in figures 11 through 17.



Representative Mach number effects for the three regimes.—Pressure-distribution curves for pure laminar separation over a step in the Mach number range between 1.3 and 3.1 are presented in figure 23 (a). These curves are for $R_L=0.13\times10^6$. The various curves qualitatively are similar, and exhibit only a small effect of Mach number on the streamwise length of dead-air region.

Pressure-distribution curves for transitional separation over a step in the Mach number range between 1.3 and 3.3 are presented in figure 23 (b) for $R_L\approx0.6\times10^6$. These curves show that transition moves downstream as the Mach number is increased. At $M_o=1.3$ the separated laminar layer is relatively unstable, resulting in transition near separation and a large pressure rise above the plateau pressure; at $M_o=3.3$ the separated laminar layer is much more stable, resulting in transition near reattachment and only a small pressure rise above the plateau.



The effect of Mach number on the pressure distribution over a step in turbulent flow at Mach numbers between 2.0 and 3.4 is presented in figure 23 (c). These data correspond to $R_L\approx2.6\times10^6$. The streamwise extent of the interaction region is seen to be not significantly affected by variations in Mach number over the range investigated. The peak pressures, though, are strongly dependent on Mach number.

Significance to wind-tunnel testing.—From one viewpoint it is fortunate that a variety of separated flows, such as supersonic flow behind a base, or subsonic flow in a corner, or the flow induced by a strong shock wave impinging on a boundary layer, turn out actually to be dominated largely by a single variable, namely, the location of transition relative to reattachment and separation positions. On the other hand, from the viewpoint of wind-tunnel testing of prototype models, it is unfortunate that a variable like transition, which is so elusive to control and difficult to predict, turns out to be so important. Nevertheless, merely an understanding of the dominating influence of transition on separated flows can be helpful. For example, it is clear that the proper simulation in a wind tunnel of any flow involving separation in flight, such as large-deflection control effectiveness, buffeting, or high angle-of-attack force characteristics, would require the relative transition location to be duplicated between wind tunnel and flight. If the relative transition location is either downstream of reattachment (pure laminar separation) or upstream of separation (turbulent separation), then the precise position of transition does not critically affect the pressure distribution provided the relative location is duplicated; but, if transition is between separation and reattachment (transitional-type separation), then the precise position is important.

The requirement of matching relative transition location between wind tunnel and flight appears particularly important at hypersonic speeds. Inasmuch as a separated laminar mixing layer is relatively stable at hypersonic Mach numbers (see next section), transition can often occur near reattachment in this speed range. Under such conditions, the type of separation could be transitional in the wind tunnel yet pure laminar in flight, or vice versa. Even if a separation is transitional both in wind tunnel and in flight, the type of flow field can be sensitive to variations in Reynolds number when transition is near reattachment, as was illustrated by figures 20 (b) and 21 (b). In the past, interest has focused more on flow at lower Mach numbers where transition is relatively near separation, under which conditions a close matching of relative transition location for transitional separations is not so important.

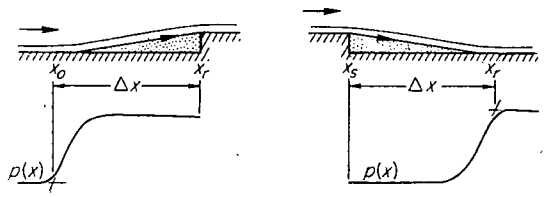
REYNOLDS NUMBER RANGE FOR PURE LAMINAR SEPARATIONS

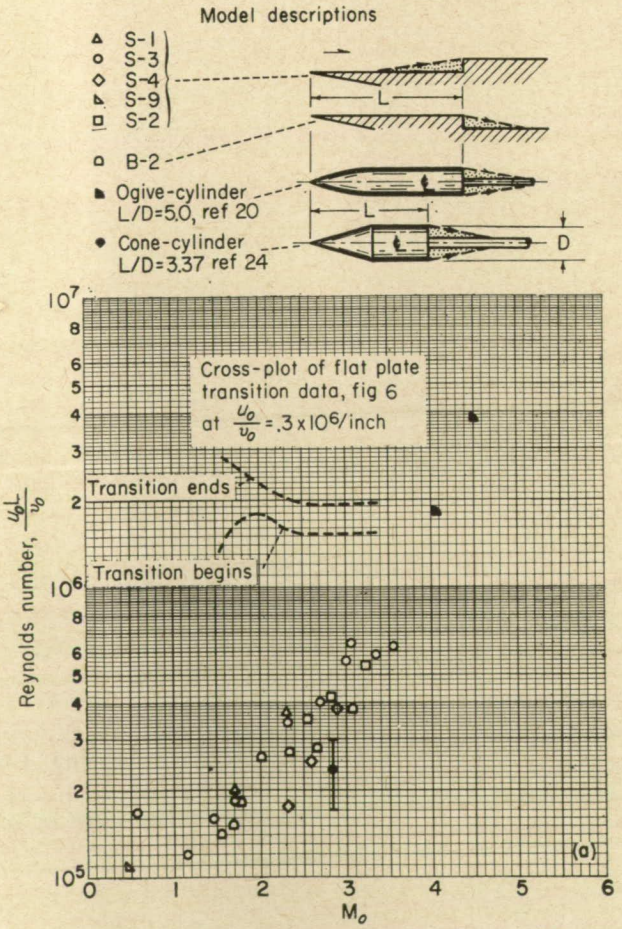


As the investigation progressed, it became evident that the prevalence of pure laminar-type separations increased as the Mach number was increased. In order to put these qualitative observations on a quantitative basis, data from various models were examined to determine the maximum Reynolds number up to which pure laminar separation was found at each Mach number. Such determinations from shadowgraphs agreed well with corresponding determinations from a break in the curves of dead-air pressure plotted against u_oL/ν_o. The values so obtained for $(u_oL/\nu_o)_{max}$ were different for various models, but for each model they consistently showed strong dependence on Mach number as illustrated in figure 24 (a) for various step and base models. Also included in this figure are two data points (at $M_o=4$ and $M_o=4.5$) determined from an examination of various unpublished spark photographs obtained by Reller and Hamaker during their investigation (ref. 20) of base pressure on bodies of revolution, and one data point determined from Kavanau's experiments on base pressure (ref. 24). The close agreement of data from bodies of revolution with that from two-dimensional models is regarded as accidental. Also shown in figure 24 (a) for purposes of comparison are two curves representing the Reynolds number for the beginning and the end of transition on an attached boundary layer over a flat plate. These two curves correspond to a Reynolds number per inch of 0.3×10^6, as obtained from a cross plot of the data of figure 6.

(c) Turbulent separation; $R_L \approx 2.6 \times 10^6$.

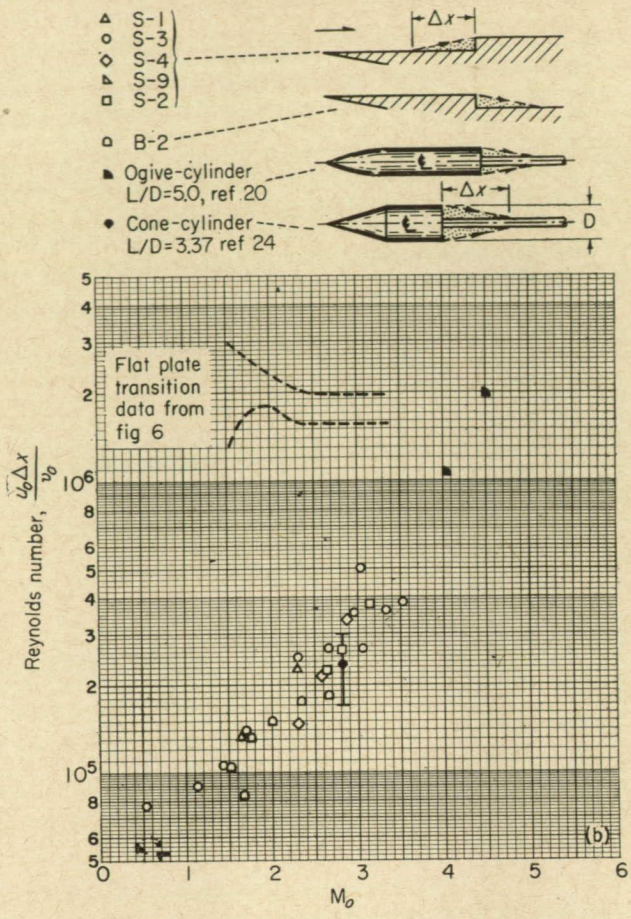
FIGURE 23.—Concluded.

Since models of different geometry have different lengths of separated layer relative to the model length, it would seem more significant to consider a Reynolds number based on some typical length of separated layer, rather than on model length. A pertinent length easy to determine from



pressure distributions is the length Δx as shown. The maximum Reynolds number for the pure laminar regime $(u_o\Delta x/\nu_o)_{max}$ is plotted as a function of Mach number in figure 24 (b).[6] It is evident from figure 24 (b) that the stability of a laminar mixing layer increases markedly with an increase in Mach number. In subsonic flow the separated laminar layer is stable only to about a Reynolds number $u_o\Delta x/\nu_o$ of 60,000, whereas at Mach numbers near 4 it is stable to a Reynolds number of about a million.

[6] In a preliminary report of this research (ref. 12) a slightly different length, x_r-x_s, between the reattachment location, x_r, and separation location, x_s, was used in place of Δx. The length Δx can be precisely determined; the length x_r-x_s was only approximate.



For purposes of comparison in figure 24 (b), the two curves are shown which represent the Reynolds numbers for beginning and end of transition on a flat plate. These transition data are directly comparable to the separated-flow data from the present experiments, inasmuch as they were obtained in the same wind tunnel, with essentially the same model leading-edge thickness, at approximately the same tunnel pressures, and under identical conditions of essentially constant pressure and zero heat transfer. The data are not comparable, however, to flight conditions. Flight conditions involve different rates of heat transfer, and different levels of external disturbance. Consequently, the quantitative values for Reynolds number in figure 24 (b) are not of central importance. Instead the important item is that, compared to an attached laminar boundary layer, the stability of a separated laminar mixing layer increases markedly with an increase in Mach number.

It is noted that the data of figure 24 correspond to models having relatively extensive regions of separated flow; that is, they represent separated flows wherein the length of separated layer Δx is roughly 0.5 to 0.7 of the model length L. If a separated flow extends over only a small portion of the model length, then the data in figure 24 might not be closely applicable. An example illustrating this is presented in figure 25. Here the step height is $0.009L$ and Δx is the order

(a) Reynolds number based on model length.

FIGURE 24.—Maximum Reynolds number for pure laminar type separation.

(b) Reynolds number based on length of separated layer.

FIGURE 24.—Concluded.

of $0.3L$. Over the Mach number range investigated, these pure laminar separations extend to higher Reynolds numbers than for the main body of data representing relatively extensive separated regions.

Although the conventional neutral stability theory—which considers only infinitesimal two-dimensional disturbances—is not a theory for transition, it has indicated certain trends which transition also follows in some cases. For example, surface cooling stabilizes a laminar boundary layer according to both neutral stability calculations and transition experiments. Neutral stability calculations for the laminar mixing layer in compressible flow have been made by Lin (ref. 25) who finds complete stability at Mach numbers above 2.5 for conditions of zero heat transfer. It can be said then that neutral stability theory for certain restricted types of disturbances indicates a strong stabilizing effect of Mach number on laminar mixing layers in accordance with the present experiments.

The experimental result that the stability of a separated laminar mixing layer increases markedly with an increase in Mach number provides an explanation of an experimental characteristic commonly encountered in conducting wind-tunnel tests. In attempting to trip the laminar boundary layer for certain wind-tunnel tests, it has been found that the diameter of wire required increases markedly at the higher Mach numbers. This can be attributed directly to the increase in stability of separated laminar mixing layers.

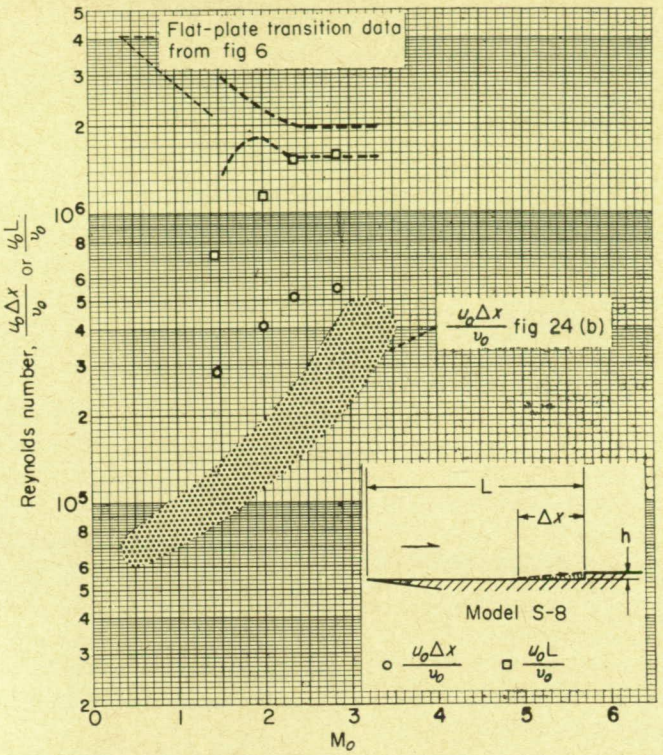


FIGURE 25.—Maximum Reynolds number for pure laminar separation on step of small height; $h/L=0.009$.

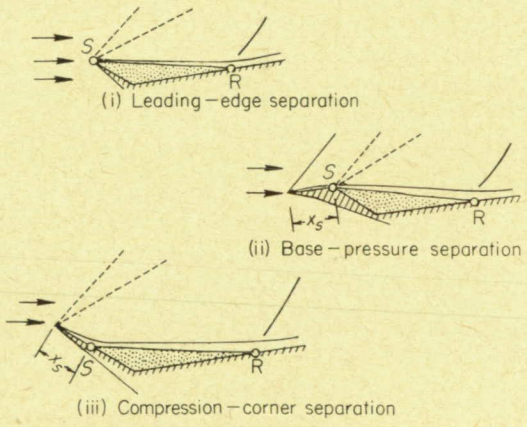
If a given wire does not effectively trip the boundary layer, then the baselike separated flow downstream of the wire, as well as the steplike separated region upstream of the wire, are of the pure laminar type. As soon as transition moves upstream of reattachment in the baselike separation downstream of the wire, then the wire trip has effectively promoted transition. Thus, the maximum Reynolds number for pure laminar-type separation downstream of the wire corresponds precisely to the minimum Reynolds number required to fix transition. Winter, Scott-Wilson, and Davies (ref. 19) have determined quantitatively from experiments with different wire diameters the critical Reynolds number (based on wire diameter) which will fix transition for various Mach numbers. If their data are converted to a Reynolds number based on Δx, the length of separated laminar layer upstream and downstream of the wire (Δx is roughly $20d$ for conditions of their experiments), then a direct comparison can be made with the data shown in figure 24. Their data have the same trend as the data in figure 24, but fall about a factor of 4 below. This situation is consistent with observations from the present experiments, inasmuch as the data in figure 24 represent only certain configurations and the data for other configurations are different (as in fig. 25). A wire trip represents one configuration which is not conducive to the promotion of extensive laminar separation.

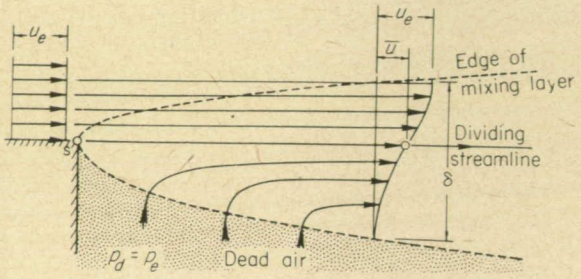


The trend of increasing stability of separated laminar layers with increasing Mach number may be practically significant inasmuch as separated laminar flows have certain uncommon characteristics which might be advantageous. After the trend evident in figure 24 was observed, it appeared desirable to investigate theoretically the heat-transfer and skin-friction characteristics of certain simple pure laminar separations. Such analysis is presented in a separate report (ref. 26) which indicates that the heat transfer and skin friction are less than those of a comparable attached laminar boundary layer.

MECHANISM DETERMINING PRESSURE IN SEPARATED REGIONS AND THEORETICAL EXPLANATION FOR IMPORTANCE OF TRANSITION LOCATION RELATIVE TO REATTACHMENT

Prior to further discussion of experimental results, a digression is made here in order to develop a theory of the mechanism which determines the dead-air pressure in a separated region. This theory is used subsequently to provide an explanation of the principal experimental result of the preceding section; namely, that transition location relative to a reattachment position is of crucial importance to separated flows.

THEORETICAL ANALYSIS OF LEADING-EDGE SEPARATION

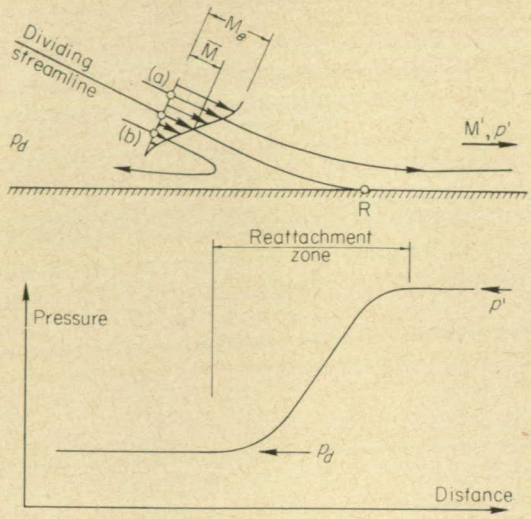


In order to establish a separated flow amenable to a simple theoretical calculation which requires no empirical knowledge, and which would thereby be helpful in analyzing the mechanism governing pressure in separated regions, a special type of model was investigated which produced leading-edge separation. This type of separation actually represents a limiting case both of separations behind a base and of separations in a compression corner, the limit being taken in each case as the distance x_s, from leading edge to

separation, approaches zero. Leading-edge separation is relatively easy to analyze because the complicated course of boundary-layer development in the region of pressure variation between the boundary-layer origin and its position of separation need not be considered. Also, calculations of the laminar mixing layer already are available (ref. 27) for flows of this type wherein the boundary-layer thickness at separation, δ_s, is zero, and the pressure is essentially constant. These theoretical calculations would apply directly, provided that transition is excluded from consideration.

Before developing the basic idea for calculating dead-air pressure, it is advantageous to outline the results of the laminar-mixing-layer theory which forms the basis for such calculations. Typical streamlines in the viscous mixing

region and a representative velocity profile are depicted below. A uniform stream of velocity u_e, Mach number M_e, and pressure p_e mixes with a dead-air region (of pressure $p_d=p_e$) having dimensions large compared to the thickness δ of the mixing layer. The mixing-layer thickness grows



parabolically with distance from the origin of mixing just as a laminar boundary layer grows, but the rate of growth is roughly three times that of a corresponding boundary layer. The velocity profiles at different streamwise stations are similar; hence, the velocity ratio $\overline{u}/u_e$ along the dividing streamline does not change with Reynolds number or with distance from separation. One consequence of this fact soon will appear. Moreover, this velocity ratio changes only slightly with variation in Mach number and in temperature-viscosity relationship. Computed values, reference 27, of $\overline{u}/u_e$ are obtained by solving the familiar nonlinear differential equation of Blasius with unfamiliar boundary conditions. Some values are tabulated as follows:

Computed values of $\overline{u}_*\equiv\overline{u}/u_e$ (ref. 27)

Mach number, M_e	for $\mu_*\sim T_*$	for $\mu_*\sim T_*^{0.76}$
0	0.587	0.587
1	.587	.588
2	.587	.591
3	.587	.593
5	.587	.597

In subsequent calculations, the ratio $\overline{u}/u_e\equiv\overline{u}_*$ appears often. From the table, it is clear that the single value $\overline{u}_*=0.587$, corresponding to the linear temperature-viscosity relationship, is a reasonable approximation for all conditions. It is noted that the tabulated values of $\overline{u}_*$ involve no empirical constants and are exact within the framework of the boundary-layer equations.

In the calculation of dead-air pressure, the essential mechanism is considered to be a balance between mass flow scavenged from the dead-air region by the mixing layer and mass flow reversed back into the dead-air region by the pressure rise through the reattachment zone. For steady flow the dividing streamline at separation as calculated from mixing-layer theory must also be a dividing streamline at reattachment. If this were not the case air would be either continually removed from or continually injected into the dead-air region, and the scavenged mass flux would not balance the reversed mass flux. The pertinent conditions are illustrated of the reattachment zone and of the corresponding pressure distribution.

In order for a particle along a streamline within the mixing layer to be able to overcome the pressure rise through the reattachment zone and to pass downstream, its total pressure p_t must be greater than the terminal static pressure p' at the end of the reattachment zone. As sketched above, particle (a) passes downstream in this manner. Particle (b), however, has a low velocity with corresponding low total pressure and is reversed before the pressure rises from p_d to p'. The dead-air pressure is determined by requiring [7] that the total pressure along the dividing streamline as it approaches the reattachment zone

$$p_t\equiv p_e\left(1+\frac{\gamma-1}{2}\overline{M}^2\right)^{\gamma/(\gamma-1)}$$

$$=p_d\left(1+\frac{\gamma-1}{2}\overline{M}^2\right)^{\gamma/(\gamma-1)} \tag{1}$$

be equal to the terminal static pressure p'. Thus the flow is divided into two regions: a viscous layer wherein the pressure is assumed to be constant, and a reattachment zone wherein the compression is assumed to be such that not much total pressure is lost along the dividing streamline. This yields

$$p_d=\frac{p'}{\left(1+\frac{\gamma-1}{2}\overline{M}^2\right)^{\gamma/(\gamma-1)}} \tag{2}$$

To cast this equation into a convenient form, it is necessary to relate $\overline{M}$ to the terminal Mach number M', or to the Mach number M_e along the outer edge of the mixing layer. From the mixing-layer calculations in which the Prandtl number is assumed to be unity,[8] the Mach number $\overline{M}$ along the dividing streamline is related to the corresponding velocity $\overline{u}$ by the Busemann isoenergetic integral of the energy equation if the

[7] As is discussed later, essentially the same idea also has been employed effectively to calculate base pressure for turbulent boundary layers in a recent paper by Korst, Page, and Childs (ref. 16).

[8] As long as temperature profiles or heat-transfer characteristics are not considered, the assumption $Pr=1$ provides a satisfactory approximation for air. For example, at $M'=2$ the calculated value of p_d/p' for $Pr=0.72$ (the approximate value for air) is only 0.025 below that for $Pr=1$. Consequently, the analysis for $Pr=0.72$ is not presented here as it is much more complex, and does not yield a final equation in closed form.

dead-air temperature T_d is equal to the outer stream total temperature.

$$T_{te} \equiv T_e\left(1+\frac{\gamma-1}{2}M_e^2\right) \tag{3}$$

and by the Crocco integral if T_d differs from T_{te}. (See ref. 27.) At present, the dead-air temperature is considered equal to the recovery temperature (T_{te} for $Pr=1$), so that Busemann's integral for a perfect gas yields

$$\overline{M}^2=\frac{(\bar{u}/u_e)^2 M_e^2}{1+\frac{\gamma-1}{2}M_e^2\left(1-\frac{\bar{u}^2}{u_e^2}\right)} \tag{4}$$

Combining the above two equations gives an equation for dead-air pressure

$$\frac{p_d}{p'}=\left[\frac{1+(1-\bar{u}_*^2)\frac{\gamma-1}{2}M_e^2}{1+\frac{\gamma-1}{2}M_e^2}\right]^{\gamma/(\gamma-1)} \tag{5}$$

where $\bar{u}_*=0.587$. Since $\bar{u}_*$ is independent of Reynolds number, p_d also is independent of Reynolds number. Body shape affects p_d only through its effect on p', the reference pressure.

A more convenient equation for p_d/p' can be obtained by expressing M_e in terms of the Mach number M' which exists just downstream of the reattachment zone. Because the outer edge of the laminar viscous layer curves smoothly, the trailing shock wave does not form within or near this viscous layer, and the flow along this outer edge is isentropic. Hence the values of M' and p' for two-dimensional flow are, in the terminology of reference 28, the same as the "equivalent free-stream conditions" approaching separation. For isentropic flow along the outer edge of the viscous layer

$$\frac{p'}{p_d}=\frac{p'}{p_e}=\left(\frac{1+\frac{\gamma-1}{2}M_e^2}{1+\frac{\gamma-1}{2}M'^2}\right)^{\gamma/(\gamma-1)} \tag{6}$$

By combining this with equation (5), there results

$$M'^2=(1-\bar{u}_*^2)M_e^2 \tag{7}$$

which yields the simple physical interpretation that the Mach number ratio across the laminar reattachment zone M'/M_e is a constant equal to $(1-\bar{u}_*^2)^{1/2}=0.81$. Equations (5) and (7) provide an explicit equation for dead-air pressure.

$$\frac{p_d}{p'}=\left[\frac{1+\frac{\gamma-1}{2}M'^2}{1+\frac{\gamma-1}{2}\frac{M'^2}{(1-\bar{u}_*^2)}}\right]^{\gamma/(\gamma-1)} \tag{8}$$

This equation was presented in reference 12 without derivation.

The foregoing theory also would apply to low-speed flow. By taking the limit of equation (8) as $M'\to 0$, there results

$$\frac{p_d-p'}{q'}=\frac{p_d-p'}{\frac{\gamma}{2}p'M'^2}=\lim_{M'\to 0}\frac{2}{\gamma M'^2}\left\{\left[\frac{1+\frac{\gamma-1}{2}M'^2}{1+\frac{\gamma-1}{2}\frac{M'^2}{(1-\bar{u}_*^2)}}\right]^{\gamma/(\gamma-1)}-1\right\}$$

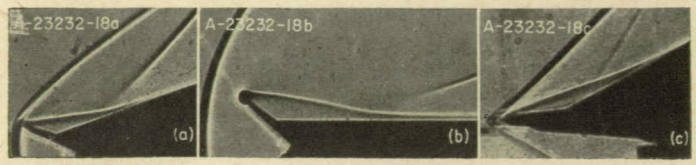
$$=-\frac{\bar{u}_*^2}{1-\bar{u}_*^2} \tag{9}$$

or, since $\bar{u}_*=0.587$,

$$\frac{p_d-p'}{\frac{1}{2}\rho u'^2}=-0.526 \tag{10}$$

Equation (10) for incompressible flow, just like equation (8) for compressible flow, would apply irrespective of the Reynolds number or the shape of the dead-air region.

The chief approximations and restricting assumptions made in the foregoing analysis should be noted. One essential approximation is that the compression is isentropic along the dividing streamline through the reattachment zone. Actually there would be some change in total pressure. Another approximation is that the dividing streamline terminates at a point where the pressure is p' rather than at the reattachment point where the pressure is p_r. Considering these two facts, the fundamental equation corresponding to equation (2) would be



$$p_d=\frac{p_r}{\eta\left(1+\frac{\gamma-1}{2}\overline{M}^2\right)^{\gamma/(\gamma-1)}}$$

where $\eta \equiv p_r/\bar{p}_t$ is a factor (not necessarily less than unity) representing the "efficiency" of compression relative to that of an isentropic process. It is evident that the use of p' in equation (2)—rather than the use of p_r/η—entails the disregard of two factors: the pressure rise downstream of reattachment and the viscous effects on the compression along the dividing streamline. Aside from these approximations it is to be remembered that the substitution $\bar{u}_*=0.587$ in equation (8) is restricted to steady, two-dimensional, pure laminar, separated flows having zero boundary-layer thickness at the separation point. If the boundary-layer thickness at separation were sizable, equation (8) would still apply, but the velocity profiles at different stations along the mixing layer would not be similar and $\bar{u}_*$ would not be 0.587. The value of $\bar{u}_*$ would have to be calculated by solving the partial differential equations of viscous flow for each case.

EXPERIMENTAL RESULTS FOR FLOWS WITH NEGLIGIBLE BOUNDARY-LAYER THICKNESS AT SEPARATION

There are two features of the theory which can be tested quantitatively by present experiments: the absence of a dependence on Reynolds number, and the calculated dependence on Mach number. Three typical shadowgraphs from the experiments on leading-edge separation are shown in figure 26. Unless specified otherwise, the measurements correspond to an attached bow wave as in figures 26 (a) and 26 (c) rather than to a detached wave as in figure 26 (b).

In principle, equation (8) should apply equally well to both types of bow wave, as long as M' and p' are known. In figure 27 the measured variation of p_d/p' with Reynolds numbers at $M'=1.8$, where the bow wave is detached, is compared with the value calculated from equation (8). There

(a) CC35°−2; $M_\infty=2.3$; $\alpha=15°$; $M'\approx1.5$; $R=\dfrac{u'L}{\nu'}=10.9\times10^3$.

(b) CC35°−2; $M_\infty=2.3$; $\alpha=35°$; $M'\approx2.0$; $R=\dfrac{u'L}{\nu'}=9.2\times10^3$.

(c) CC20°−1; $M_\infty=2.3$; $\alpha=-5°$; $M'\approx1.3$; $R=\dfrac{u'L}{\nu'}=22.8\times10^3$.

FIGURE 26.—Pure laminar separations with negligible boundary-layer thickness at separation.

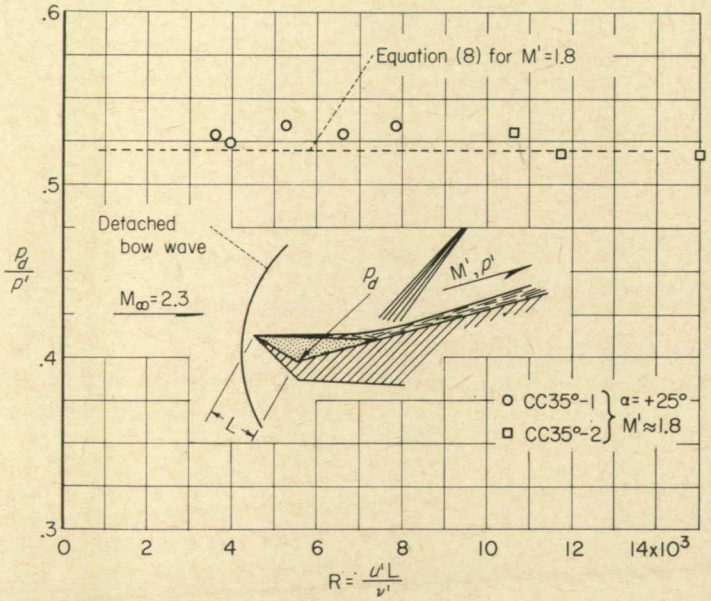


FIGURE 27.—Absence of significant Reynolds number effect on dead-air pressure for wedge models with leading-edge laminar separation.

is seen to be no marked variation with Reynolds number. A similar absence of such variation also was observed at other Mach numbers investigated (1.3 to 2.0). It is apparent also from figure 27 that the calculated and experimental values agree rather well. Agreement of this nature extends to the other Mach numbers investigated, as is shown in figure 28 where the various data points plotted at each Mach number represent measurements at different Reynolds numbers. The several data points corresponding to a detached bow wave fall somewhat below the general trend, but not far below. Considering the simple nature of the theory and the fact that the calculation involves no empirical information or adjustable constants, the observed correspondence of theory and experiment is quite satisfactory. This establishes considerable confidence in the mechanism postulated for the calculations.

Although the present experiments did not include cases of pure laminar leading-edge separation at low speeds, some recent experiments of Roshko (ref. 29) approximate such conditions and provide further test of the theory. In order largely to avoid the usual unsteadiness of subsonic wakes, Roshko employed the splitter-plate technique. His data for cylinders and a flat plate normal to the flow are shown in figure 29. These data do not show any significant dependence either on body shape or Reynolds number. This lack of dependence is in accord with the theory. For quantitative comparison with the theory, it is assumed that $p'=p_\infty$ which is indicated to be closely the case by several streamwise wake pressure distributions presented by Roshko. The agreement exhibited in figure 29 is quite good. The close agreement should be viewed with reservation inasmuch as the splitter plates did not always render the flow perfectly steady, and the mixing layer may not be entirely laminar. The Reynolds numbers are low enough though (5,000 to 17,000), so that extensive laminar flow would be expected along the mixing layer.

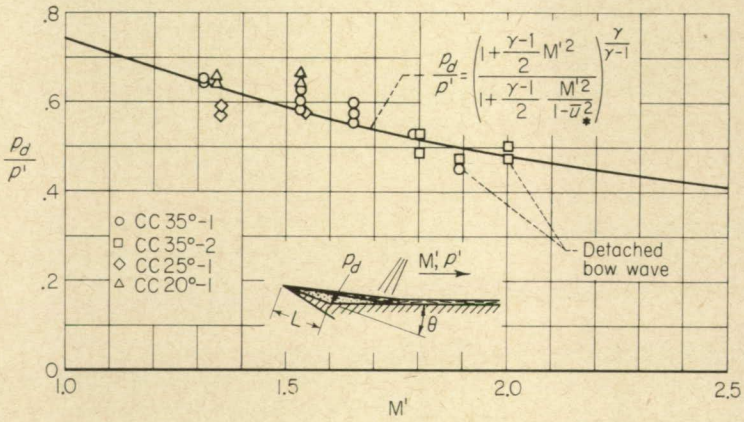

FIGURE 28.—Comparison of theory and experiment for pure laminar separations with negligible boundary-layer thickness at separation.

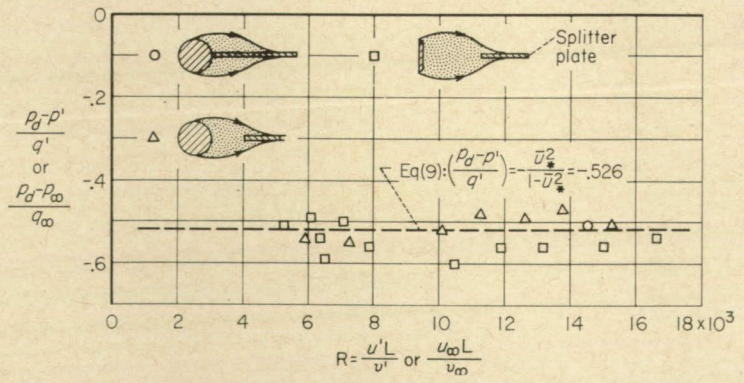

FIGURE 29.—Comparison of theory with experiments of Roshko conducted at low speed; $M'\approx0$.

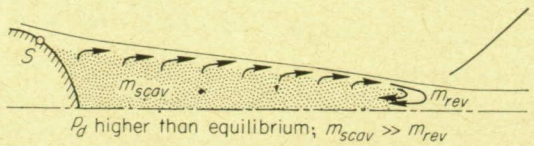
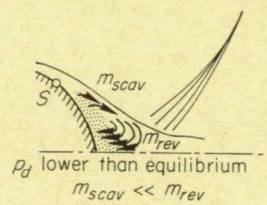
For incompressible flow, a comparison of the present theory can be made with a numerical solution to the full Navier-Stokes equations obtained by Kawaguti (ref. 30) for the steady flow over a circular cylinder at Reynolds number 40. His solution yields a value of −0.55 for the pressure coefficient at the rear of the cylinder. The corresponding experimental value (ref. 30) is about the same. This is surprisingly close to the value −0.526 obtained from the present theory.



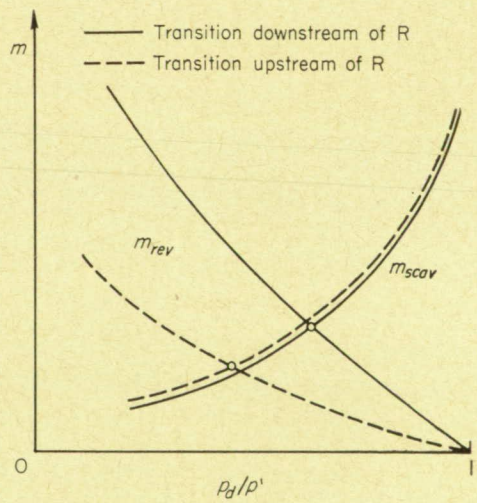
Additional evidence as to the soundness of the basic calculation method is provided by an independent theoretical analysis of Korst, Page, and Childs (ref. 31), which became available during preparation of reference 12. In their analysis, the same basic method is used for calculating dead-air pressure. Since they were concerned with fully turbulent flow rather than with pure laminar flow, their results complement the results of the present research. A direct comparison of their equations with equation (8) cannot be made since they did not present an explicit equation for dead-air pressure, but a comparison can be made of the various assumptions employed in the two analysis. Such comparison indicated only small, relatively unimportant differences in the two calculation methods. For calculating the velocity ratio $\overline{u}_*$ along the dividing streamline they employed a simplified equation since the rigorous equations for turbulent flow are unsolvable. They obtain values of $\overline{u}_*$ for turbulent flow ranging between 0.62 at zero Mach number to apparently 1.00 at infinite Mach number, whereas the corresponding value for laminar flow is 0.59, as noted earlier. They used the oblique shock equations across the reattachment region, whereas the isentropic equations are applied above for pure laminar flow. The dead-air pressure was calculated by equating the total pressure along the dividing streamline to the static pressure downstream; this is the essential idea common to both analyses. They obtain very close agreement with base pressure measurements for turbulent flow over a wide range of conditions, and this strengthens further the simple idea common to the two calculations.

It is noted that the values of p_d/p' in figure 28 for pure laminar separations with $\delta_s \approx 0$ are not much greater than for turbulent base pressure measurements (ref. 17) with $\delta_s \approx 0$. From the theoretical viewpoint, this arises because the corresponding values of $\overline{u}_*$ are not greatly different. Thus, a thin reattaching laminar layer can undergo a pressure rise comparable to that of a thin reattaching turbulent layer. Hence, with $\delta_s \approx 0$, the movement of transition from downstream to upstream of reattachment would not markedly alter such flows. Experiments confirm this. For example, at Reynolds numbers beyond those shown in figure 27, at which the separations on both CC35°—1 and CC35°—2 were transitional, the values of p_d/p' were only slightly smaller. On the other hand, when δ_s is relatively large and $\overline{u}_*$ for laminar flow is much less than 0.587 (corresponding to $\delta_s=0$), then the movement of transition from downstream to upstream of reattachment can markedly alter flow conditions.



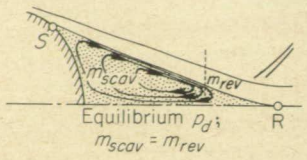
In regard to theoretical methods for calculating dead-air pressure in a separated flow, it is noted that there is one aspect of the Crocco-Lees theory (ref. 9) which appears to be at variance with both the present theory and with certain experiments. This aspect is discussed in Appendix B.

AN EXPLANATION OF THE IMPORTANCE OF TRANSITION LOCATION RELATIVE TO REATTACHMENT



The basic mechanism assumed in the calculations of dead-air pressure appears well confirmed and thus can be used now to provide an explanation of one of the main experimental results described earlier, namely, an explanation of why a separated flow changes markedly when transition moves upstream of the reattachment position. For equilibrium, the basic requirement is that the mass flow scavenged (m_{scav}) from the dead-air region by the mixing layer balance the mass flow reversed (m_{rev}) by the pressure rise through the reattachment zone. This can be made clear by considering the variation of m_{scav} and m_{rev} with dead-air pressure for conditions removed from equilibrium. It is assumed temporarily that transition is slightly downstream of reattachment. For simplicity the external flow is assumed to be supersonic and two-dimensional. If p_d/p' is near unity the mixing layer is long and m_{scav} is large

since it depends on the product $\rho_e u_e$ as well as the length of mixing; but if p_d/p' is near zero, the mixing layer is short, $\rho_e u_e$ is small,



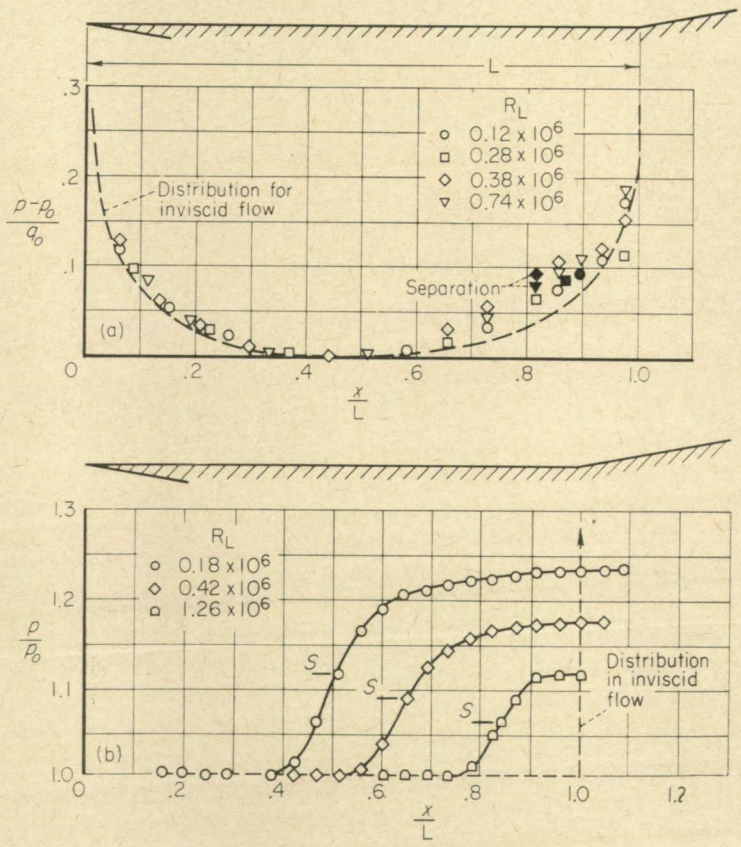
and m_{scav} is small. Thus the scavenged air increases as p_d increases, as illustrated. The reversed flow, however, follows an opposite trend;

if p_d/p' is near unity, the pressure rise $p'-p_d$ is small and m_{rev} is small, but if p_d/p' is near zero the pressure rise is large and m_{rev} is large; hence, m_{rev} decreases as p_d increases, as illustrated in the mass-flow curves. Intersection of the curves determines p_d for equilibrium (provided no mass flow is injected or removed by external means). If transition were now to move suddenly to a new position slightly upstream of reattachment, say, to the position of the dotted

526597—60——30

line in the lower right portion of the following sketch representing the equilibrium

condition, then m_{scav} would be affected only negligibly since the distance between transition and reattachment is negligible compared to the distance between separation and transition. The new m_{scav} curve (dotted line in the above mass-flow curves) would be close to the corresponding m_{scav} representing transition slightly downstream of reattachment (solid line in the above mass-flow curves). Because of the turbulence, however, the m_{rev} curve would be much lower. The energy imparted to the low-velocity portion of the mixing layer would be much increased by the transport of eddies from the outer stream and this energizing process would greatly reduce the amount of air reversed for a given pressure ratio p_d/p'. The new equilibrium dead-air pressure would be represented by the intersection of dotted mass-flow curves. As transition moves upstream of reattachment, therefore, the ratio p_d/p' would be expected to decrease substantially. This agrees with the experimental observations described earlier, irrespective of whether the separation is induced by a base, compression corner, curved surface, step, or an incident shock wave.



Transition actually should begin to affect a separated flow as soon as it occurs in the small recompression region downstream of the reattachment point, even if negligible turbulence exists upstream of the reattachment point. In this region, where the pressure is between p_r and p', the introduction of turbulence would permit a greater pressure rise $p'-p_r$ to occur after the reattachment point, and this would change the dead-air pressure. Obviously transition is not a steady, point phenomenon, but is spread over some distance. Strictly speaking then, the pure laminar regime would end as soon as appreciable turbulence occurs in the downstream portion of a reattachment zone. A separated flow that is laminar only to the reattachment *point* could be quite different from the pure laminar type, which is defined as being laminar through the reattachment zone.

CHARACTERISTICS INDEPENDENT OF THE MODE OF INDUCING SEPARATION (FREE INTERACTIONS)

During the course of experimentation, it was observed that certain characteristics of separated flows did not depend on the object shape or on the mode of inducing separation. Similar observations previously have been made in the researches of Gadd, Holder, and Regan (ref. 15) and of Bogdonoff and Kepler (ref. 14). Any phenomenon near separation which is independent of object shape would not depend on geometric boundary conditions which describe the flow downstream, but would depend only on the simultaneous solution of the equations for flow in the boundary layer together with the equations for flow external to the boundary layer. Such flows that are free from direct influences (though not free from indirect influences) of downstream geometry, and are free from complicating influences of the mode of inducing separation, arbitrarily will be termed "free interactions" for brevity. In the present section, some pressure distributions are compared first for a given body in supersonic and in subsonic flow. Free interaction is observed in supersonic separation, though not in subsonic separation on this body. A simple analysis is then made of the Reynolds number dependence of free interactions in supersonic flow. Subsequent to this analysis, various experimental results are presented and compared with the analysis where possible.

RESULTS FOR VARIOUS SEPARATED FLOWS

Difference between subsonic and supersonic separations.—A fundamental difference between subsonic and supersonic separations can be seen from pressure distributions obtained at various Reynolds numbers in subsonic and in supersonic flow for a given model geometry. Measured distributions for laminar separation ahead of a 10° compression corner in subsonic flow are shown in figure 30 (a)

(a) Subsonic; CC10°−3; $0.4<M_\infty<0.8$; $\alpha=-4°$.

(b) Supersonic; CC10°−2; $M_o=2.0$.

FIGURE 30.—Comparison of subsonic and supersonic flows at various Reynolds numbers.

together with the calculated distribution that would exist in an incompressible, inviscid fluid (dotted line).[9] At these subsonic speeds ($0.4\leq M_\infty\leq 0.8$) variation in Reynolds number brings about only small changes in pressure dis-

[9] These calculations were made with small-disturbance theory by superimposing the appropriate thickness pressure distributions for wedges with the appropriate lift pressure distribution for an inclined flat plate.

tribution and no measurable change in pressure rise to separation ($(p_s-p_o)/q_o$ is equal to 0.08 ± 0.005 for all R). Moreover, the distribution is roughly that which would exist in an inviscid flow, as represented by the dotted line. In contrast, the pressure distributions shown in figure 30 (b), which also were obtained on a 10° compression corner, in the same wind tunnel, and over the same Reynolds number range, exhibit relatively large changes in pressure distribution as well as easily measurable changes in the position of and the pressure rise to separation. Further contrast is exhibited by the disparity between the measured distributions at supersonic speed and the calculated distribution for inviscid flow (a constant pressure with discontinuous jump as indicated by the dotted line). These data illustrate how the pressure distribution in subsonic flow near and upstream of separation is determined primarily by the inviscid flow pressure distribution about the object shape, and only secondarily by the Reynolds number dependent interaction between boundary layer and external flow; whereas, in supersonic flow, the pressure distribution near separation is determined primarily by a Reynolds number dependent interaction (free interaction) and only secondarily by the inviscid flow pressure distribution.

Only in supersonic flow were free interactions commonly observed in the present experiments. The fact that they were not observed at subsonic speed does not necessarily mean that free interactions cannot occur at such speeds. Lighthill (ref. 32) has made an analysis of the incompressible flow upstream of a step, which, in effect, assumes that the pressure distribution is determined by interaction of boundary layer and external flow. In the present experiments, relatively small steps were employed and the pressure distribution was determined primarily by the geometry of the model, and only secondarily by interaction phenomena. Consequently, the present experiments and Lighthill's theory for incompressible flow upstream of a step are not comparable. It would appear possible, by using a step with larger ratio of step height to plate length, and a model with smaller leading-edge angle, that the pressure distribution in subsonic flow might be determined primarily by interaction phenomena and only secondarily by external constraints imposed through model geometry.

Simplified analysis for free-interaction regions.—If a pressure distribution is determined locally by free interaction of boundary layer and external supersonic flow, then the applicable equations are the momentum equation for steady flow in the viscous layer coupled with the following equation for external supersonic flow:

$$p=p_{inviscid}+\frac{\rho_e u_e^2}{\sqrt{M_e^2-1}}\frac{d\delta^*}{dx} \tag{11}$$

This equation would apply for both laminar and turbulent flow. For the special case of free interaction in regions where the inviscid pressure distribution (first term in eq. (11)) is constant or is small compared to the interaction term, certain information about the effects of Reynolds number can be extracted from order-of-magnitude arguments alone. Since the rate of boundary-layer growth is small, equation (11) for a free interaction is written as

$$\frac{p-p_o}{q_o}=\frac{2}{\sqrt{M_o^2-1}}\frac{d\delta^*}{dx} \tag{12}$$

The subscript o designates conditions at the beginning of interaction, that is, at the downstream-most point upstream of which the pressure is sensibly the same as the inviscid flow. If l_i is a length characteristic of the streamwise extent of free interaction, then order-of-magnitude considerations applied to equation (12) yield

$$\frac{p-p_o}{q_o}\sim\frac{\delta^*}{l_i\sqrt{M_o^2-1}} \tag{13}$$

Turning now to the equation for viscous flow, the usual boundary-layer momentum equation

$$\rho u\frac{\partial u}{\partial x}+\rho v\frac{\partial u}{\partial y}=-\frac{dp}{dx}+\frac{\partial \tau}{\partial y} \tag{14}$$

would apply provided the transverse pressure gradients within the layer are small compared to the streamwise gradients. This would be the case for laminar flow but is questionable for turbulent flow, since the detailed surveys of Bogdonoff and Kepler (ref. 14) at $M_o=2.9$ reveal the *average* transverse gradient near separation to be larger, in fact, than the streamwise gradient. Since large curvature of streamlines is required for large transverse pressure gradients, and since the streamlines must approach straight lines in the immediate vicinity of a straight wall, it follows that only in the outer part of a boundary layer is the streamline curvature large near separation and the turbulent boundary-layer equations locally questionable. For this reason, the boundary-layer equation is applied at the wall where it becomes

$$\frac{dp}{dx}=\left(\frac{\partial \tau}{\partial y}\right)_w \tag{15}$$

This application places emphasis on the low-velocity part of the boundary layer, which appears desirable in analyzing the flow approaching separation. By applying order-of-magnitude considerations to equation (15) there results for constant Mach number M_o,

$$\frac{p-p_o}{l_i}\sim\frac{\tau_w}{\delta}\sim\frac{\tau_{wo}}{\delta^*} \tag{16}$$

In this last step, the wall shear τ_{wo} at the beginning of interaction has been taken as a measure of the variable wall shear τ_w. What this and the previous steps amount to is the consideration of a family of similar flows having a fixed Mach number, but differing in the Reynolds number.

Mach number dependent factors have been omitted from equation (16) since they arise from density variations across the boundary layer and would be smoothly varying functions of M_o. In contrast, the factor $(\sqrt{M_o^2-1})^{-1}$ arising from density variations along the edge of the boundary layer was retained in equation (13) since it is a singular function at $M_o=1$, and would be the dominant factor if M_o is only

slightly greater than 1. By multiplying equations (16) and (13) there results

$$\frac{p-p_o}{q_o}\sim\left(\frac{\tau_{wo}}{q_o\sqrt{M_o^2-1}}\right)^{1/2}\sim\frac{\sqrt{c_{f_o}}}{(M_o^2-1)^{1/4}} \tag{17}$$

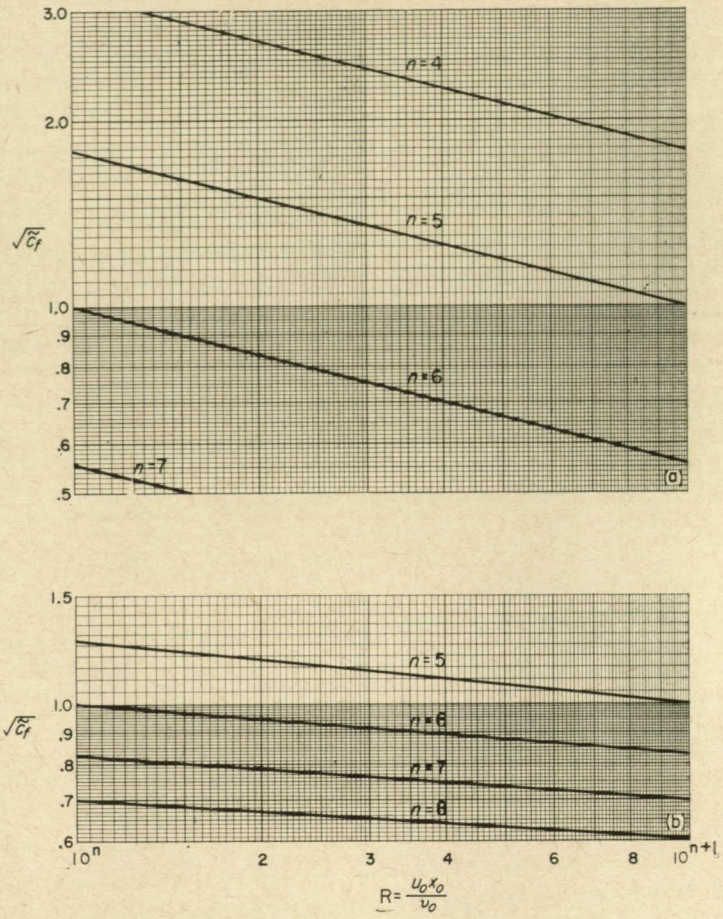
and, by dividing them, there results

$$\frac{l_i}{\delta^*}\sim\left(\frac{q_o}{\tau_{wo}\sqrt{M_o^2-1}}\right)^{1/2}\sim\frac{1}{\sqrt{c_{f_o}}(M_o^2-1)^{1/4}} \tag{18}$$

For convenience, the ratio $\tilde{c}_f$ of skin friction at a given Reynolds number to skin friction at a Reynolds number of one million, is introduced

$$\tilde{c}_f\equiv\frac{(c_{f_o})}{(c_{f_o})_{R=10^6}} \tag{19}$$

At constant M_o, then, equations (17) and (18) become



$$\frac{p-p_o}{p_o}\sim\sqrt{\tilde{c}_f} \tag{17a}$$

$$\frac{l_i}{\delta^*}\sim\frac{1}{\sqrt{\tilde{c}_f}} \tag{18a}$$

Equation (17a) was originally presented in reference 12 without derivation. Curves of $\sqrt{\tilde{c}_f}$ as a function of Reynolds number are shown in figure 31 for both laminar and turbulent boundary layers. The curves for laminar layers represent a $(R_{x_o})^{-1/4}$ variation. The curves for turbulent layers represent the variation indicated by the Kármán-Schoenherr equation applicable to incompressible flow. A more accurate variation applicable to compressible turbulent flow is unknown at present.

The above results, as regards variation with Reynolds number, would apply to the pressure rise in either laminar or turbulent flow, provided the flow is determined by free interaction and not complicated by influences of downstream geometry; they would apply to the separation pressure rise (p_s-p_o), to the peak or plateau pressure rise (p_p-p_o), and to the over-all configuration pressure rise for incipient separation if such rises were determined by free interaction. For the particular case of pressure rise to a laminar separation point, equation (17a) agrees with the first analysis of this problem made by Lees (ref. 33), who obtained a $R_{x_o}{}^{-1/4}$ variation. Subsequent analyses have obtained different results (e. g., $R_{x_o}{}^{-2/5}$ variation in ref. 34). It should be noted that the approach used above considers interaction of boundary layer and external flow to be the heart of the problem (as also is considered, though in more detail, in refs. 9, 33, and 35). Other approaches to the problem of boundary-layer separation in supersonic flow have disregarded this interaction (e. g., refs. 36, 37, and 38).

Experiments on effects of geometry, Reynolds number, and Mach number for laminar separation.—Inasmuch as the pressure distribution in laminar separation depends on Reynolds number and Mach number, it is necessary in assessing the effects of model geometry to hold these numbers fixed. Some pressure distributions obtained with four different models—a step, a compression corner, a curved surface, and an incident shock model—are presented in figure 32 for the fixed conditions of $M_o=2.3$ and $R_{x_o}=0.20\times10^6$. The dotted lines rising from terminal data points designate the eventual rise in pressure observed as the separated laminar layer either begins to reattach or to be affected by transition. It is evident that the pressure distribution does not depend significantly on the mode of inducing laminar separation (this independence will be further substantiated

(a) Laminar flow.

(b) Turbulent flow.

FIGURE 31.—Square root of local skin friction as function of Reynolds number.

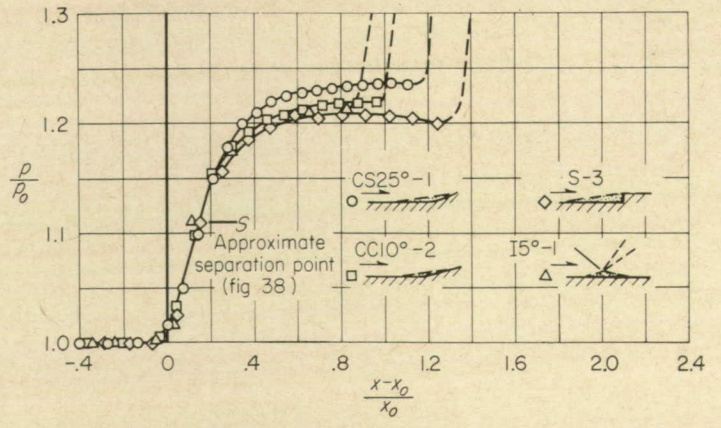


FIGURE 32.—Independence of pressure distribution and method of inducing laminar separation; $M_o=2.3$; $R_{x_o}=0.20^{\pm.01}\times10^6$.

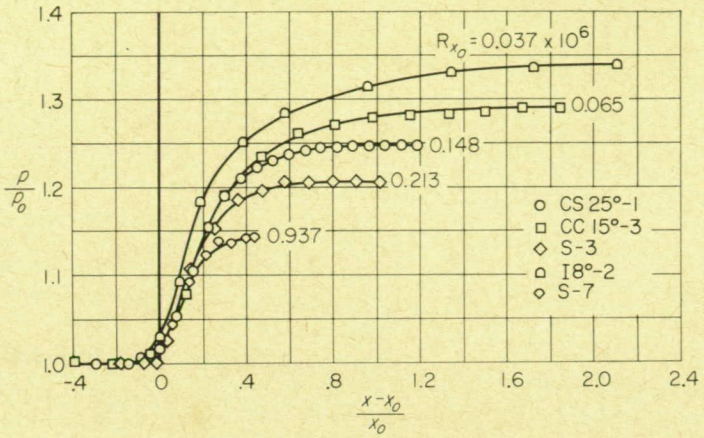
in subsequent figures). Such pressure distributions represent free interactions.

To assess the influence of Reynolds number, only the Mach number is held fixed. As is illustrated by the data in figure 33 for $M_o=2.3$, the curves for various Reynolds



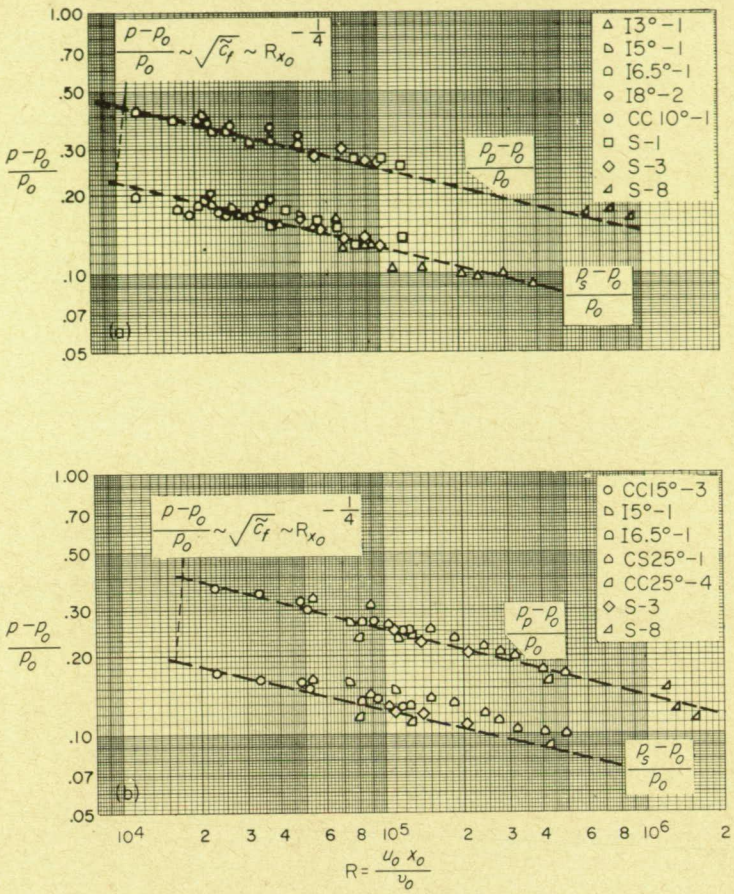


FIGURE 33.—Effect of Reynolds number on pressure distribution in laminar separation; $M_o=2.3$.

numbers are qualitatively similar but quantitatively quite different. An analogous spread of the curves was observed at the other supersonic Mach numbers investigated. For quantitative comparison with results from the simple dimentional analysis, the pressure at separation, p_s, and the plateau pressure, p_p, are plotted in figure 34 as a function of R_{x_o}. Common reference lines (dashed) are shown in both figures 34 (a) and 34 (b), from which it appears that both p_s and p_p approximately follow the same curve irrespective of whether transition is upstream or downstream of reattachment. Actually, when the type of separation changes from pure laminar to transitional, the distance x_o changes, but not the relation between pressure and R_{x_o}. It is noteworthy that the result from the simple order-of-magnitude analysis of free interactions ($\Delta p/p_o \sim \sqrt{\bar{c}_f} \sim (R_{x_o})^{-1/4}$ for laminar flow) is in good agreement with the experimental data over the wide range of R_{x_o} investigated (1.2×10^4 to 1.2×10^6).

Attention is called to several restrictions pertinent to the correlation of the laminar pressure rise data of figure 34. One such restriction is to two-dimensional flow. The oil-film technique revealed readily any flow that was not two-dimensional. Shadowgraphs likewise indicated occasional departures from two-dimensional flow. An example of this, where the shadowgraph indicates multiple separation lines (and the oil film similarly indicated lack of two-dimensionality) is shown in figure 35. The downstream geometry of this particular model was not uniform across the span. Under such conditions the peak-pressure rise was found to be less (up to about 30 percent) than for the correlated data of figure 34. In figure 36 some data are presented which illustrate an additional restriction for correlation of transitional data, namely, that transition not be too close to separation. In this figure the pressure at three different points is plotted for a step model: the pressure at separation p_s, the plateau pressure p_p, and the pressure measured in the step corner p_c. At Reynolds numbers below 10^5 the

(a) Pure laminar separation; $M_o=2.3$.

(b) Transitional separation; $M_o=2.3$.

FIGURE 34.—Effect of Reynolds number on pressure rise to separation and plateau pressure.

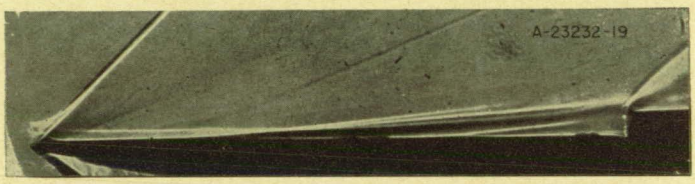

FIGURE 35.—Shadowgraph indicating lack of two-dimensional flow; S−3; $M_o=3.0$; $R_L=0.57\times10^6$.

separation is of the pure laminar type, since p_c does not differ from p_p; both p_s-p_o and p_p-p_o are close to the dashed lines representing the correlation of figure 34. Between Reynolds numbers of 10^5 and about 2.5×10^5, the separation is of the transitional type since p_c rises well above p_p, but both p_s-p_o and p_p-p_o still follow the same $R_{x_o}^{-1/4}$ variation as the correlated data. Above $R_{x_o}=2.5\times10^5$, the separation type remains transitional, and the pressure distributions (not shown) reveal transition to be approaching closely the separation point. Both p_s and p_p depart from the correlated data above this Reynolds number. When transition is close to separation, the flow in the neighborhood of separation would not be expected to be steady and often was not. Examination of various data obtained in the present experiments revealed two sufficient conditions for correlation: (1) that the pressure distribution have a length of sensibly constant plateau pressure not less than about 1.5 times the

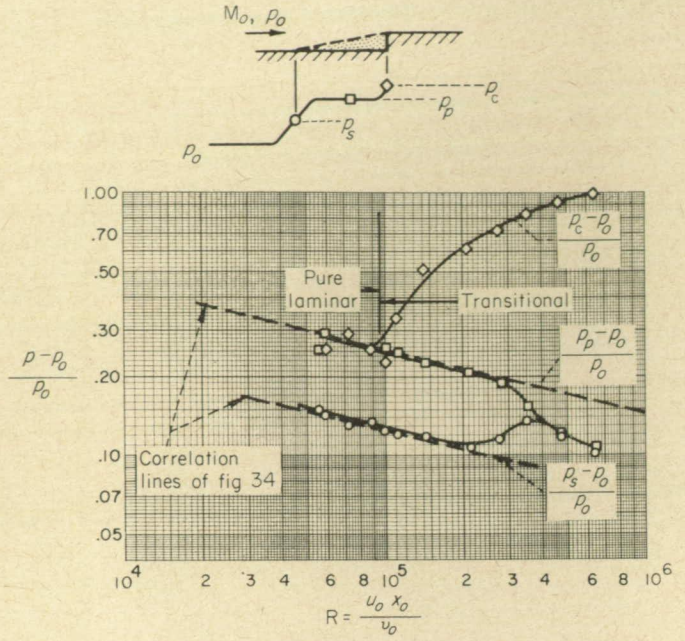

FIGURE 36.—Data illustrating restriction for correlation of transitional data; S−3; $M_o=2.3$.

length over which it takes the pressure to rise from p_o to p_p; (2) that the disturbance due to transition—as measured by the magnitude of pressure rise above the laminar plateau—not exceed two to three times the pressure rise to the laminar plateau. No necessary conditions for correlation could be observed from the data obtained, but it would be expected from theoretical considerations that the laminar separation should be steady and have at least a short length of plateau. These various restrictions may account for the lack of consistency in some previous measurements of pressure rise in laminar separation.

The fact that $(p_s-p_o)/p_o$ and $(p_p-p_o)/p_o$ in laminar flow vary nearly as $\sqrt{\bar{c}_f}\sim R_{x_o}{}^{-1/4}$, in agreement with the simple dimensional analysis, encourages a further test of the analysis by examination of the entire pressure distribution. In laminar flow $\delta^*\sim x(R_x)^{-1/2}\sim x\bar{c}_f$, so that equation (18a) for the characteristic interaction distance l_i becomes

$$l_i\sim\frac{\delta^*}{\sqrt{\bar{c}_f}}\sim\frac{x_o\bar{c}_f}{\sqrt{\bar{c}_f}}\sim x_o\sqrt{\bar{c}_f} \tag{19}$$

Since $\Delta p/p_o\sim\sqrt{\bar{c}_f}$, it follows that correlation of the pressure-distribution curves would be expected by plotting $[(p-p_o)/p_o](\bar{c}_f)^{-1/2}$ versus $[(x-x_o)/x_o](\bar{c}_f)^{-1/2}$. A plot of the data in figure 33 using these special coordinates is shown in figure 37. Data from a compression corner, a curved surface, two steps, and an incident shock-wave-induced separation are included in this figure. The various pressure distributions in the special coordinate system appear independent of Reynolds number as well as independent of object shape in conformity with the simple analysis of free interactions.

In view of the correlation observed for Reynolds number effects on the pressure distribution in laminar separation, it follows that the essential results pertaining to pressure rises can be obtained from a plot of the quantities $[(p_s-p_o)/p_o](\bar{c}_f)^{-1/2}$ and $[(p_p-p_o)/p_o](\bar{c}_f)^{-1/2}$ as functions of Mach number. Such a plot is shown in figure 38. Near $M_o=1$ the

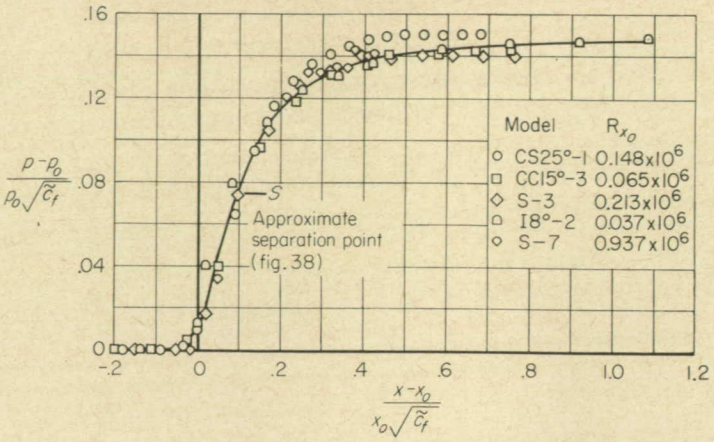

FIGURE 37.—Correlation of pressure distribution for laminar separation for various model configurations and Reynolds numbers; $M_o=2.3$.

singularity $(M_o^2-1)^{-1/4}$ should dominate in equation (17) and the plateau pressure rise $(p_p-p_o)/q_o$ should asymptotically follow a $(M_o^2-1)^{-1/4}$ variation as M_o approaches unity. Hence $(p_p-p_o)/p_o$ should asymptotically follow a $M_o^2(M_o^2-1)^{-1/4}$ variation. The dotted line in figure 38 represents

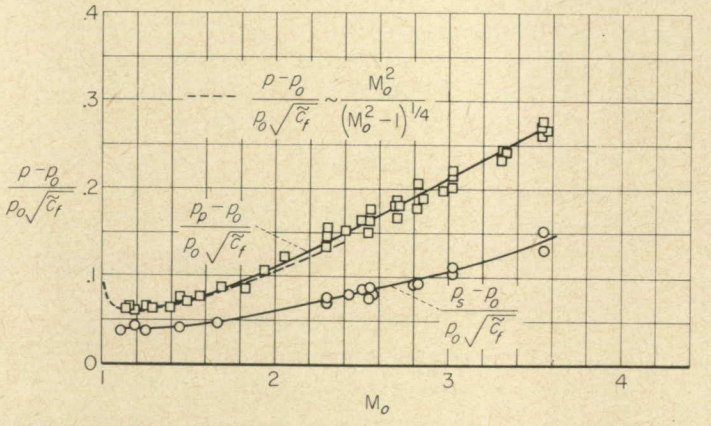

FIGURE 38.—Effect of Mach number on characteristics of laminar separation for a series of model configurations and Reynolds numbers.

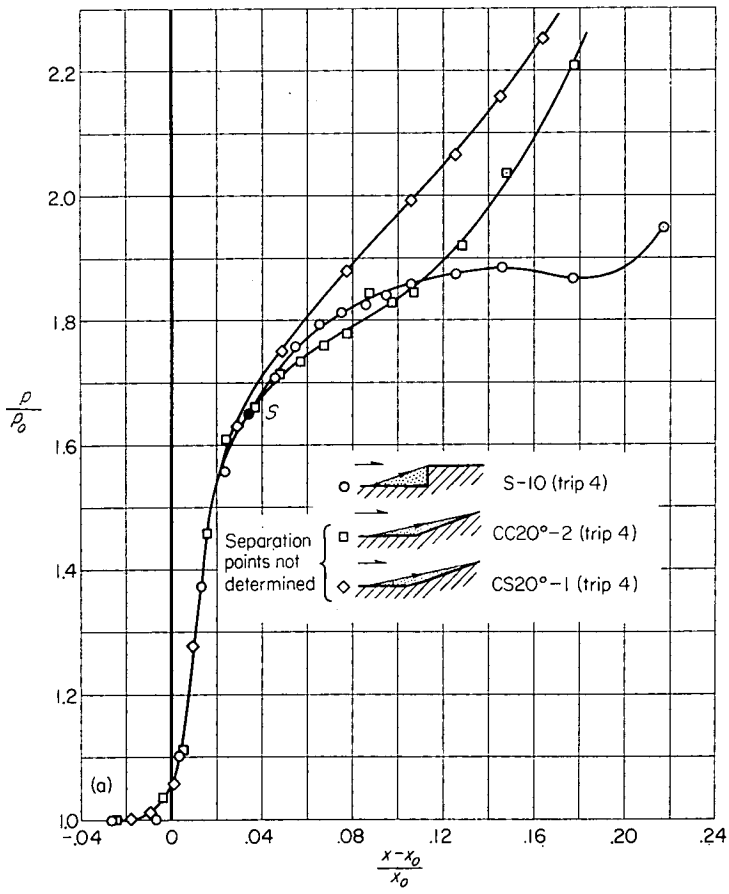
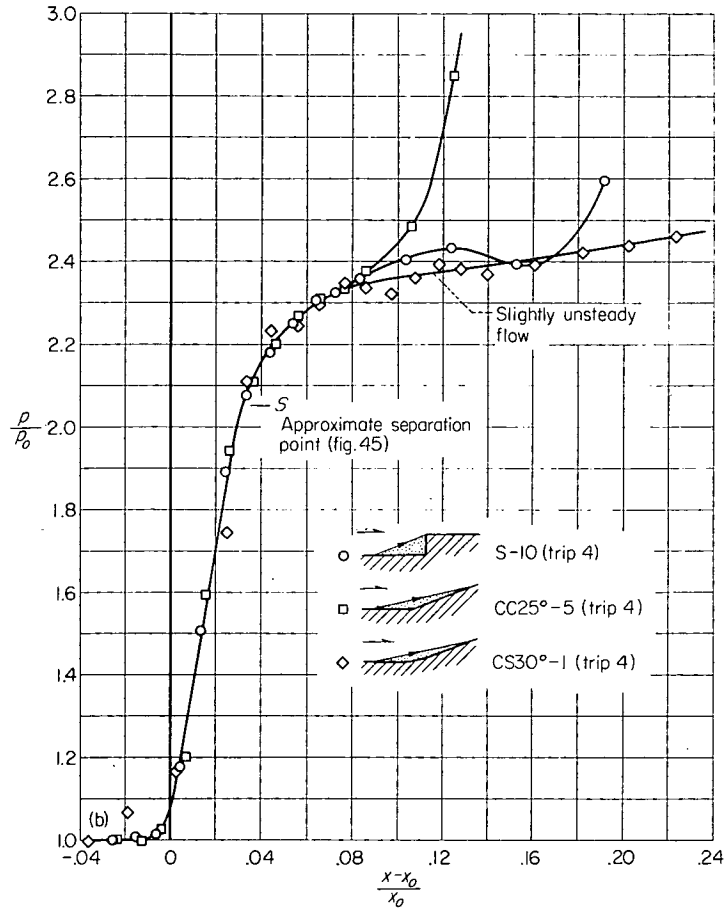


such a variation. Unfortunately the data do not extend to sufficiently low Mach numbers to test critically the predicted increase in pressure rise near $M_o=1$. Over the range of data obtained, however, there is surprising consistency with the theoretical variation. This consistency accidentally extends to supersonic Mach numbers much higher than could be expected from a knowledge of the assumptions made in the analysis.

Experiments on effects of geometry, Reynolds number, and Mach number for turbulent separation.—The pressure distributions for turbulent separation over a step, a compression corner, and a curved surface are shown in figure 39 (a). These distributions are for a constant Mach number of 2.0 and a constant Reynolds number of 3.1×10^6. Only the model shape differs for these three pressure distributions. The three curves are essentially the same up to the separation point, but beyond this they begin to depart from each other. It is evident also from figure 39 (a) that the separated flow over a step is the only flow of those investigated which exhibits a definite peak in the pressure distribution within

the separated region. Analogous results are presented in figure 39 (b) for three similar configurations at a Mach number of 3.0. In this case the three curves practically coincide for a short distance downstream of separation, but do not coincide at the station where the peak in pressure occurs for the step. This result is similar to one of Bogdonoff and Kepler (ref. 14) who compared distributions for a step and a strong incident shock.

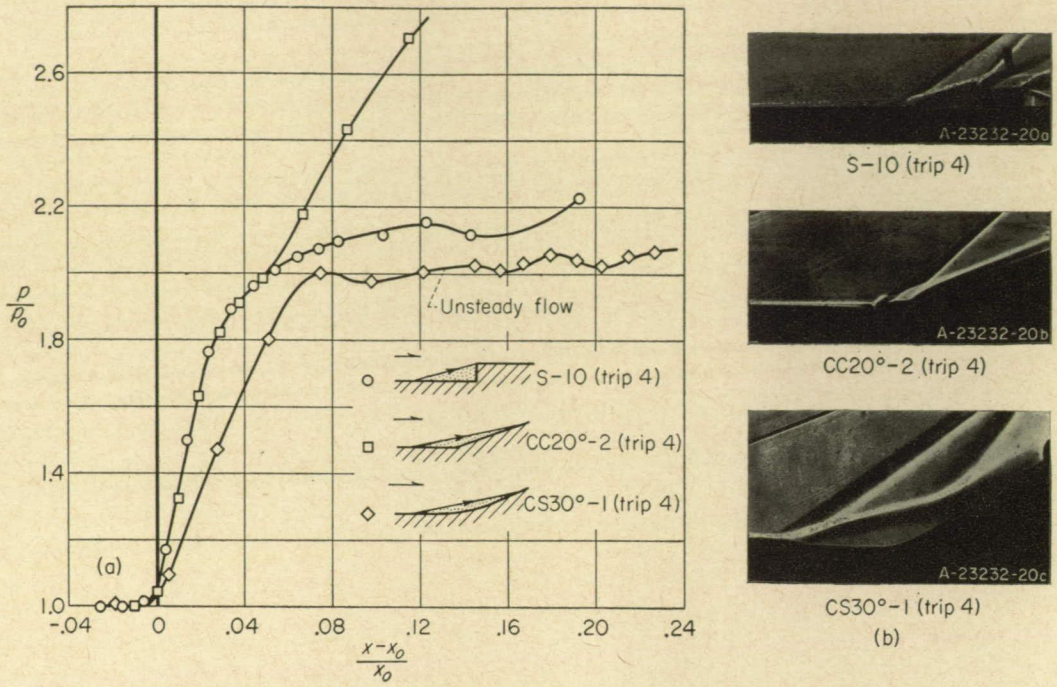


It is evident already that there is an essential difference between the qualitative characteristics of laminar separations and turbulent separations. Since turbulent separations follow a single curve only as far downstream as the separation point (or perhaps a little farther), only the flow up to the separation point would represent free interaction; the flow downstream of separation, and hence the peak pressure, would not. A possible exception might be the step which shows a definite peak pressure, but the other configurations investigated definitely do not represent free interaction phenomena downstream of the point of separation. In contrast, for laminar separations the pressure distribution well downstream of separation—including the plateau pressure—represents a free-interaction-type flow for all of the various configurations tested.

In order for the pressure distributions up to separation to represent a free interaction independent of the mode of inducing separation, it is necessary that the flow be steady.

(a) $M_o=2.0$; $R_{x_0}=3.1\times10^6$

FIGURE 39.—Effect of body shape on the pressure distribution for turbulent separation at a fixed Mach number and Reynolds number.



(b) $M_o=3.0$; $R_{x_0}=3.1\times10^6$

FIGURE 39.—Concluded.

Actually, the curved-surface model (represented by diamond symbols) in figure 39 (b) shows a little irregularity in pressure distribution which is attributed to a slight unsteadiness of the turbulent separation over this particular model. At Mach numbers lower than that represented in figure 39 (b), the turbulent separation on this model was sufficiently unsteady to bring about both irregularities in pressure distribution as well as sizable departures from the mean curves representing steady turbulent separations. An example is illustrated in figure 40 (a) which corresponds to a Mach number of 2.4. Since the turbulent separation on the curved-surface model is unsteady, the interaction takes place over a much larger streamwise distance that for the steady turbulent separations (on the step and the compression corner). Evidence of the unsteadiness is provided by the jagged pressure distribution and by the lack of sharpness in the corresponding shadowgraph in figure 40. It should be emphasized that most of the turbulent separations were relatively steady and unsteadiness to the degree illustrated in figure 40 was more an exception than a rule.

In assessing the effects of variation in Reynolds number on turbulent separations it is necessary to keep the model shape and the Mach number fixed. This requirement is unlike the case for laminar separation where only the Mach number needed to be held fixed. Some pressure distributions at various Reynolds numbers are shown in figure 41 for turbulent separation over a step at a Mach number of 2.0.

(a) Pressure distribution. (b) Shadowgraphs.

FIGURE 40.—Effects of flow unsteadiness on the pressure distribution and the corresponding shadowgraphs for turbulent separation; $M_o=2.4$; $R_{x_o}=2.7\times10^6$.

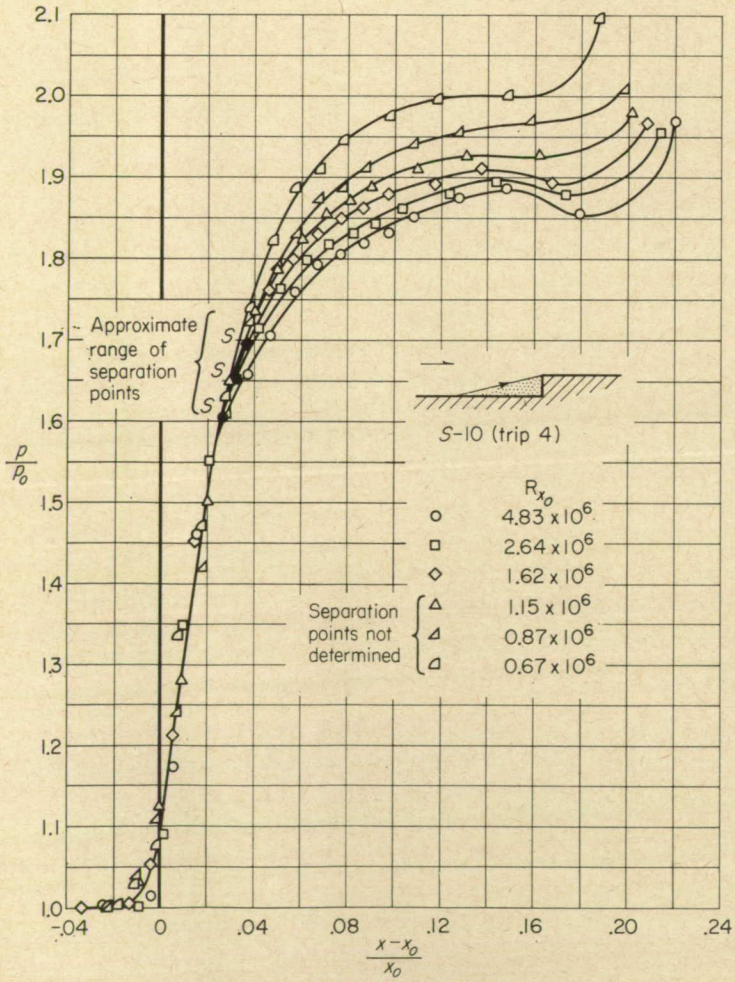


FIGURE 41.—Effect of Reynolds number on the pressure distribution for a step with turbulent separation; $M_o=2.0$.

The step model is selected inasmuch as it is the only model of those investigated which exhibits a clearly defined peak in pressure distribution. The data of figure 41 cover a range in Reynolds number corresponding to a variation by a factor of about 7 to 1, and show no large effect of such variation. These particular data do show, however, a small but consistent effect in the direction of decreasing peak pressure with increasing Reynolds number. The trend of decreasing pressure rise with increasing Reynolds number is the same as that predicted by the simple analysis for free interactions which indicates the pressure rise to vary as $\sqrt{\bar{c}_f}$. A quantitative comparison of this theoretical result with the measurements on step model S–10 (trip 4) over the M_o range between 2.0 and 3.4 is presented in figure 42. The various lines shown represent a variation proportional to $\sqrt{\bar{c}_f}$ for turbulent flow. At a Mach number of 2.0 the data indicate somewhat less variation than $\sqrt{\bar{c}_f}$, but at Mach numbers near 3 they indicate somewhat greater variation. Part of the experimental variation, particularly at the higher Mach numbers, is due to the fact that the effective origin of the turbulent boundary layer was not always at the boundary-layer trip. At low tunnel pressures, where the boundary-layer trip was not completely effective, transition could be anywhere between the trip and the beginning of separation. Data points taken under these conditions are represented by filled symbols in figure 42. For such points the Reynolds number plotted is somewhat greater than the effective Reynolds number of the turbulent boundary layer; consequently, small arrows have been attached to these points, indicating the direction in which they would move if plotted as a function of the true effective Reynolds number. It is noted that these points with arrows correspond to a pure-laminar-type separation

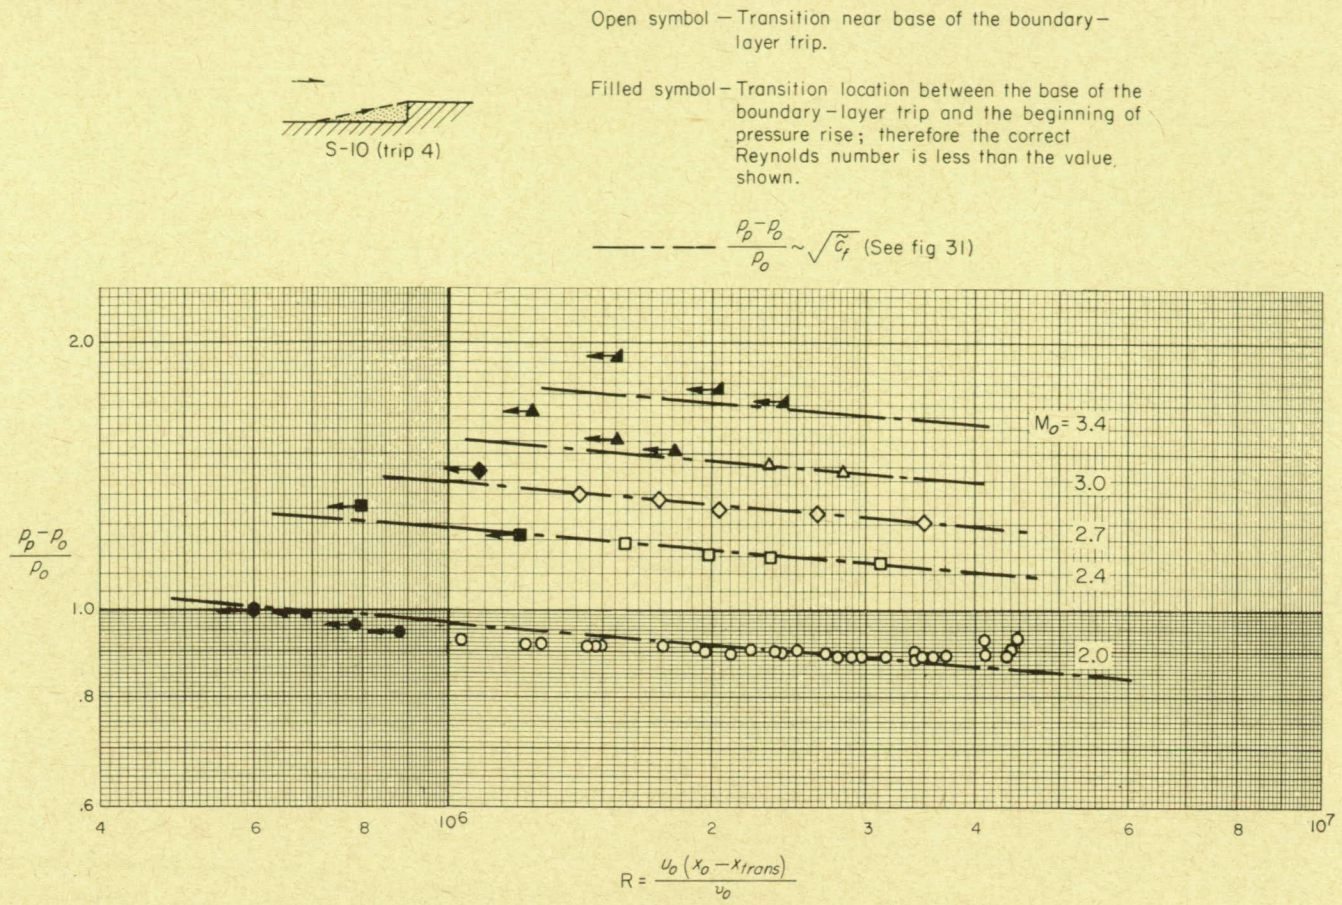

FIGURE 42.—Reynolds number effect on the peak pressure ratio for a step with turbulent separation at various Mach numbers.

behind the base of the trip (as determined by measurements of base pressure on the trip) but to a fully turbulent separation over the step.

Although the data in figures 41 and 42 for model S–10 (trip 4) show a consistent decrease in peak pressure rise with increasing Reynolds number, not all of the data for turbulent separations showed this trend. Model S–5 (trip 2) revealed no appreciable variation in p_p-p_o with R_{x_o} over the range of M_o and R_{x_o} investigated. Similarly, Love (ref. 39) found no appreciable variation of p_p-p_o with R_{x_o} over a wide range of M_o and R_{x_o}. On the other hand, the several compression-corner and curved-surface models investigated herein exhibited essentially the same trend of decreasing p_p-p_o with increasing R_{x_o} as model S–10 (trip 4). The reason for these different results is not known. These apparent discrepancies, however, are consistent with the interpretation that the flow downstream of supersonic turbulent separation—unlike the flow downstream of supersonic laminar separation—usually is not a free-interaction phenomenon, and, thus should not necessarily follow a variation approximately as $\sqrt{\bar{c}_f}$.

In figure 43 a comparison is made between the measured variation with Reynolds number of the pressure rise to a turbulent separation point and the theoretical variation predicted by the analysis. In this comparison, various model shapes are employed inasmuch as p_s-p_o (unlike p_p-p_o) is regarded as being determined by free interaction. Experimental data of Gadd, Holder, and Regan (ref. 15) are shown in figure 43 by the dashed lines. The calculated trend proportional to $\sqrt{\bar{c}_f}$ is seen to be in approximate, though not accurate, agreement with the various measurements.

As a further test of the dimensional analysis for turbulent free interactions, pressure measurements can be plotted in coordinates which should make the pressure distributions—at least up to the separation point—independent of both Reynolds number and object shape. According to equations (17) and (18), the quantity $[(p-p_o)/p_o]\bar{c}_f^{-1/2}$ should be plotted against $(x-x_o)/(\delta^*\bar{c}_f^{-1/2})$, just as in the case of laminar separation. In the absence of better information, δ^*/x_o for turbulent flow is taken as proportional to $\bar{c}_f$.[10] The appropriate longitudinal coordinate is then $[(x-x_o)/x_o]\bar{c}_f^{-1/2}$. A replot of the data of figure 41 in these appropriate coordinates is presented in figure 44. By observing that p/p_o is plotted in figure 41 and $\Delta p/p_o$ in figure 44, it is seen that the small spread due to variation of Reynolds number is approximately, though not entirely, accounted for by the simple analysis. The same coordinates which correlate the pressure distribution in laminar separation up to the plateau pressure, also correlate reasonably well the turbulent separation data up to at least the separation pressure.

The effect of Mach number on the pressure rise to the

[10] Approximate formulae for incompressible turbulent flow with 1/7-power velocity profile are: $\delta^*\sim\delta\sim x(R_x)^{-1/5}$ and $\bar{c}_f\sim R_x^{-1/5}$. These combine to give $\delta^*/x\sim\bar{c}_f$. If more refined analysis is made, such as by combining the wall law with the velocity defect law for incompressible flow, then δ^*/x is proportional to about the 1.2 power of $\bar{c}_f$. At present, appropriate formulae for compressible flow are not accurately known; hence the simplest relation $\delta^*/x\sim\bar{c}_f$ is used.

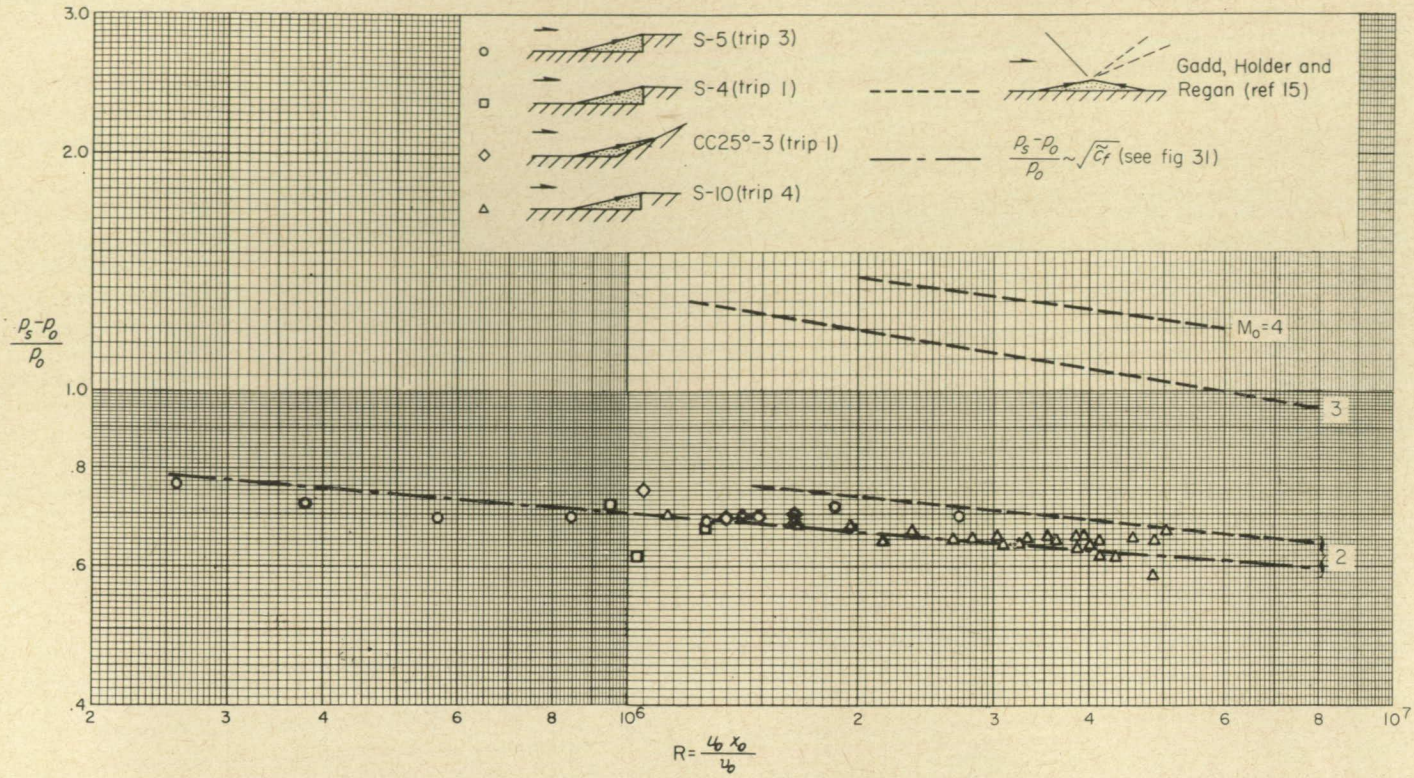

FIGURE 43.—Reynolds number effect on pressure rise to turbulent separation for various Mach numbers.

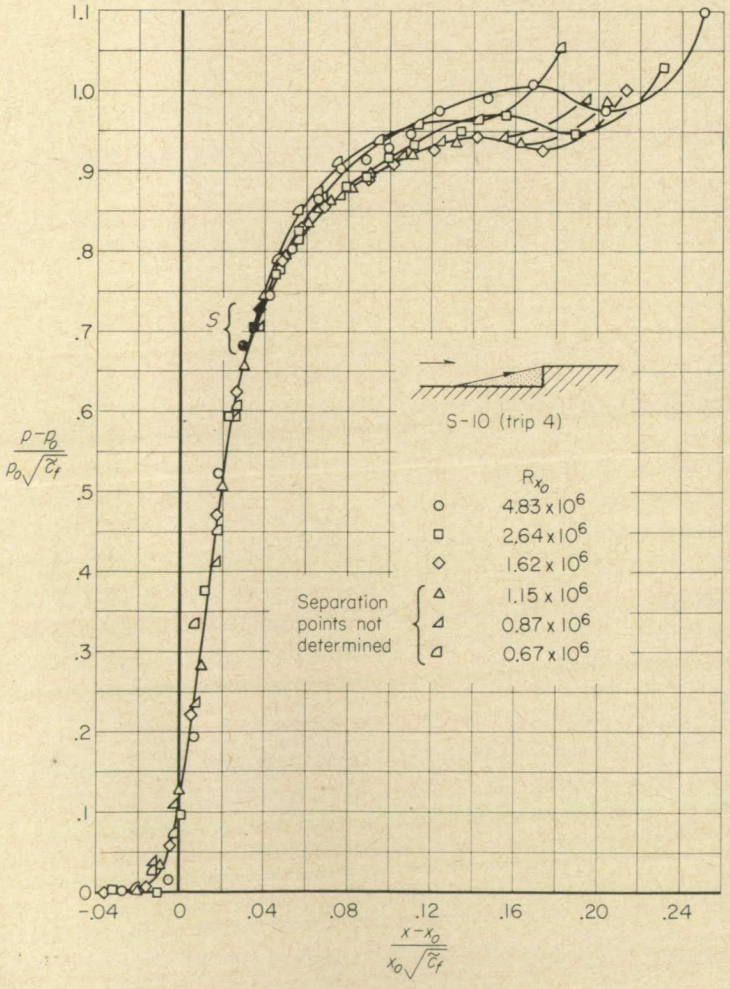

FIGURE 44.—Correlation of pressure distribution at various Reynolds numbers for turbulent separation over a step; M_0=2.0.

turbulent separation point of various models is shown in figure 45. The pressure rise $(p_s-p_0)/p_0$ is divided by $\sqrt{\bar{c}_f}$ as this would roughly account for the influence of Reynolds number. Data from various sources for steps, compression corners, and incident shock reflections are included in this figure. Two different techniques were employed in measuring the separation point as indicated in the figure legend. The Reynolds number range for the data from the present investigation is 0.3 to 6.0×10^6; whereas for the data of Bogdonoff it is approximately 8 to 36×10^6 and for the

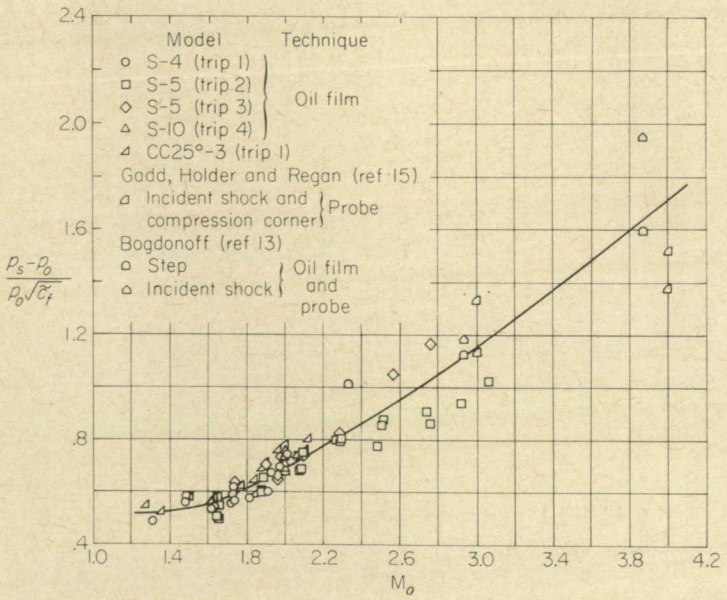

FIGURE 45.—Effect of Mach number on pressure rise to separation point for turbulent flow for steps, compression corners, and incident shocks.

data of Gadd, Holder, and Regan it is from 2 to 8×10^6. Although there is considerable scatter in the measurements (since the pressure rise to the separation point is a difficult quantity to measure accurately), there is no systematic trend discernible between the various configurations. This is consistent with the view that the pressure rise to a separation point in supersonic turbulent flow is a free-interaction phenomenon and should be independent of the mode of inducing separation.

The effect of Mach number on peak pressure rise for steps in turbulent flow is shown in figure 46. Data from experiments of Bogdonoff (ref. 13) and Love (ref. 39) are included in this figure. Two extremes are represented for Bogdonoff's data at each Mach number; they correspond to the smallest and largest step heights used in his experiments. At Mach numbers above about 2.6 the present measurements for S–6 (trip 1) show considerably higher values of p_p-p_o than do the measurements of Bogdonoff and Love. The large spread of data, as represented by the crosshatched area, is attributed primarily to the effect of boundary-layer thickness on p_p-p_o. Models for which the step height h is considerably smaller than δ_o (e. g., the lower data points of Bogdonoff in fig. 46) yield peak pressure values only slightly greater than the separation pressure, whereas the model with the largest ratio h/δ (model S–6 with trip 1 for which $h/\delta\approx6$) yields the largest values for peak pressure. The upper limit of Bogdonoff's data corresponds to an intermediate case of $h/\delta\approx2$.

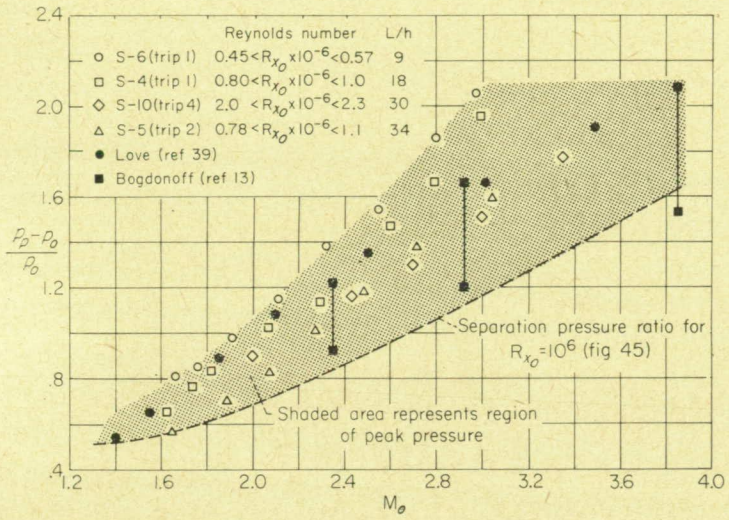

FIGURE 46.—Effect of Mach number on peak pressure ratio for steps with turbulent separation.

CONCLUSIONS

The conclusions which follow were drawn mainly from experiments with boundary layers of essentially constant pressure preceding a two-dimensional separated region. Sufficiently wide variations in model geometry (steps, bases, compression corners, curved surfaces, shock reflections) were covered to regard the conclusions as rather general, although some of these conclusions may not apply for an initial boundary-layer history of strongly rising or falling pressure.

1. For a given model shape, the location of transition relative to the reattachment and separation positions is dominant in controlling the characteristic features of pressure distribution irrespective of Mach number and Reynolds number. This dominance leads to classification of each separated flow into one of three types: pure laminar, transitional, and turbulent.

2. Pure laminar separations (transition downstream of reattachment zone) were steady in a supersonic stream and depended only to a relatively small extent on Reynolds number. The dead-air pressure for pure laminar separations having negligible boundary-layer thickness at separation can be calculated from a simple theory involving no empirical information; the theory is applicable to both subsonic and supersonic flow.

3. Transitional separations (transition between separation and reattachment) generally were unsteady and often depended markedly on Reynolds number. In transitional separations an abrupt pressure rise often occurs at the location of transition, especially when transition is only a short distance upstream of reattachment.

4. Turbulent separations (transition upstream of separation) depended only to a minor extent on Reynolds number. Most of the supersonic turbulent separations were relatively steady compared to transitional separations.

5. The stability of a separated laminar mixing layer increases markedly with an increase in Mach number. As a result, pure laminar separations, which are uncommon at subsonic speed, may become of some practical interest at hypersonic speed. Because of this marked increase in stability, laminar separations warrant additional research in hypersonic flow.

6. In a region where boundary layer and external flow interact freely, a simple analysis indicates that pressure rises vary as the square root of the skin friction. Experiments at supersonic speed substantiated this result accurately for laminar separation, and approximately for turbulent separation.

7. The pressure rise to separation is independent of the mode of inducing separation for either laminar or turbulent separation in supersonic flow. The plateau pressure rise in laminar separation is similarly independent, but the peak pressure rise in turbulent separation depends significantly on model geometry.

APPENDIX A

ANOMALOUS OIL-FILM OBSERVATIONS

When the oil-film technique was used, two threadlike lines of accumulation sometimes occurred simultaneously. They were never observed in laminar separation, but only in turbulent separation, and only over a certain Mach number range. Both lines of accumulation were stable, repeatable, and normal to the stream direction of flow. They were displaced streamwise a distance equivalent to several boundary-layer thicknesses. Depending upon test conditions, the downstream line could appear by itself, the two lines could appear simultaneously, or the upstream line could appear by itself. The upstream line corresponded to a pressure rise of about 0.3 p_o, whereas the downstream line corresponded to between 0.6 p_o and 1.0 p_o rise, depending on the Mach number. Comparable measurements of Bogdonoff and of Gadd, derived from a different technique of location of separation (near-surface pitot-pressure surveys) corresponded to the downstream line. To determine directly whether the two techniques inherently produce different results, Professor S. M. Bogdonoff volunteered cooperation by trying the oil-film technique with the Princeton apparatus on which the pitot-pressure surveys previously had been made. He immediately confirmed his earlier result on pressure rise to separation at $M_o=2.9$ (corresponding to the downstream line in the present experiments), and did not find any evidence of a second line. Although this left unexplained the simultaneous occurrence of two lines, it did remove suspicion of excessive probe interference and place suspicion on the physical significance of the upstream line of oil accumulation. It appeared possible that the upstream line did not accumulate at a separation position, but actually represented a second, stable, equilibrium position, due to wind forces acting downstream and buoyancy forces acting upstream. Sizable buoyancy forces arise from the large streamwise pressure gradients near turbulent separation. (The gradients near laminar separation are an order of magnitude smaller.)

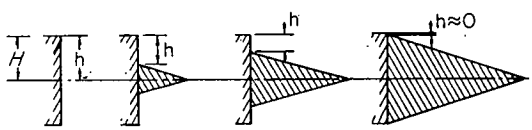
By regarding the thread of oil as a cylinder of fixed dimensions in a wind stream of density ρ_w and velocity proportional to $(\partial u/\partial y)_w$, the drag per unit span would be proportional to $\rho_w(\partial u/\partial y)_w^2$. The upstream-acting buoyancy force would be proportional to $(dp/dx)\sim(p_o/\delta_o)$, so that

$$\hat{r}\equiv\frac{\text{buoyance forces}}{\text{wind forces}}\sim\frac{p_o}{(\delta_o)\rho_w\left(\frac{\partial u}{\partial y}\right)_w^2}\sim\frac{p_o}{\left(\frac{x_o}{R_{x_o}^{1/5}}\right)\rho_w\left(\frac{c_f\rho_o u_o^2}{\mu_w}\right)^2}$$

or, since $\rho_w=\rho_e T_e/T_w\sim\rho_o T_o$ (approximately),

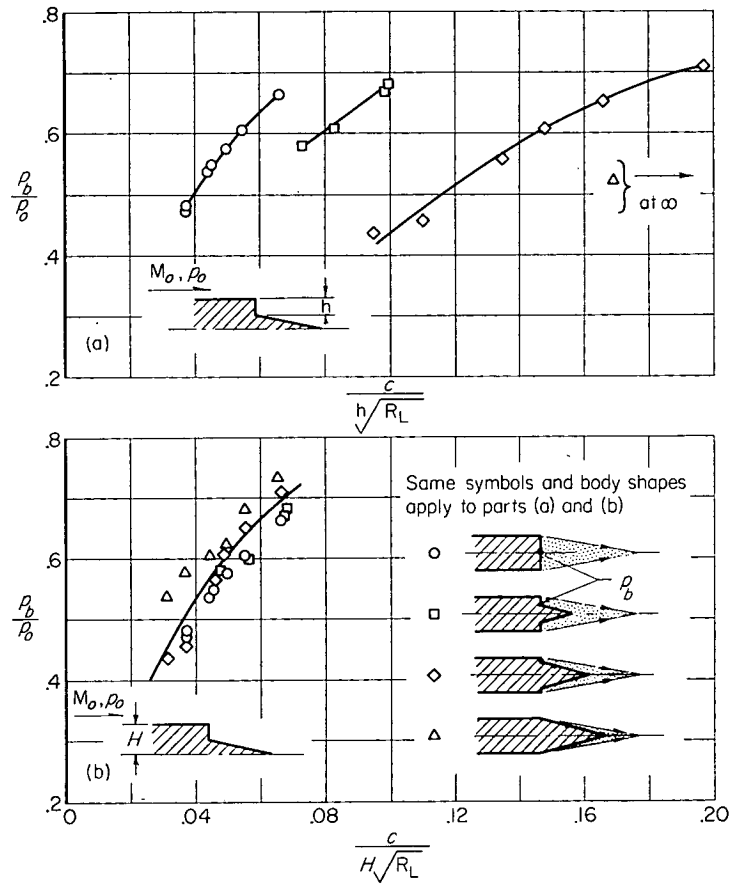
$$\hat{r}\sim\frac{R_{x_o}^{1/5}}{x_o\rho_o^2 c_f^2 u_o^4}$$

For fixed M_o and x_o, $\hat{r}\sim p_o^{1/5}/p_o^2(p_o^{-1/5})^2\sim p_o^{-7/5}$. From this brief analysis three inferences can be drawn: first, an increase in tunnel pressure for fixed M_o and x should decrease the importance of buoyancy forces; second, an increase in model length for fixed M_o and p_o should decrease the importance of buoyancy forces since $\hat{r}\sim x_o^{1/5}/x_o\sim x_o^{-4/5}$; third, for fixed x_o and p_o, the variation of $\hat{r}$ with an increase in M_o is dominated by the decrease in ρ_o and c_f; hence an increase in Mach number should increase the importance of buoyancy forces. In view of these inferred trends, a special model (S–5 with trip 2) having double the length x_o was constructed. Whereas the regular models exhibited the upstream line above about $M_o=1.9$, the larger model exhibited such lines above about $M_o=2.5$. This is consistent with both the second and third inferences above. It was found also that increasing tunnel pressure caused the upstream line to disappear. This is consistent with the first inference. Consequently, it is deduced that the upstream line, which corresponded to a pressure rise of $\Delta p/p_o=0.3\pm0.1$, is not a separation line but represents a second position for stable equilibrium of buoyancy forces and wind forces.



APPENDIX B

SPECIAL EXPERIMENTS PERTAINING TO THE CROCCO-LEES THEORY



The Crocco-Lees theory (ref. 9) is unusually broad in scope, covering laminar-, transitional-, and turbulent-type separations. Because of this extensiveness, many untested approximations are introduced in their analysis where appropriate experimental data are missing and cannot provide a guide. Also, because of the broad scope, it is important to supplement this theory wherever possible with pertinent experimental information. The present experiments suggest a way in which the Crocco-Lees theory for base pressure might be improved. This possible improvement may have no bearing, however, on the Crocco-Lees theory for other types of separation.

In the Crocco-Lees analysis the wake thickness is an important variable appearing throughout their analysis; it determines, among other things, the initial condition for integration of their differential equation which governs the dead-air pressure. On the other hand, the theory of this report indicates that the total wake thickness of a separated region would not influence the dead-air pressure.

The special experiments designed to provide a decisive test of the importance of the thickness of wake were conducted during the initial experiments (1953) on models with triangular inserts as is illustrated. The two-dimensional channel appratus was employed.

The experimental test conditions were especially selected to be in a Reynolds number range where in the separation was of the transitional type, and wherein the Crocco-Lees theory would indicate the dead-air pressure to be sensitive to changes in the initial wake thickness $h+\delta$. If the total thickness of wake were dominant in determining base pressure, then the dead-air pressure for a fixed Reynolds number R (based on the chord length c of the airfoil) should correlate roughly as a function of the parameter h/δ, or as a function of the equivalent parameter $c/(h\sqrt{R})$ where c is the model length. On the other hand, if the thickness of wake is totally unimportant, it would be expected that the dead-air pressure would be unaffected by the triangular-shaped inserts and would correlate much better when plotted as a function of H/δ, or of the equivalent parameter $c/(H\sqrt{R})$. The experimental data plotted in figure 47 are definitive in

(a) h as characteristic length.
(b) H as characteristic length.

FIGURE 47.—Base pressure measurements for transitional type separation with various wedge inserts in the dead-air region; $M_0=2.0$.

showing that H is the essential characteristic length in the problem; and hence that the total wake thickness is not important in determining base pressure. It is believed that in the Crocco-Lees theory the base height should more appropriately be introduced in a way which determines the length of mixing layer, rather than in a way which determines the initial thickness of the wake.

REPORT 1357

EXPERIMENTAL DETERMINATION OF EFFECTS OF FREQUENCY AND AMPLITUDE ON THE LATERAL STABILITY DERIVATIVES FOR A DELTA, A SWEPT, AND AN UNSWEPT WING OSCILLATING IN YAW [1]

By Lewis R. Fisher

SUMMARY

Three wing models were oscillated in yaw about their vertical axes to determine the effects of systematic variations of frequency and amplitude of oscillation on the in-phase and out-of-phase combination lateral stability derivatives resulting from this motion. The tests were made at low speeds for a 60° delta wing, a 45° swept wing, and an unswept wing; the swept and unswept wings had aspect ratios of 4.

The results indicate that large changes in the magnitude of the stability derivatives due to the variation of frequency occur at high angles of attack, particularly for the delta wing. The greatest variations of the derivatives with frequency take place for the lowest frequencies of oscillation; at the higher frequencies, the effects of frequency are smaller and the derivatives become more linear with angle of attack.

Effects of amplitude of oscillation on the stability derivatives for the delta wing were evident for certain high angles of attack and for the lowest frequencies of oscillation. As the frequency became high, the amplitude effects tended to disappear.

The algebraic addition of the component derivatives determined in separate investigations were generally in good agreement with the combination derivatives obtained herein. The major contributions to the out-of-phase derivatives are made by the sideslipping acceleration derivatives, whereas the contribution to the in-phase derivatives are made chiefly by the sideslipping velocity derivatives.

INTRODUCTION

Recent investigations have shown that stability derivatives of large magnitude exist at high angles of attack for wings undergoing rotary accelerations in yaw or transverse accelerations in sideslip. The results of one such investigation are presented in reference 1 for which wing models were forced to oscillate in a pure yawing motion (zero sideslip) at a constant frequency of oscillation. The stability derivatives resulting from this investigation include the rate of change of yawing- and rolling-moment coefficients with yawing velocity $C_{n_{r,\omega}}$ and $C_{l_{r,\omega}}$ and the rate of change of yawing- and rolling-moment coefficients with yawing acceleration $C_{n_{\dot{r},\omega}}$ and $C_{l_{\dot{r},\omega}}$, where the subscript ω indicates oscillatory derivatives. These derivatives were measured for a 60° delta wing, a 45° sweptback wing, and an unswept wing; the swept and unswept wings had aspect ratios of 4.

The same wing models were oscillated in a pure sideslipping motion for the investigation of reference 2. The measured stability derivatives resulting from this type of motion included the yawing- and rolling-moment coefficients due to sideslipping velocity $C_{n_{\beta,\omega}}$ and $C_{l_{\beta,\omega}}$ and the yawing- and rolling-moment coefficients due to sideslipping acceleration $C_{n_{\dot{\beta},\omega}}$ and $C_{l_{\dot{\beta},\omega}}$. These derivatives were measured primarily at one frequency of oscillation; however, some limited data involving a variation of oscillation frequency in reference 2 indicated that the sideslipping derivatives at high angles of attack were dependent upon frequency. The results presented in reference 3 substantiated these effects of frequency at high angles of attack on the lateral stability derivatives for a similar set of wings. Reference 3 also includes a comprehensive discussion of the probable origin of the acceleration derivatives of large magnitude, and reference 4 points out the importance of including these derivatives in dynamic stability calculations, particularly at high angles of attack where the derivatives assume large magnitudes.

A reasonably simple oscillation-test technique for extracting the lateral stability derivatives for a model is the method of oscillating the model in yaw about its vertical wind axis. Since the motion of the model is then a combination of yawing and sideslipping, the stability derivatives measured by this technique are the combination derivatives $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$, $C_{l_{r,\omega}}-C_{l_{\dot{\beta},\omega}}$, $C_{n_{\beta,\omega}}+k^2C_{n_{\dot{r},\omega}}$, and $C_{l_{\beta,\omega}}+k^2C_{l_{\dot{r},\omega}}$, where k is the reduced frequency parameter $\omega b/2V$. The present investigation employed this technique for the purpose of determining the effects of a systematic variation of frequency and amplitude of oscillation on the resulting combination stability derivatives. Furthermore, in order to establish the relative importance of the individual derivatives which form the combination derivatives, the results of the investigation of reference 1 and of additional tests similar to those of reference 2 are compared individually and as an algebraic sum with the results of the present investigation. These comparisons provide an indication of the degree to which the results of the individual sideslipping and yawing tests are additive and attest to the linearity of the aerodynamic phenomena responsible for the large-magnitude derivatives.

SYMBOLS

The data are referred to the system of stability axes and are presented in the form of standard coefficients of forces and moments about the quarter-chord point of the mean aerodynamic chord of each wing tested. (See fig. 1.) The coefficients and symbols used herein are defined as follows:

b	span, ft
c	local chord, ft
$\bar{c}$	mean aerodynamic chord, ft
C_D	drag coefficient, Drag/qS
C_L	lift coefficient, Lift/qS
C_l	rolling-moment coefficient, Rolling moment/qSb
C_m	pitching-moment coefficient, Pitching moment/$qS\bar{c}$
C_n	yawing-moment coefficient, Yawing moment/qSb
k	reduced-frequency parameter, $\omega b/2V$
q	dynamic pressure, $\frac{1}{2}\rho V^2$, lb/sq ft
r	rate of change of yaw angle, $\dot{\psi}$, radians/sec
$\dot{r}$	yawing acceleration, $\partial\dot{\psi}/\partial t$
S	wing area, sq ft
t	time, sec
V	free-stream velocity, ft/sec
α	angle of attack, deg
β	angle of sideslip, radians or deg
$\dot{\beta}$	rate of change of sideslip angle, $\partial\beta/\partial t$
β_0	amplitude of sideslip, deg
ρ	mass density of air, slugs/cu ft
ψ	angle of yaw, radians or deg
$\dot{\psi}$	rate of change of yaw angle, $\partial\psi/\partial t$

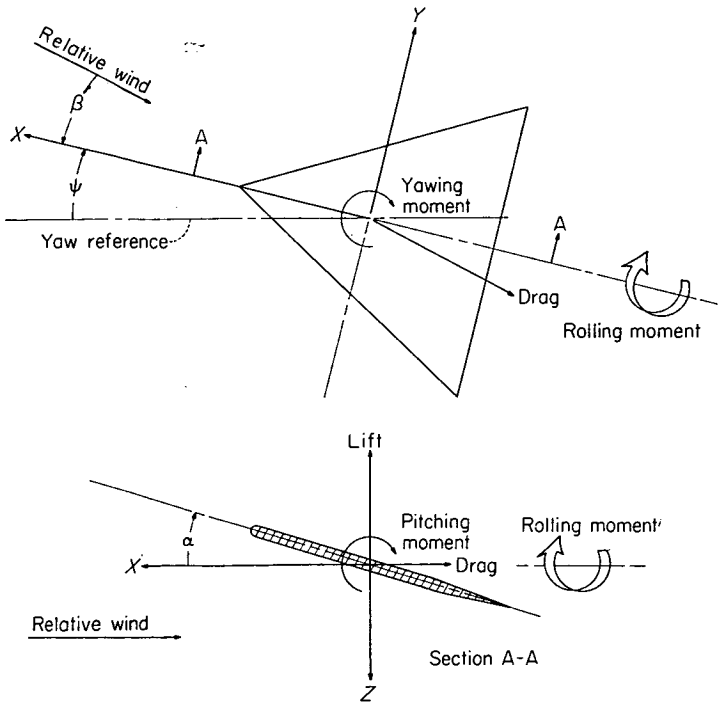

FIGURE 1.—System of stability axes. Arrows indicate positive forces, moments, and angular displacements. Yaw reference is generally chosen to coincide with initial relative wind.

ψ_0	amplitude of yawing oscillation measured from zero yaw, deg
ω	circular frequency of oscillation, radians/sec

Derivatives: Following are formulas for the lateral stability derivatives used in presenting the results. All derivatives are nondimensionalized (1/radians).

$$C_{n_\beta}=\frac{\partial C_n}{\partial\beta} \qquad C_{n_r}=\frac{\partial C_n}{\partial\left(\frac{rb}{2V}\right)}$$

$$C_{n_{\dot{\beta}}}=\frac{\partial C_n}{\partial\left(\frac{\dot{\beta}b}{2V}\right)} \qquad C_{n_{\dot{r}}}=\frac{\partial C_n}{\partial\left(\frac{\dot{r}b^2}{4V^2}\right)}$$

$$C_{l_\beta}=\frac{\partial C_l}{\partial\beta} \qquad C_{l_r}=\frac{\partial C_l}{\partial\left(\frac{rb}{2V}\right)}$$

$$C_{l_{\dot{\beta}}}=\frac{\partial C_l}{\partial\left(\frac{\dot{\beta}b}{2V}\right)} \qquad C_{l_{\dot{r}}}=\frac{\partial C_l}{\partial\left(\frac{\dot{r}b^2}{4V^2}\right)}$$

The subscript ω used with a derivative denotes the oscillatory derivative.

APPARATUS AND MODELS

OSCILLATION APPARATUS

The equipment used to oscillate the models consisted of the motor-driven flywheel, connecting rod, crank arm, and model-support strut shown schematically in figure 2 and photographically in figures 3 and 4. The connecting rod was pinned to an eccentric center on the flywheel and transmitted a sinusoidal yawing motion to the support strut by means of the crank arm. Because the models were mounted to the support strut at their assumed centers of gravity, the oscillation was forced about the vertical wind (or stability) axis of the models. The apparatus was driven by a 1-horsepower direct-current motor through a geared speed reducer.

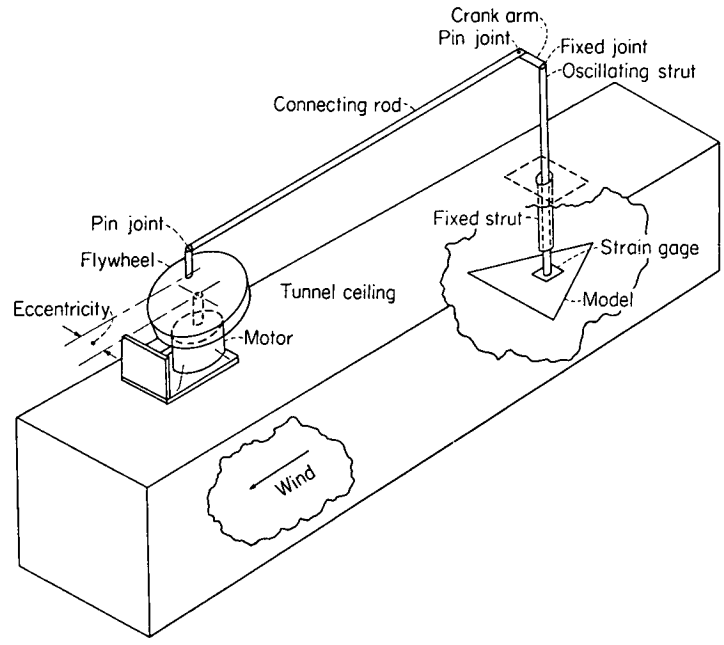

FIGURE 2.—Sketch of oscillation-in-yaw equipment.

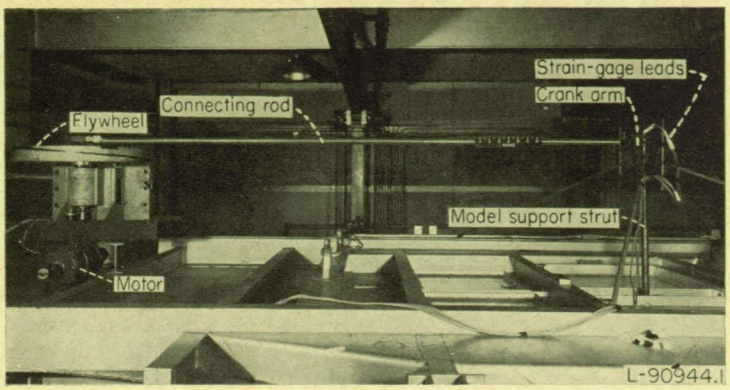

FIGURE 3.—Oscillation-in-yaw equipment on top of tunnel test section.

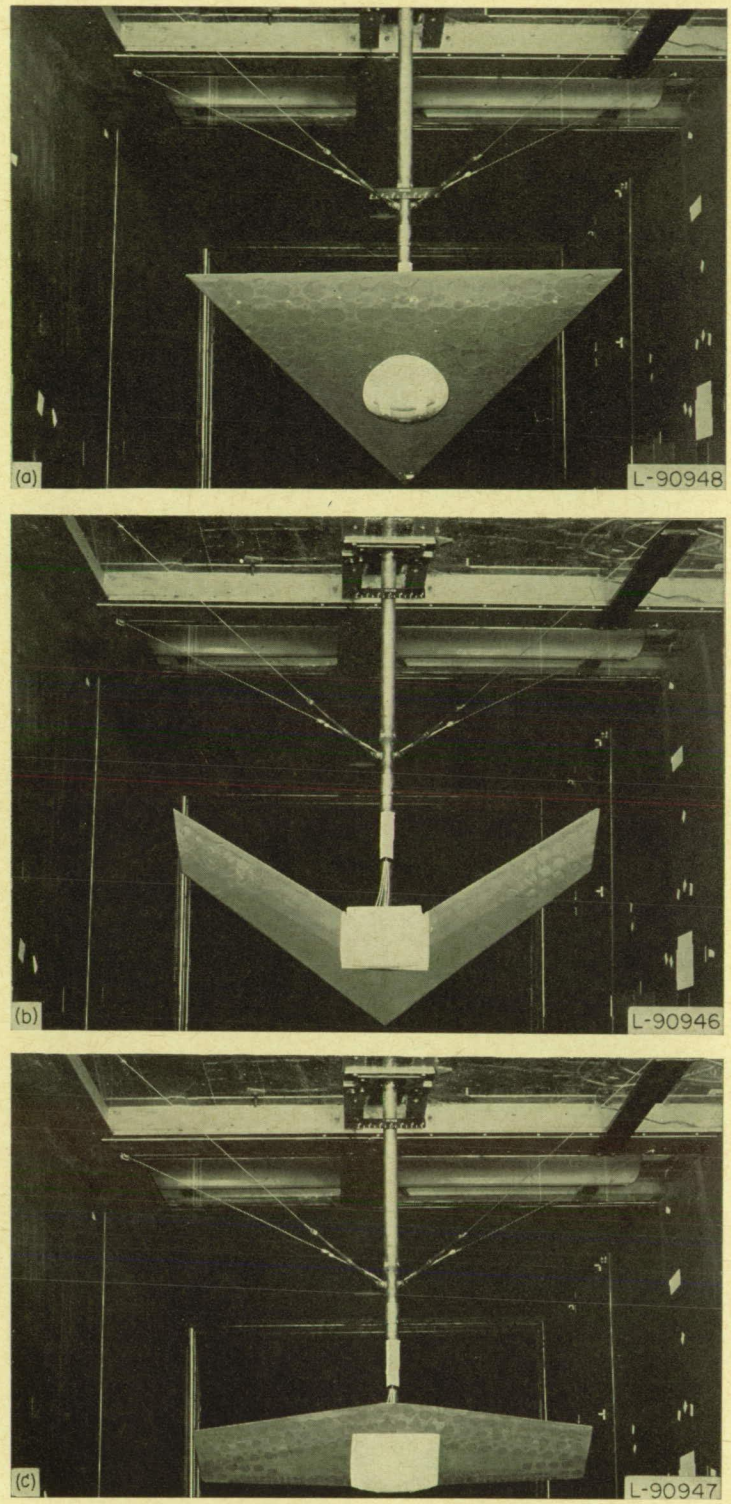


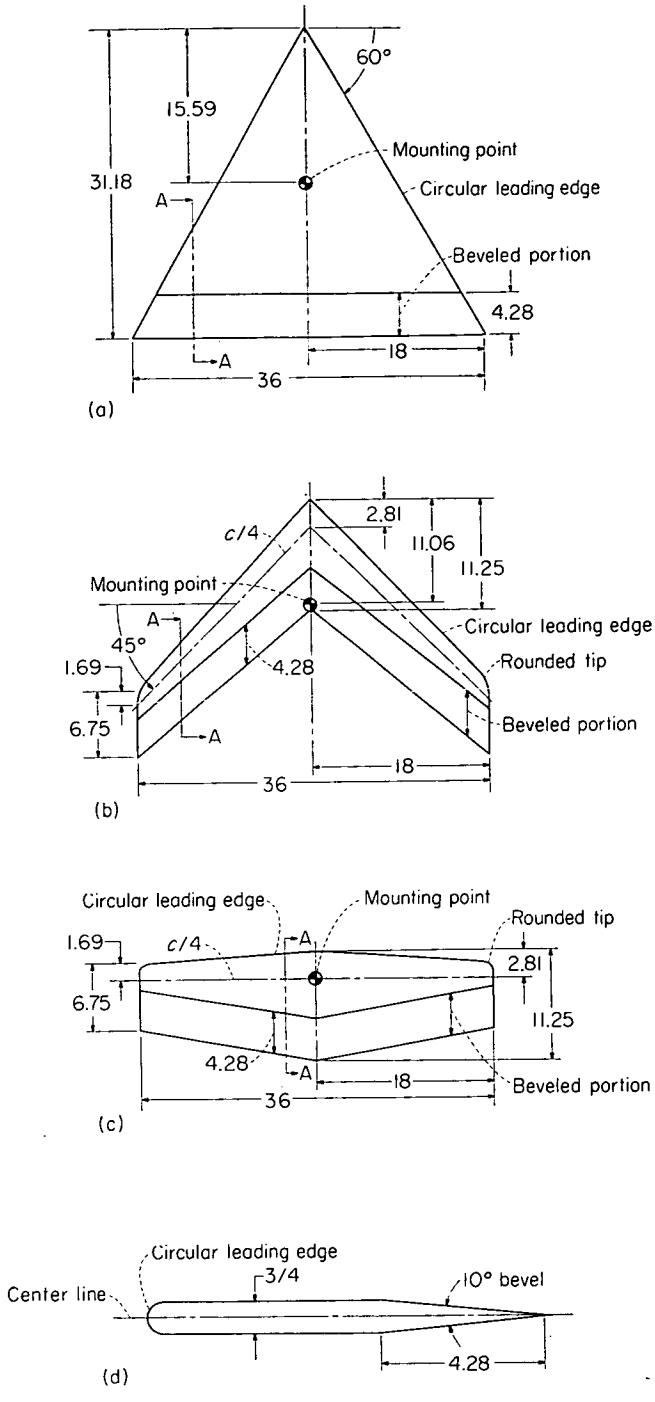
The frequency of oscillation was varied by changing the voltage supplied to the motor, and the amplitude of oscillation was varied by adjusting the throw of the eccentric on the flywheel.

Because the reduced frequency of the tests of reference 2 differed from that of reference 1, some additional tests similar to those of reference 2 were made for this investigation at a reduced frequency which corresponded to that of reference 1. The results in reference 2 were obtained from freely damped sideslipping oscillation tests in which the motion was forced by a set of coil springs. For these additional tests, however, the coil springs were replaced by a flywheel and crank mechanism similar to that used for the yawing-oscillation tests. The resulting motion, therefore, was a continuous sideslipping oscillation of constant amplitude. Check tests for comparable frequencies indicated that the derivatives measured by either technique were about the same.

MODELS

The models tested were the three wings used for the investigations of references 1 and 2 and are shown in figure 4. These models included a 60° delta wing, a 45° sweptback wing, and an unswept wing (fig. 5). The swept and unswept wings had aspect ratios of 4, taper ratios of 0.6, and rounded tips. Each of the three wings was constructed from ¾-inch plywood and had essentially a flat-plate airfoil section with a circular leading edge and a beveled trailing edge (fig. 5 (d)). The trailing edges of all wings were beveled to provide a trailing-edge angle of 10° that was constant across the span. Model dimensions are shown in the sketches of the three wings presented in figure 5, and other pertinent parameters are listed in the following table:

Item	Delta Wing	Swept wing	Unswept wing
Aspect ratio	2. 31	4. 0	4. 0
Taper ratio	0	0. 6	0. 6
Sweep angle, deg	(At L. E.) 60	(At $c/4$) 45	(At $c/4$) 0
Dihedral angle, deg	0	0	0
Twist, deg	0	0	0
Airfoil section	Flat plate	Flat plate	Flat plate
Area, sq in.	561. 20	324	324
Span, in.	36. 00	36	36
Mean aerodynamic chord, in.	20. 79	9. 19	9. 19



(a) 60° delta wing.
(b) 45° swept wing.
(c) Unswept wing.

FIGURE 4.—Models in tunnel test section.

RECORDING OF DATA

The data obtained in this investigation were recorded by means of the equipment described in the appendix of reference 1. Briefly, the rolling and yawing moments acting on the model during oscillation were measured by means of resistance-type strain gages mounted on the oscillating strut to which the model was attached. The moments were modified by a sine-cosine resolver driven by the oscillating

(a) Delta wing.
(b) Swept wing.
(c) Unswept wing.
(d) Airfoil section (all models).

FIGURE 5.—Sketches of the three wing models investigated. All dimensions are in inches.

mechanism so that the out-put signals of the strain gages were proportional to the in-phase and out-of-phase components of the strain-gage signals. These signals were read visually on a highly damped direct-current meter and the aerodynamic coefficients were obtained by multiplying the meter readings by the appropriate constants, one of which was the system calibration constant. The additional sideslipping oscillation tests required for the present investigation made use of this new equipment rather than the equipment used in the investigation of reference 2.

TESTS

All tests were conducted in the 6- by 6-foot test section of the Langley stability tunnel at a dynamic pressure of 24.9 pounds per square foot which corresponds to a Mach number of 0.13. The Reynolds number based on the mean aerodynamic chord was approximately 1.6×10^6 for the 60° delta wing and 0.71×10^6 for the swept and unswept wings.

The oscillation tests with the delta wing were conducted for nominal frequencies of oscillation of 0.5, 1.0, 2.0, 3.0, and 3.3 cycles per second. These frequencies correspond to values of the reduced-frequency parameter k of 0.033, 0.065, 0.130, 0.195, and 0.215. The amplitudes of oscillation ψ_0 for each of these frequencies was $\pm2°$, $\pm4°$, $\pm6°$, $\pm8°$, and $\pm10°$ for the delta wing. For the swept and unswept wings, the reduced frequency of 0.195 and the amplitude of 8° were omitted from the tests.

The in-phase and out-of-phase yawing and rolling moments were measured for the delta wing in angle-of-attack increments of 4° from $\alpha=0°$ to $\alpha=16°$ and thereafter in 2° increments up to $\alpha=32°$. For the swept wing, these measurements were taken in increments of 4° from $\alpha=0°$ to $\alpha=20°$ and also at $\alpha=10°$, 18°, and 22°. For the unswept wing, the measurements were taken in increments of 2° from $\alpha=0°$ to $\alpha=16°$.

For each amplitude, frequency, and angle-of-attack condition, both a wind-on test and a wind-off test were made. The effects of the inertia of the model were eliminated from the data by subtracting the results of the wind-off tests from those of the wind-on tests.

The value of reduced-frequency parameter k of 0.215 (or 3.3 cycles per second) was selected because it corresponded to the reduced frequency of the tests of reference 1. The tests of reference 2 were made at lower values of the reduced frequency. In order to arrive at a better basis of comparison for frequency, the additional tests made by the method similar to that of reference 2 were for $k=0.22$ and $\beta_0=\pm6°$. These tests, however, were made by the forced-oscillation method rather than the free-oscillation method used in reference 2.

RESULTS AND DISCUSSION

PRESENTATION OF RESULTS

In figure 6 are shown the lift, drag, and pitching-moment coefficients as functions of angle of attack for the three wings tested. These data are taken from reference 2 and are for a dynamic pressure of 39.8 pounds per square foot, which is somewhat higher than the dynamic pressure used for the present tests. The static variations of rolling moment and yawing moment with sideslip angles up to $\pm10°$ are presented in figure 7 for given angles of attack. These data exhibit no extreme nonlinearities in the range of sideslip angles being considered.

The data measured during these oscillation tests are presented for the delta wing in figure 8, for the swept wing in figure 9, and for the unswept wing in figure 10. These data are for four combination lateral stability derivatives resulting from the combined oscillatory yawing and sideslipping motion employed for the tests. The derivatives are shown as functions of angle of attack for five frequencies of oscillation of the delta wing and four frequencies of oscillation for the

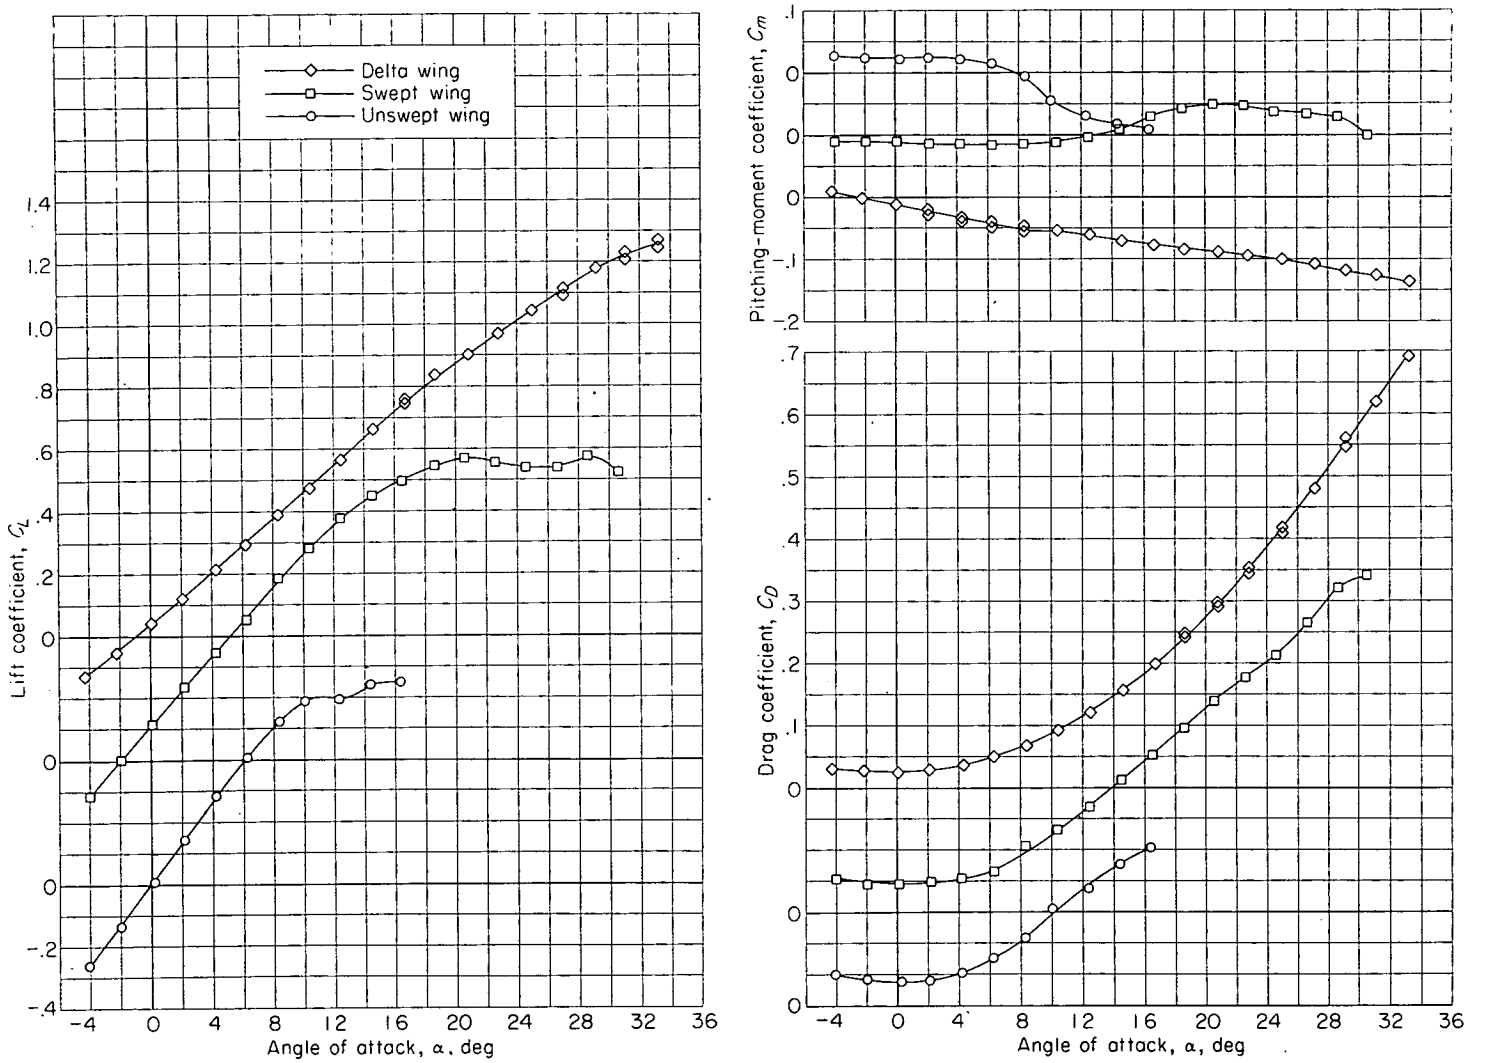


FIGURE 6.—Lift, drag, and pitching-moment characteristics as a function of angle of attack for the unswept, the 45° swept, and the 60° delta wings. $q=40$ lb/sq ft.

swept and unswept wings. Each part of figures 8, 9, and 10 presents the data for a different amplitude of oscillation from $\psi_0=\pm 2°$ to $\psi_0=\pm 10°$. In these figures the static derivatives C_{n_β} and C_{l_β} are also shown for comparison with the oscillatory derivatives $C_{n_{\beta,\omega}}+k^2C_{n_{\dot{r},\omega}}$ and $C_{l_{\beta,\omega}}+k^2C_{l_{\dot{r},\omega}}$, respectively. The static derivatives were taken from reference 2 and were measured at Reynolds numbers slightly higher than those for the present tests.

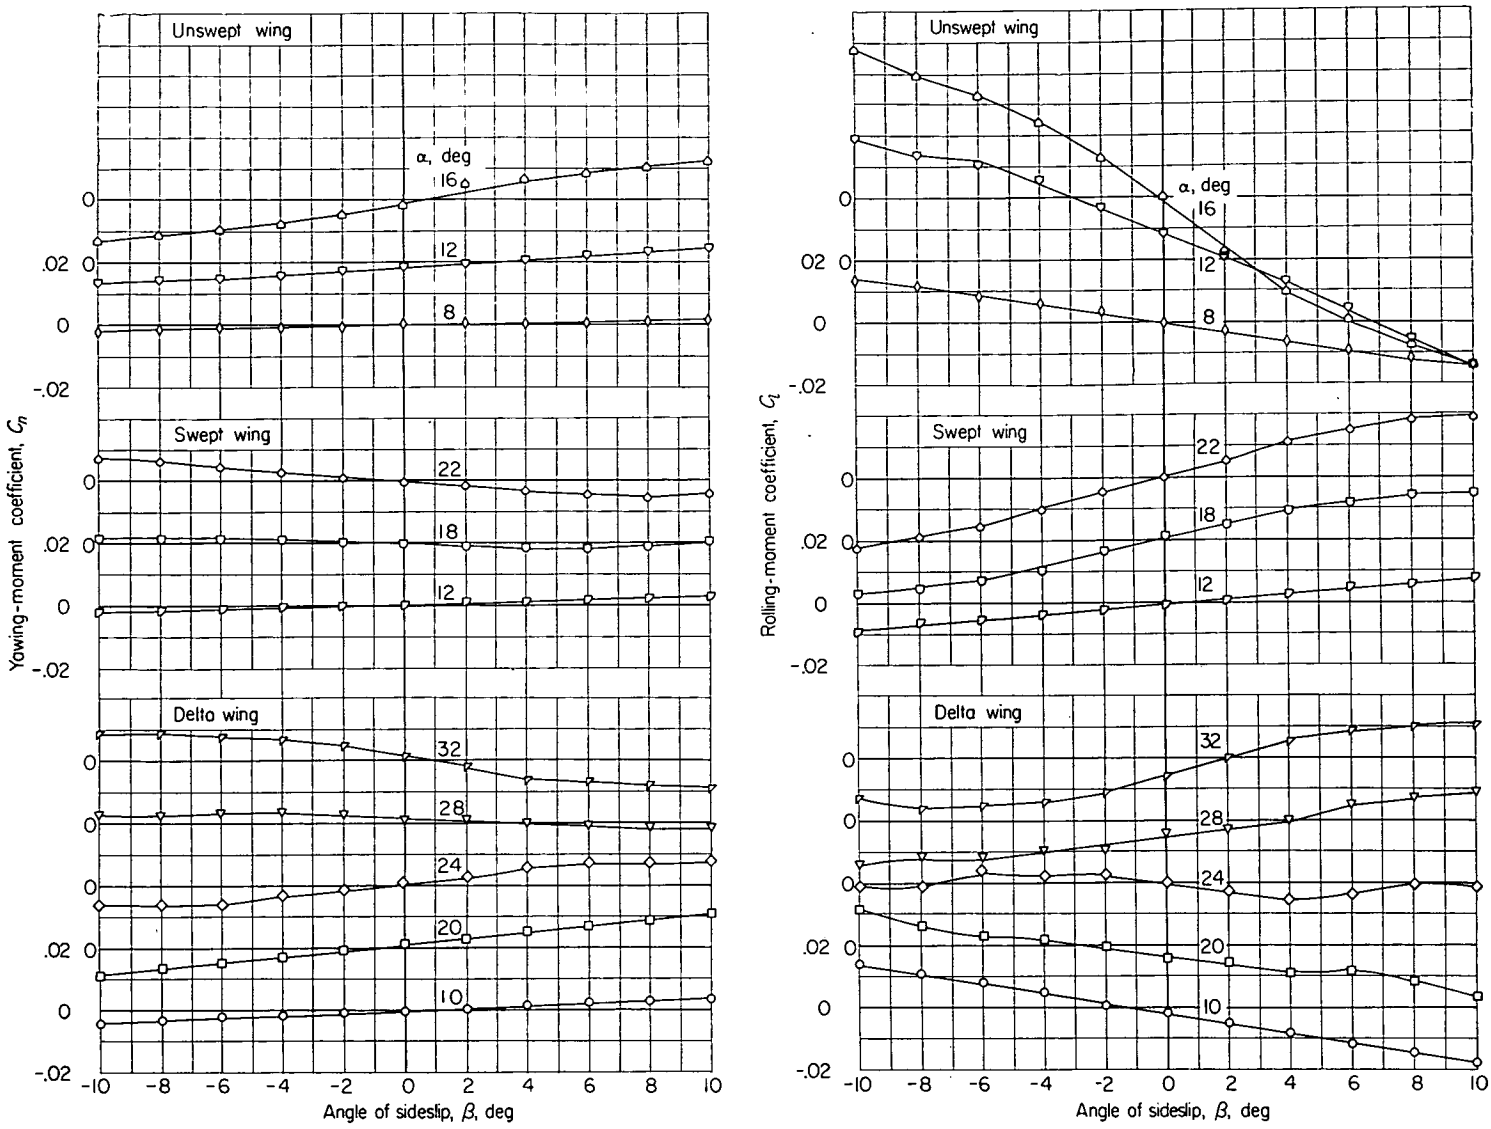
The effects of the reduced-frequency parameter k on the measured stability derivatives are shown for the three wings in figures 11 to 14. These cross-plotted data are given for four angles of attack for each wing. The measured stability derivatives are also cross-plotted as functions of amplitude of oscillation for the three wings in figures 15 to 18 for the same angles of attack given in figures 11 to 14.

In figure 19, the values of the derivative $C_{n_{r,\omega}}$ measured during the tests of reference 1 are added algebraically to the values of the derivative $C_{n_{\dot{\beta},\omega}}$ measured by means of tests similar to those of reference 2. The sums of these derivatives are compared with experimental values of $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$ for a corresponding frequency and amplitude of oscillation. Figures 20, 21, and 22 present similar comparisons for the derivatives $C_{l_{r,\omega}}-C_{l_{\dot{\beta},\omega}}$, $C_{n_{\beta,\omega}}+k^2C_{n_{\dot{r},\omega}}$, and $C_{l_{\beta,\omega}}+k^2C_{l_{\dot{r},\omega}}$, respectively.

Although the following discussion has been divided into sections on the effects of angle of attack, of frequency, and of amplitude, it should be pointed out that, because of the apparent interrelationship among all three quantities, it is not possible to isolate the discussion concerning these parameters without discussing the related quantities as well. However, each of the following sections concerns itself primarily with the effect of the parameter being considered.

EFFECT OF ANGLE OF ATTACK

In the discussion of the effects of angle of attack on the measured stability derivatives, it is convenient to separate the low range of angle of attack from the high range of angle of attack. This division takes place at $\alpha\approx 18°$ for the delta wing, at $\alpha\approx 10°$ for the swept wing, and at $\alpha\approx 8°$ for the unswept wing. These are the angles, for the respective wings, below which frequency effects appear to be relatively small and above which frequency effects are relatively large. (See figs. 8, 9, and 10.) In figure 6, these angles of attack are shown to correspond to the angles at which initial changes take place in the lift-curve slopes for each wing; this change in slope indicates that these are the angles of attack at which flow separation has begun. Reference 3 shows that the



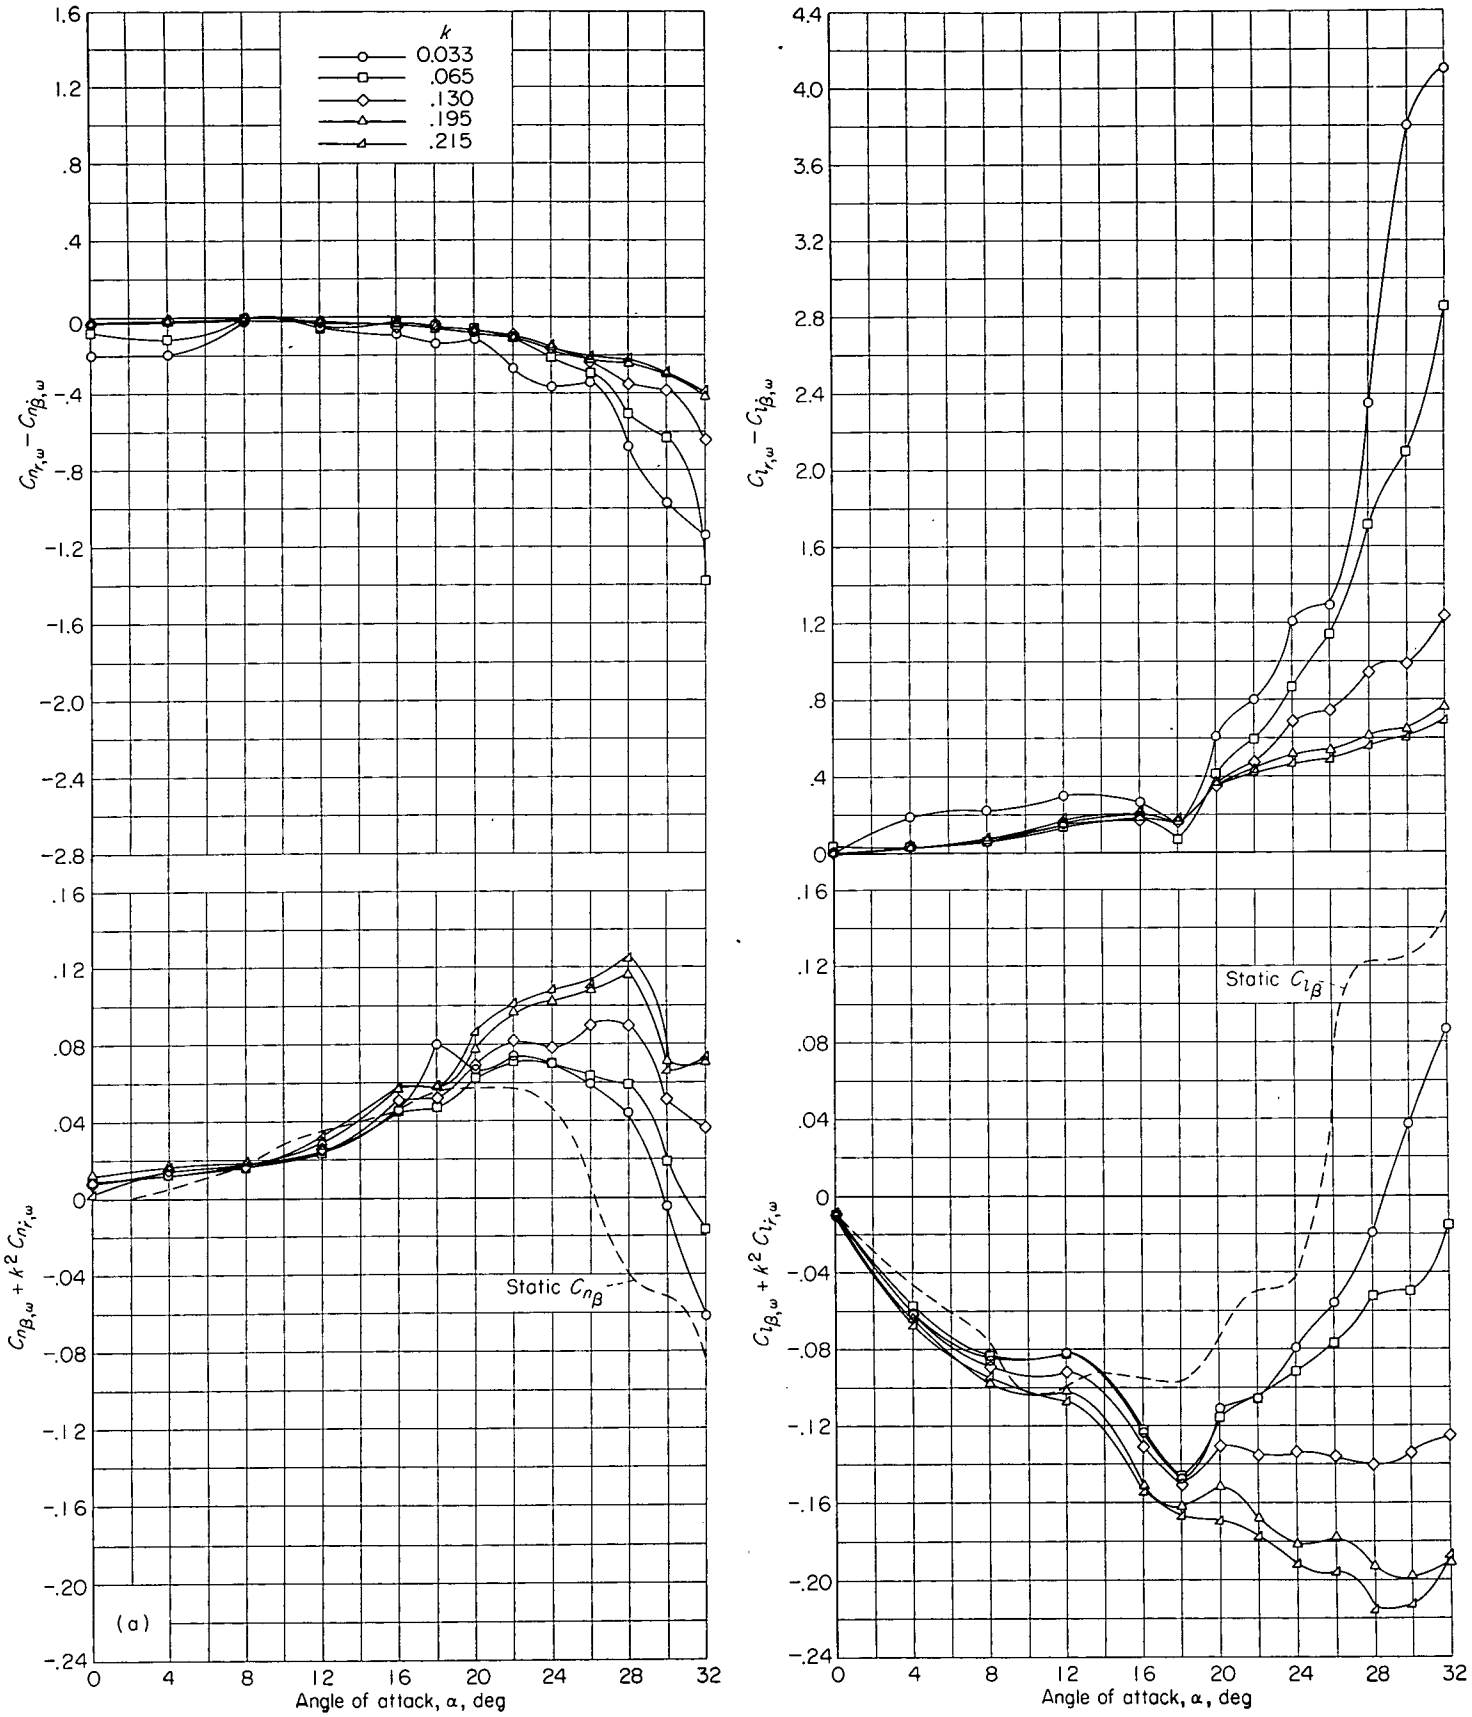


FIGURE 7.—Variation of yawing-moment and rolling-moment coefficients with angle of sideslip for $q=25$ lb/sq ft.

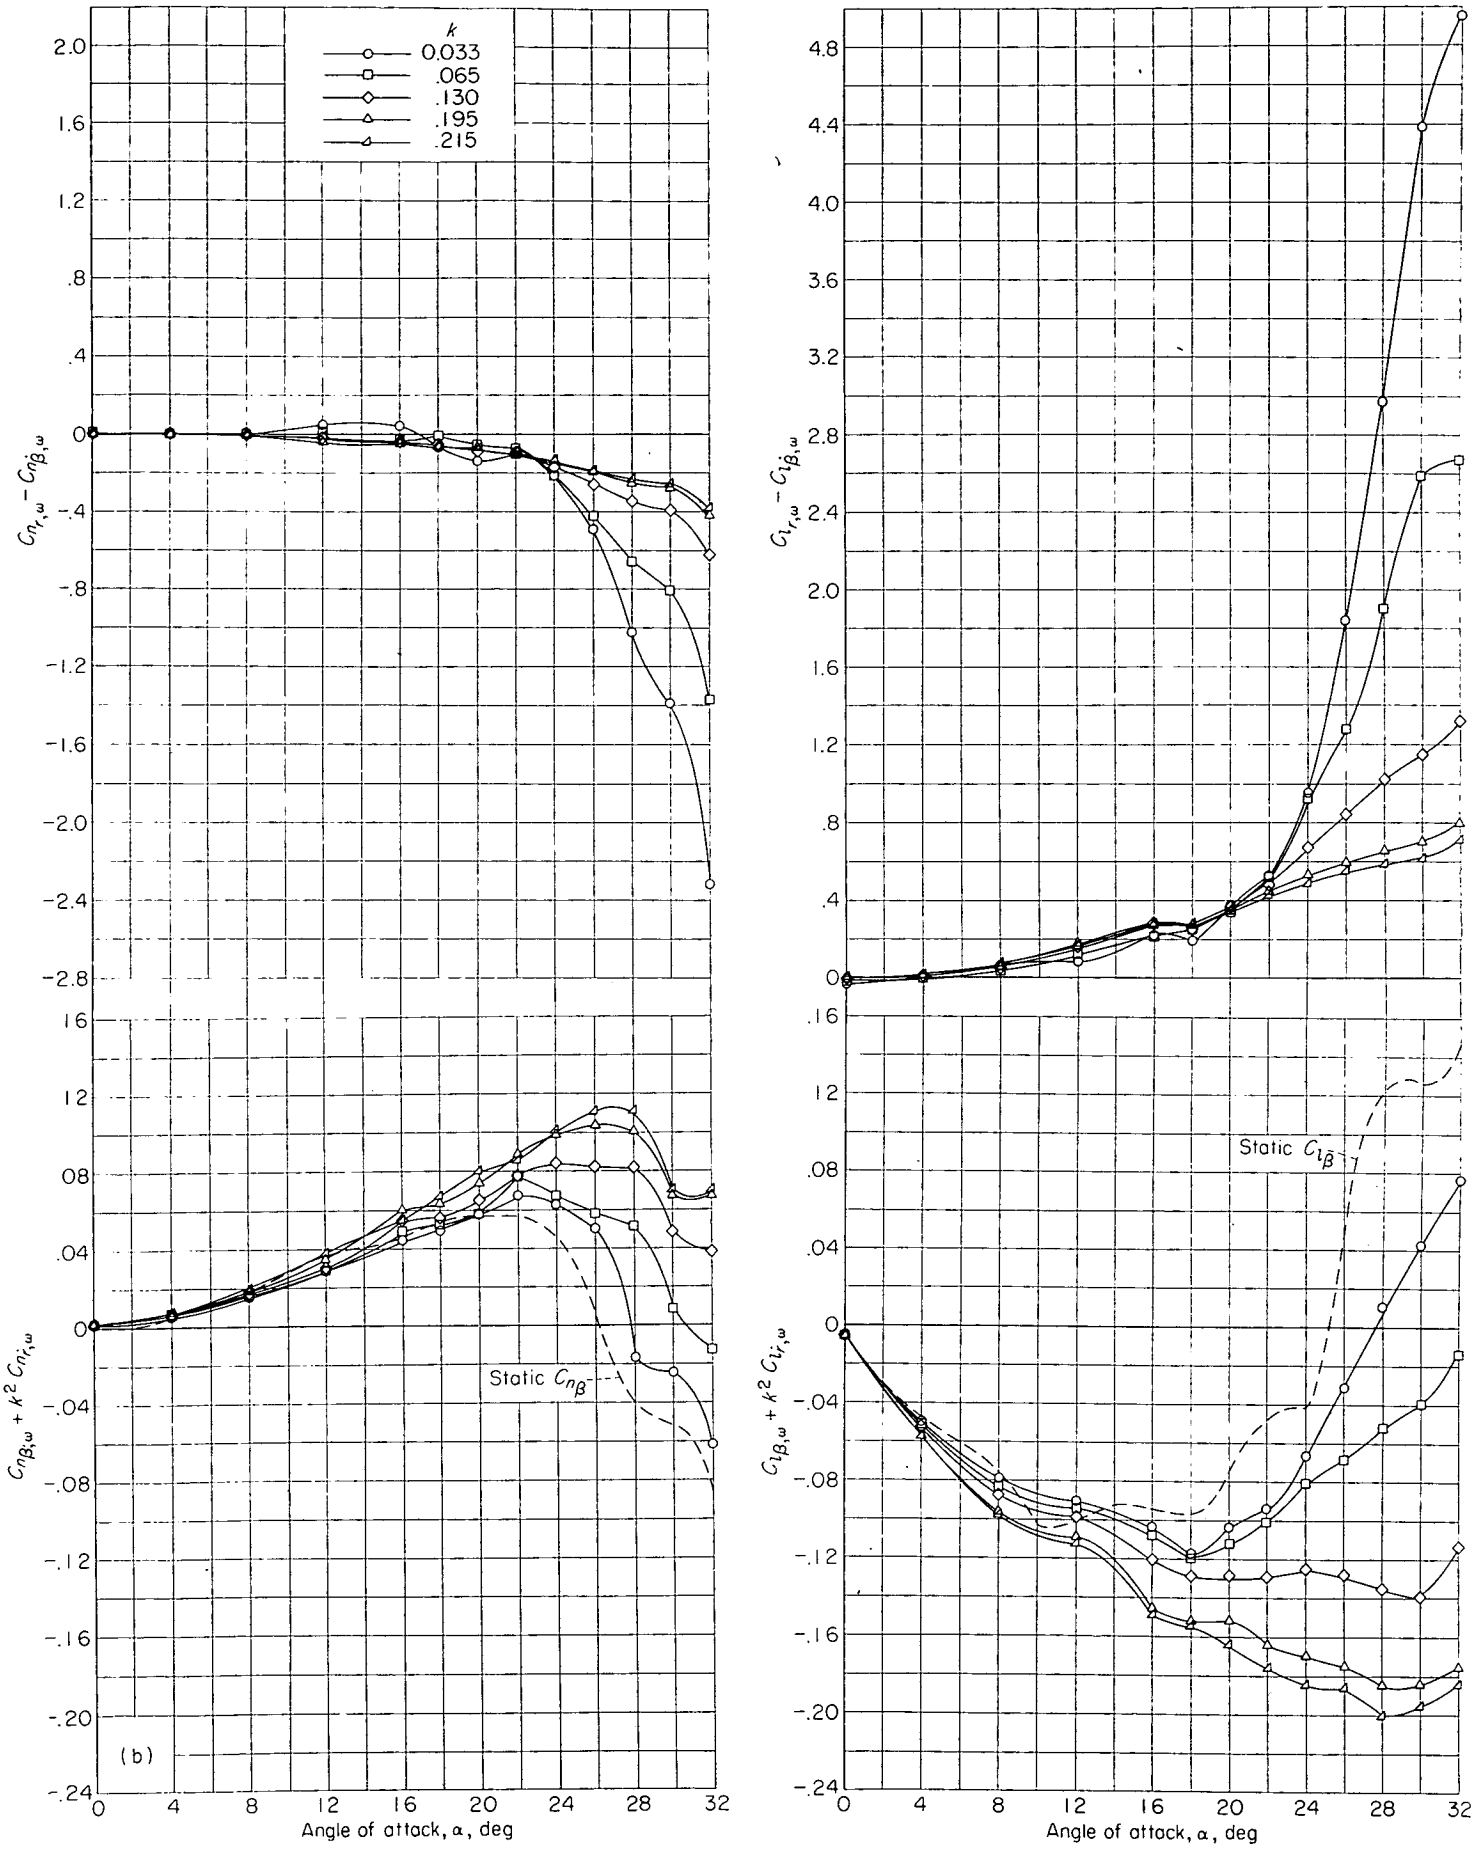
magnitude of these stability derivatives depends substantially upon the degree of separation present on the wing.

The data shown in figures 8, 9, and 10 are presented as functions of the nominal values of the uncorrected angle of attack. The same angles of attack corrected for jet-boundary effects are shown in figure 6. The largest effects of frequency on the stability derivatives take place in the high angle-of-attack range for each wing. At low angles of attack, a variation of reduced frequency had a slight effect on the magnitude of the derivatives but, at high angles of attack, frequency had a determining effect on the magnitude and, in some instances, on the sign of the derivatives. These results are, generally, in agreement with the effects of angle of attack and frequency presented in reference 3 for a set of wings of similar plan form as those tested for this investigation.



Damping in yaw.—The damping-in-yaw derivative $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$ has small negative values at low angles of attack for each of the three wings tested (figs. 8, 9, and 10). At high angles of attack, the derivative becomes large and negative for the delta and swept wings (figs. 8 and 9), with the largest negative values resulting for the lowest frequencies of oscillation. For the unswept wing (fig. 10), the derivative becomes positive at high angles of attack, with the largest positive values resulting for the lowest frequencies of oscillation. The derivatives obtained for the swept wing at its highest angle of attack are substantially smaller than those measured for the delta wing at its highest angle of attack. The absolute magnitudes of $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$ for the unswept wing are likewise much smaller than for the swept wing at the highest angle of attack for each wing.

Rolling moment due to yawing.—The parameter representative of the rolling moment due to yawing $C_{l_{r,\omega}}-C_{l_{\dot{\beta},\omega}}$ is small and generally positive at low angles of attack for the delta and swept wings (figs. 8 and 9). As the angle of attack is increased, the derivative increases positively for these wings, with the largest values being realized for the lowest frequencies of oscillation. With an increase in frequency, the derivative tends to become more nearly linear with increasing angle of attack. The magnitudes of the derivative reached for the swept wing are not so large as those for the delta wing at the highest angle of attack for each wing.

(a) $\psi_0 = \pm 2°$. (b) $\psi_0 = \pm 4°$.

FIGURE 10.—Stability derivatives measured during oscillation for unswept wing.

In the case of the unswept wing (fig. 10), $C_{l_{r,\omega}} - C_{l_{\dot{\beta},\omega}}$ is generally small and positive at low angles of attack, except for perhaps the lowest frequency of oscillation for which some small negative values were measured. At high angles of attack, $C_{l_{r,\omega}} - C_{l_{\dot{\beta},\omega}}$ for the unswept wing becomes large and negative with the magnitude of the derivative again depending upon frequency. At $\alpha = 14°$ for this wing, the variation of the derivative with angle of attack tends to reverse itself. At this angle of attack, figure 6 indicates this wing to be completely stalled.

Directional stability.—The directional-stability parameter $C_{n_{\beta,\omega}} + k^2 C_{n_{\dot{r},\omega}}$ for the delta and the swept wings is positive and increases with angle of attack at low angles of attack (figs. 8 and 9). At the high angles of attack, and for the lowest frequencies of oscillation, the derivative decreases and, for certain conditions, reverses sign and becomes negative. The higher frequencies reduce this trend toward the negative direction and make the variation of the derivative with angle of attack more nearly linear. The derivative for the unswept wing is a small positive value at low angles of attack and increases positively as the angle of attack is increased through the high range (fig. 10). Frequency has only a small effect on this derivative for this wing at high angles of attack but, again, the lower test frequencies produce the largest values of the derivative.

The values of the static derivative C_{n_β} are also shown in figures 8, 9, and 10 for comparison with the oscillatory values of $C_{n_{\beta,\omega}} + k^2 C_{n_{\dot{r},\omega}}$. These static derivatives were measured for the investigation of reference 2 at slightly higher Reynolds numbers than those for the present tests. The values of

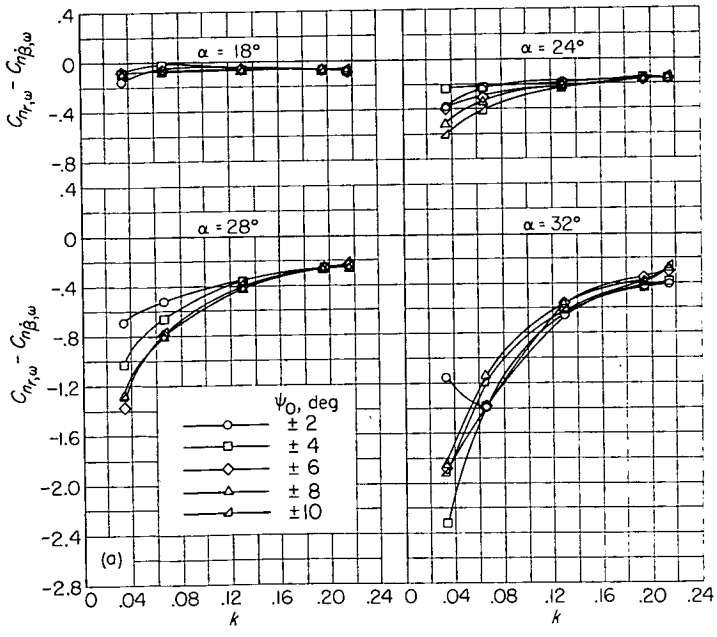
(c) $\psi_0 = \pm 6°$. (d) $\psi_0 = \pm 10°$.

FIGURE 10.—Concluded.

C_{n_β} exhibit the same trend with angle of attack as is shown by the oscillatory derivative at the lowest frequencies.

Effective dihedral.—The effective dihedral parameter $C_{l_{\beta,\omega}} + k^2 C_{l_{\dot{r},\omega}}$ is negative at zero angle of attack and increases negatively as the angle of attack is increased in the low angle-of-attack range for all three wings. For the delta and swept wings (figs. 8 and 9), the variation with angle of attack tends to reverse itself at high values of α and, for the lowest frequencies of oscillation, the reversal causes a definite reduction in the derivative and a change of sign under certain conditions. As the frequency is increased, the derivative tends to become more nearly linear with angle of attack, at least for the delta wing (fig. 8). In the case of the swept wing (fig. 9), the derivative becomes positive at high angles of attack for all frequencies with the possible exception of the highest frequency for which the derivative approaches zero magnitude at $\alpha \approx 16°$ and then increases in the negative direction at higher angles of attack. The derivative for the unswept wing continues increasing in the negative direction as the angle of attack is increased to its largest value (fig. 10). The largest negative values of the derivative were obtained for the lowest frequency of oscillation.

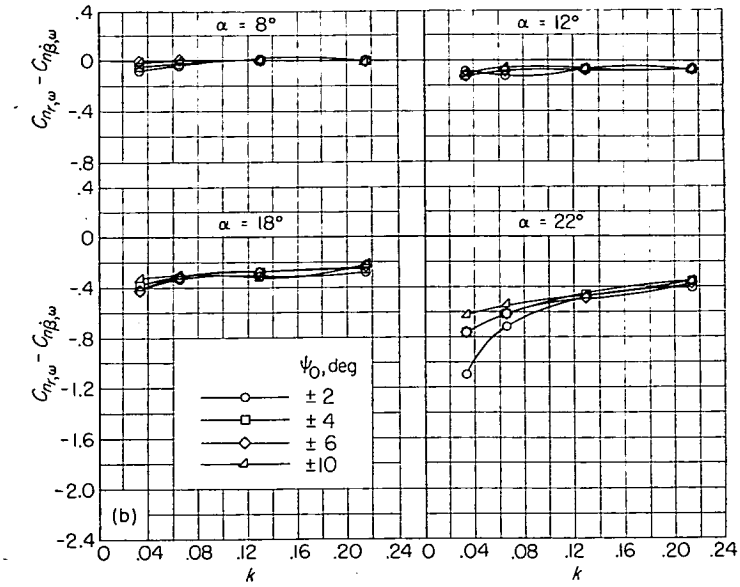
The values of the static derivative C_{l_β} from reference 2 are shown in figures 8, 9, and 10 for comparison with the oscillatory derivatives $C_{l_{\beta,\omega}} + k^2 C_{l_{\dot{r},\omega}}$. The static values of C_{l_β} had about the same variation with angle of attack as is shown by the oscillatory derivatives. The change of sign of C_{l_β} for the swept wing occurred at a somewhat higher angle of attack than it did for the oscillatory deriviatve.



Check tests, however, indicated that the proper Reynolds number would shift this angle of attack to the lower value shown by the oscillation data.

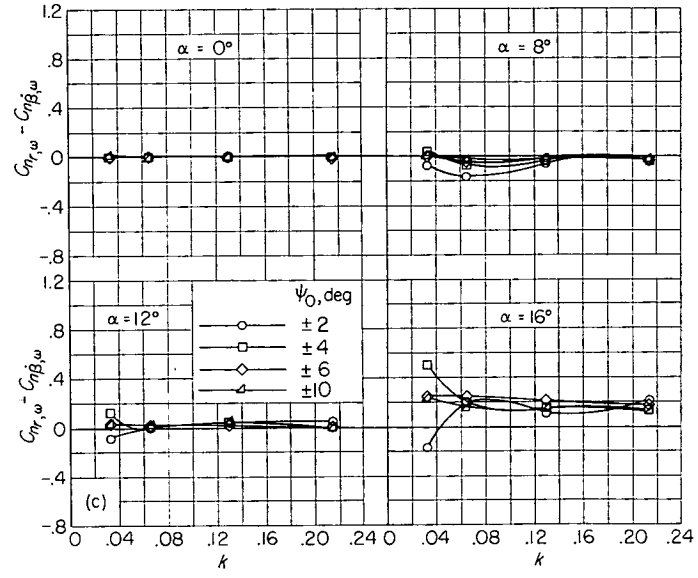
EFFECT OF FREQUENCY

Damping in yaw.—The effect of frequency on the damping in yaw $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$ is shown in figure 11 for the delta, swept, and unswept wings. These cross plots are presented for four angles of attack for each wing and for all amplitudes of oscillation. At $\alpha=18°$ for the delta wing, frequency has little or no effect on the damping (fig. 11 (a)) but, for each succeedingly higher angle of attack, the effect of frequency is to make the overall variation of $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$ greater as the angle of attack is increased. The largest values of the derivative result for the smallest values of the reduced frequency for each angle of attack. For the swept wing (fig. 11 (b)), frequency has only a slight effect on the derivative at $\alpha=18°$ and a somewhat larger effect at $\alpha=22°$. These curves show trends with frequency similar to those for the delta wing with the difference being that the frequency effects are much smaller. The results for the unswept wing in figure 11 (c), in general, indicate no frequency effects on $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$ up to the highest angle of attack at which tests were made.



Rolling moment due to yawing.—The parameter for the rolling moment due to yawing $C_{l_{r,\omega}}-C_{l_{\dot{\beta},\omega}}$ is shown as a function of reduced frequency in figure 12 for the three wings. There is little effect of frequency indicated for the delta wing at $\alpha=18°$ but, as the angle of attack increases thereafter, the variation due to frequency became greater for each successive angle of attack. The largest effects of frequency were found at the lower frequencies of oscillation for each angle of attack.

A small frequency effect on the derivative is indicated for the swept wing in figure 12 (b) at $\alpha=18°$ and a somewhat larger effect at $\alpha=22°$. These changes due to frequency

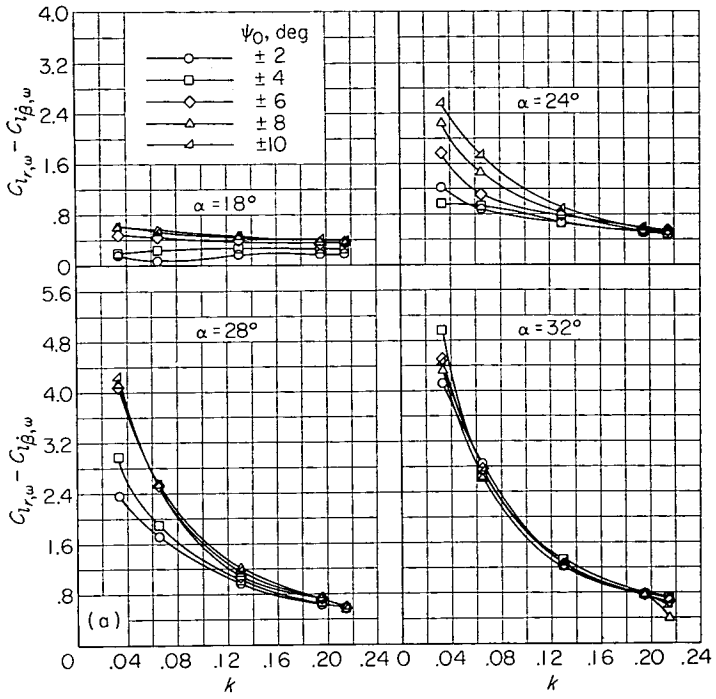


(a) Delta wing.

FIGURE 11.—The effect of reduced-frequency parameter on damping in yaw.

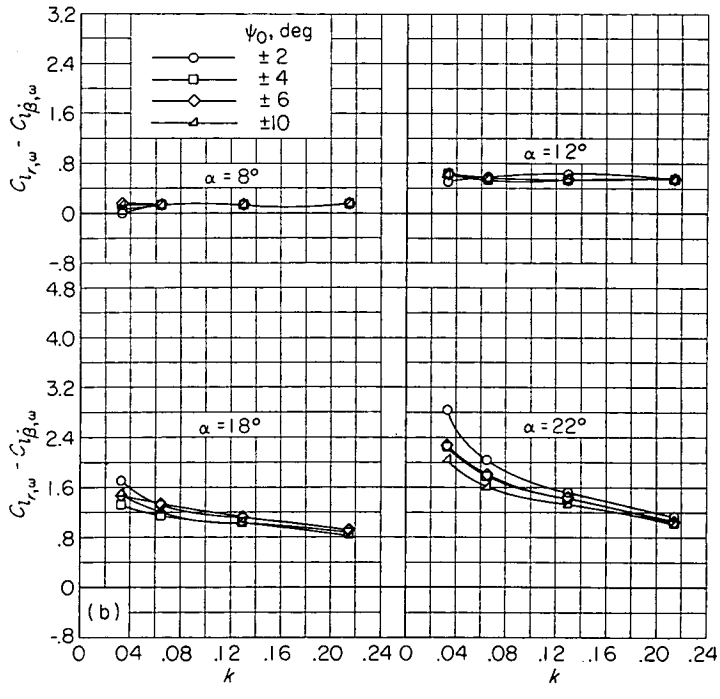
(b) Swept wing.

FIGURE 11.—Continued.



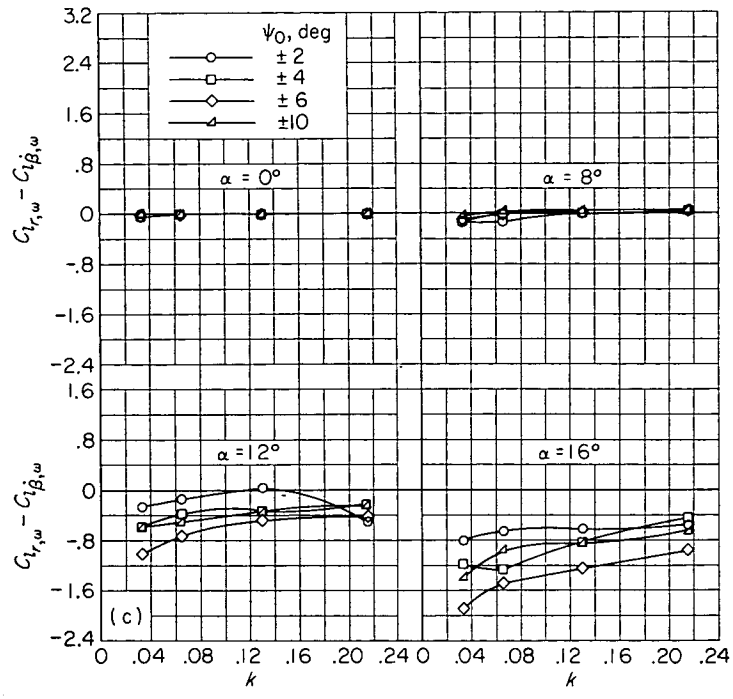
(c) Unswept wing.

FIGURE 11.—Concluded.



are similar to but are much smaller than those indicated for the delta wing in figure 12 (a). The unswept wing in figure 12 (c) exhibits values of $C_{l_{r,\omega}}-C_{l_{\dot{\beta},\omega}}$ which vary slightly with frequency at the two higher angles of attack in a manner opposite to the variations shown by the delta and swept wings. The derivative becomes less negative as the frequency is increased rather than more negative as in the plots for the delta and swept wings.

Directional stability.—The derivative $C_{n_{\beta,\omega}}+k^2C_{n_{\dot{r},\omega}}$ is shown in figure 13 as a function of the reduced frequency for four angles of attack for each of the three wings. As the frequency parameter is increased from its lowest value at $\alpha=18°$ for the delta wing (fig. 13 (a)), a slight positive increase in the derivative occurs. This effect of frequency becomes larger at the higher angles of attack until, at $\alpha=32°$, $C_{n_{\beta,\omega}}+k^2C_{n_{\dot{r},\omega}}$ may be either negative (at the lowest frequencies) or positive depending on the frequency. For



(a) Delta wing.

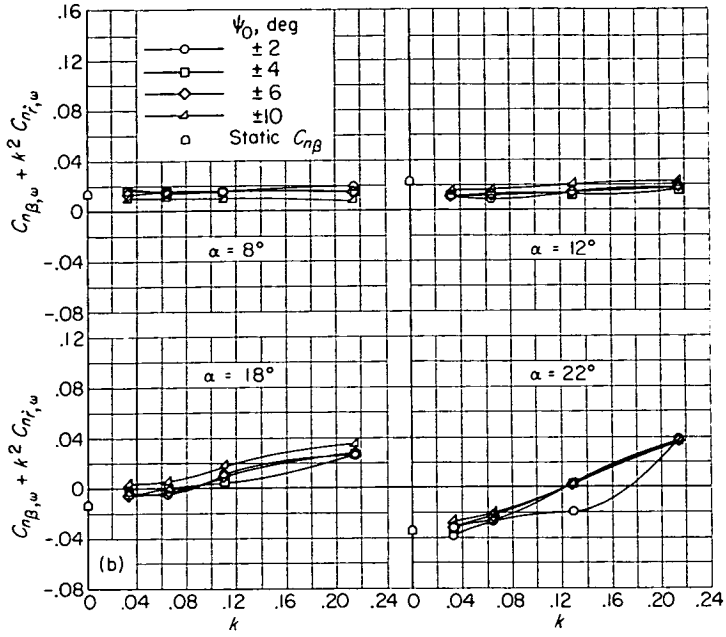
(b) Swept wing.

FIGURE 12.—Continued.

(c) Unswept wing.

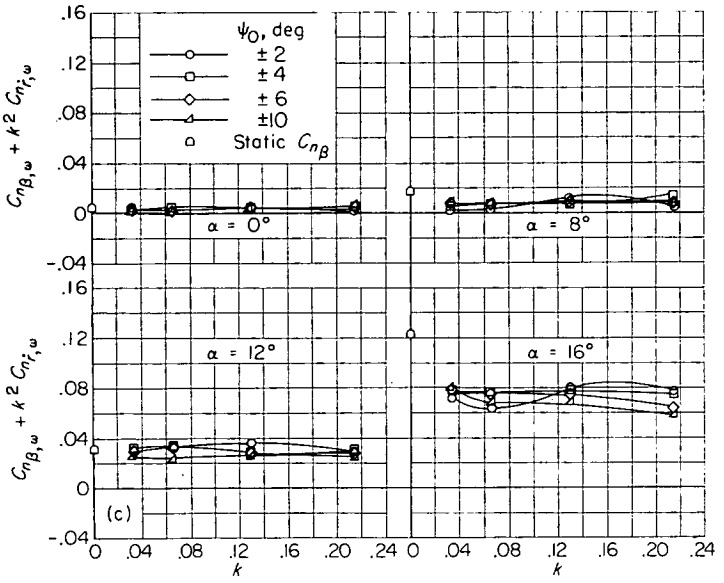
FIGURE 12.—Concluded.



(a) Delta wing.

FIGURE 13.—The effect of reduced-frequency parameter on directional-stability derivative.

the swept wing in figure 13 (b), the directional stability varies with frequency at the higher angles of attack in the manner of, but not as much as for, the delta wing. No particular effects of frequency on this derivative are indicated for the unswept wing in figure 13 (c) at any angle of attack.

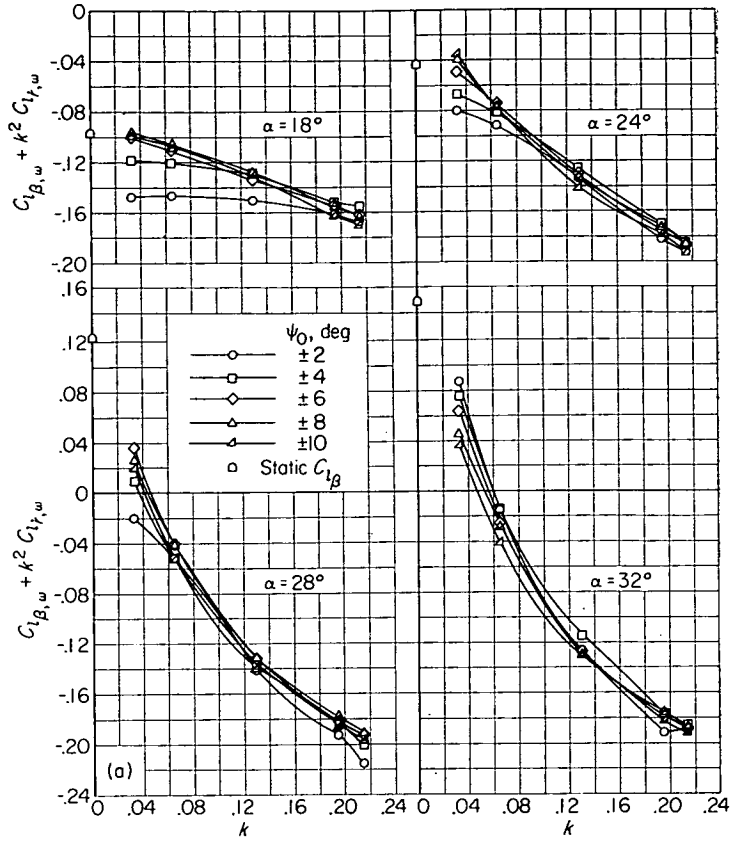


The values of the static stability derivative C_{n_β} appear in figure 13 as the value of $C_{n_{\beta,\omega}}+k^2C_{n_{\dot{r},\omega}}$ for $k=0$. In general, the variation of the oscillatory derivative with the frequency parameter approaches the static C_{n_β} for each angle of attack for all wings. This approach to zero frequency appears to be somewhat smoother for the larger amplitudes of oscillation than for the smaller amplitudes.

Effective dihedral.—The effect of the frequency parameter on $C_{l_{\beta,\omega}}+k^2C_{l_{\dot{r},\omega}}$ is shown in figure 14. The frequency effect

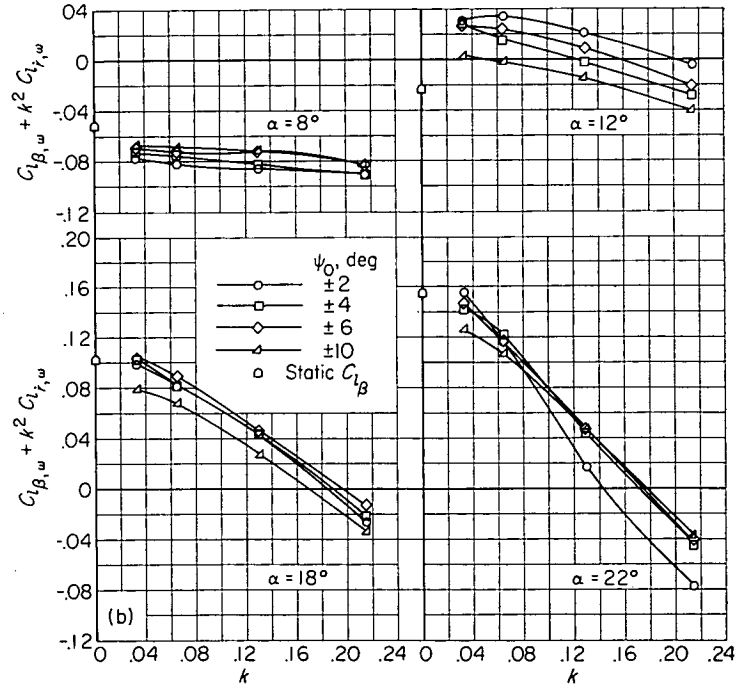
(b) Swept wing.

FIGURE 13.—Continued.



(c) Unswept wing.

FIGURE 13.—Concluded.

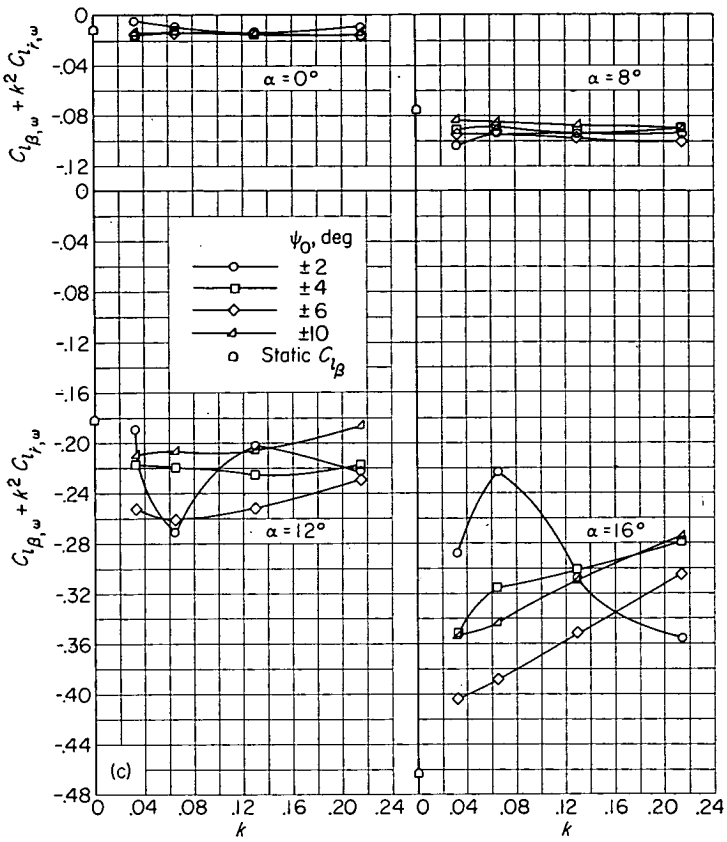


that is indicated at $\alpha=18°$ for the delta wing (fig. 14 (a)) becomes larger for each angle as the angle of attack is increased. At high frequencies of oscillation, the derivative has about the same magnitude regardless of the angle of attack but, at the low frequencies, the derivative becomes more nearly positive as the angle of attack grows larger. For the two highest angles of attack, the derivative becomes positive at the lowest frequency of oscillation.

The results for the swept wing in figure 14 (b) indicate that the effective dihedral derivative generally has higher positive values than for the delta wing but that the effect of frequency is roughly the same. The unswept wing in figure 14 (c) shows little effect of frequency except at $\alpha=16°$ where the frequency effect appears to be somewhat dependent upon amplitude of oscillation. For the largest amplitudes, the derivative becomes less negative as the frequency is

(a) Delta wing.

FIGURE 14.—The effect of reduced-frequency parameter on effective-dihedral derivative.



(b) Swept wing.

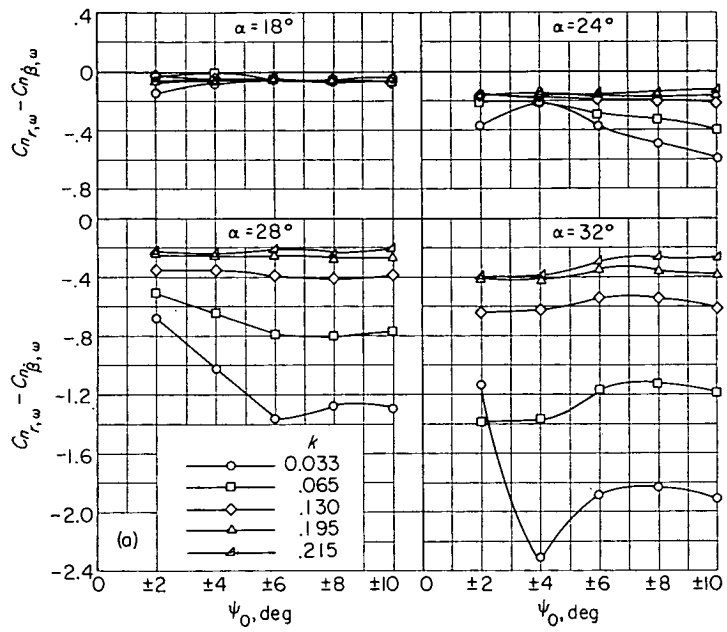
FIGURE 14.—Continued.

increased; for the smallest amplitude, however, the derivative in general becomes more negative at the higher frequencies of oscillation.

The extreme nonlinearities which occur, particularly for low-frequency and small-amplitude oscillations such as are shown for the unswept wing in figure 14 (c), may be at least

(c) Unswept wing.

FIGURE 14.—Concluded.



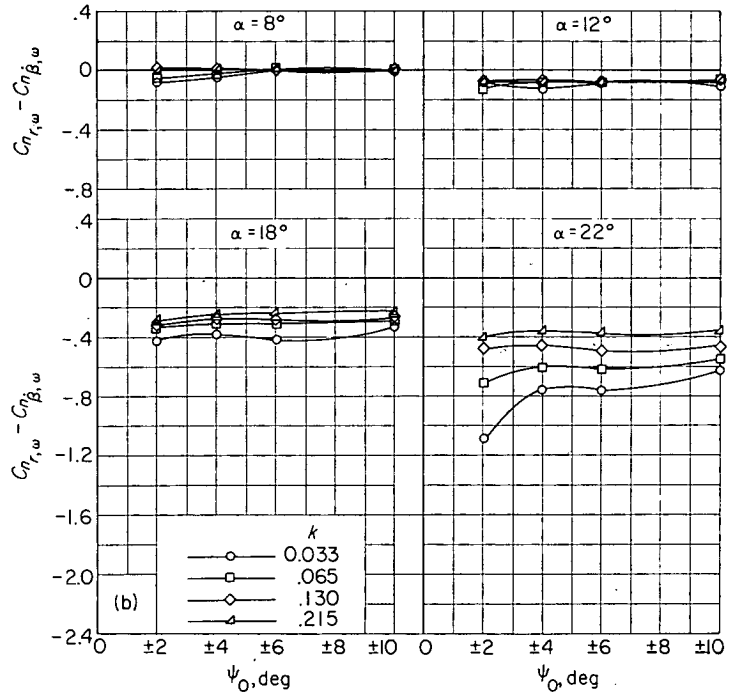
partially the fault of the data-reduction process employed. Because the measured moments were divided by the frequency and the amplitude in order to evolve the derivative form, small errors of measurement tend to be exaggerated for low-frequency and small-amplitude conditions of oscillation.

The oscillatory values of $C_{l_{\beta,\omega}}+k^2C_{l_{\dot{r},\omega}}$, in general, tend to approach the static values of C_{l_β} for all wings, especially for the higher amplitudes of oscillation. The static C_{l_β} is shown in figure 14 as the $k=0$ value of the oscillation derivative.

EFFECT OF AMPLITUDE

The effect of the variation of amplitude on the oscillatory derivatives under consideration is not as clear cut or consistent as is the effect previously discussed of the variation of frequency. The amplitude effects that appear in the data are interdependent with both frequency and angle of attack in that certain trends with amplitude may appear at one angle or one range of amplitude variation, whereas reverse trends may appear at a slightly different angle of attack or another range of the amplitude variation.

Damping in yaw.—The effects of amplitude ψ_0 on the damping-in-yaw derivative $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$ are presented in figure 15. When amplitude effects on the damping in yaw do occur, they appear to be most important at the lowest values of k. For those angles of attack at which an amplitude effect is in evidence, this effect diminishes as the k is increased and generally disappears at the highest frequencies. For example, in figure 15 (a) where $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$ is shown as a function of oscillation amplitude for the delta wing, certain effects of amplitude are indicated. For the

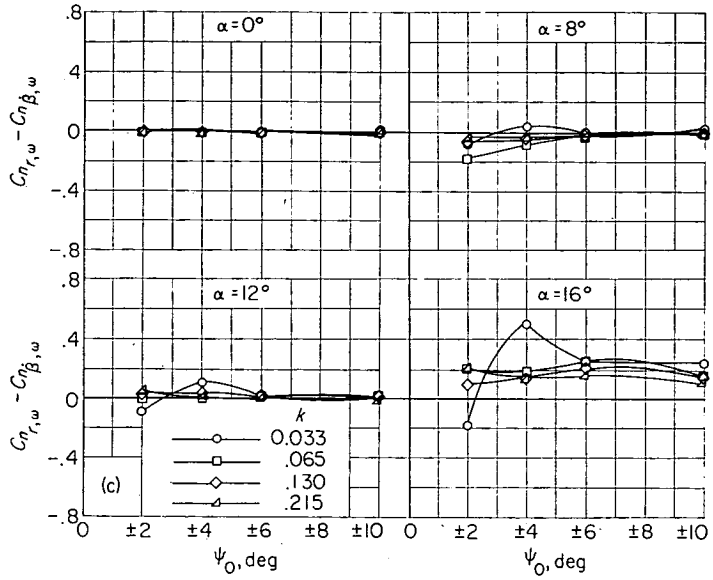


(a) Delta wing.

FIGURE 15.—The effect of amplitude on damping-in-yaw derivative.

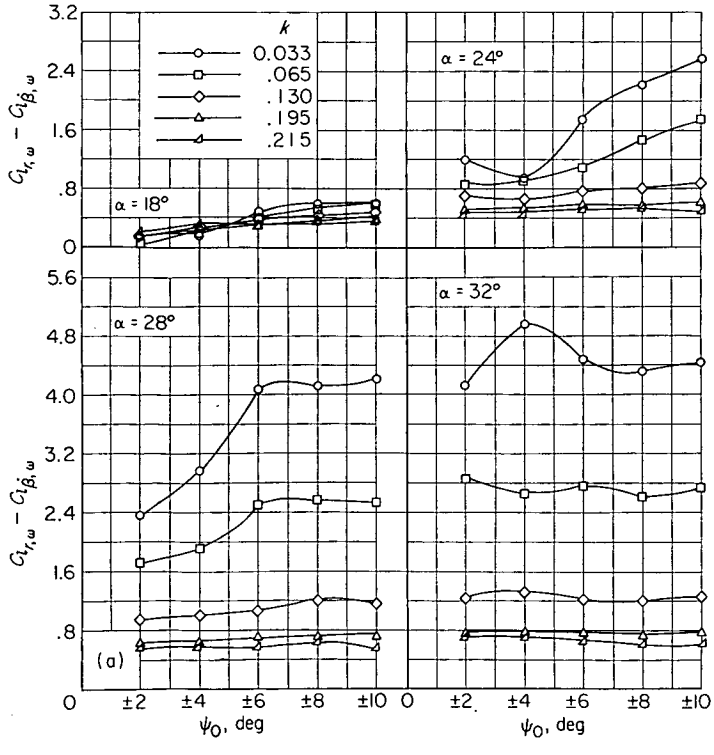
lowest frequency ($k=0.033$) at $\alpha=18°$ a slight reduction in damping takes place as the amplitude is increased from $\psi_0=2°$ to $\psi_0=6°$, but as the amplitude is increased further the damping remains constant. At $\alpha=24°$ for the lowest frequency, the damping increases as the amplitude becomes larger than 4°, whereas at $\alpha=28°$ and $\alpha=32°$ the damping generally increases at low amplitudes but decreases and then levels off at the larger amplitudes. Higher frequencies of oscillation tend to diminish the amplitude effect until at the highest frequency the damping shows a variation with amplitude only at $\alpha=32°$, and this effect is small.

The swept wing in figure 15 (b) exhibits an effect of amplitude on the damping only at $\alpha=22°$ for the lower frequencies



(b) Swept wing.

FIGURE 15.—Continued.



of oscillation. The unswept wing in figure 15 (c) shows some effects at low frequencies and small amplitudes of oscillation.

Rolling moment due to yawing.—The effects of the oscillation amplitude ψ_0 on $C_{l_{r,\omega}}-C_{l_{\dot{\beta},\omega}}$, which are indicated in figure 16, are similar to those described for $C_{n_{r,\omega}}-C_{n_{\dot{\beta},\omega}}$. For the delta wing at $\alpha=18°$, the derivative has higher positive values with increased amplitude, although as the frequency is increased, this effect is diminished. At $\alpha=24°$, the greatest change in the derivative takes place at the large amplitudes and the lowest frequency, whereas at $\alpha=28°$, the greatest change takes place at the small amplitudes and the lowest frequency.

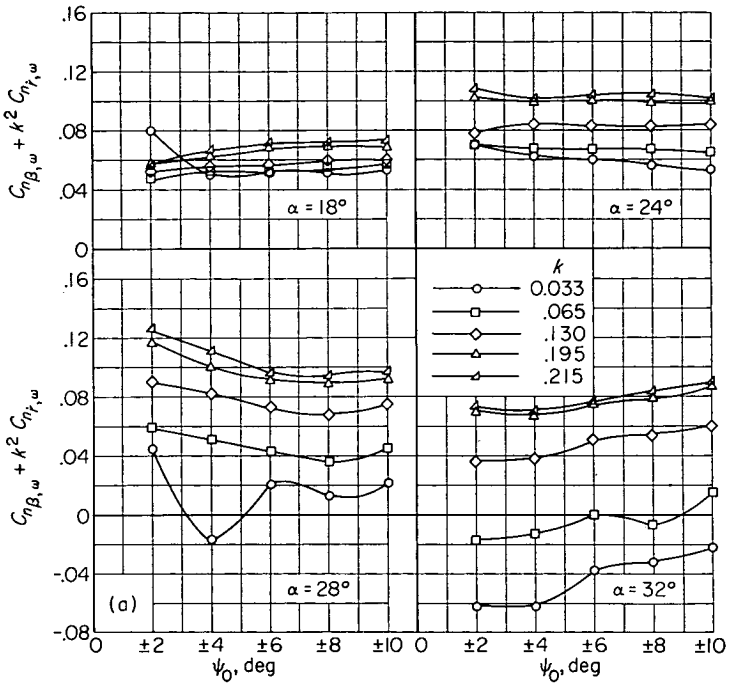

FIGURE 16.—Continued.

(c) Unswept wing.

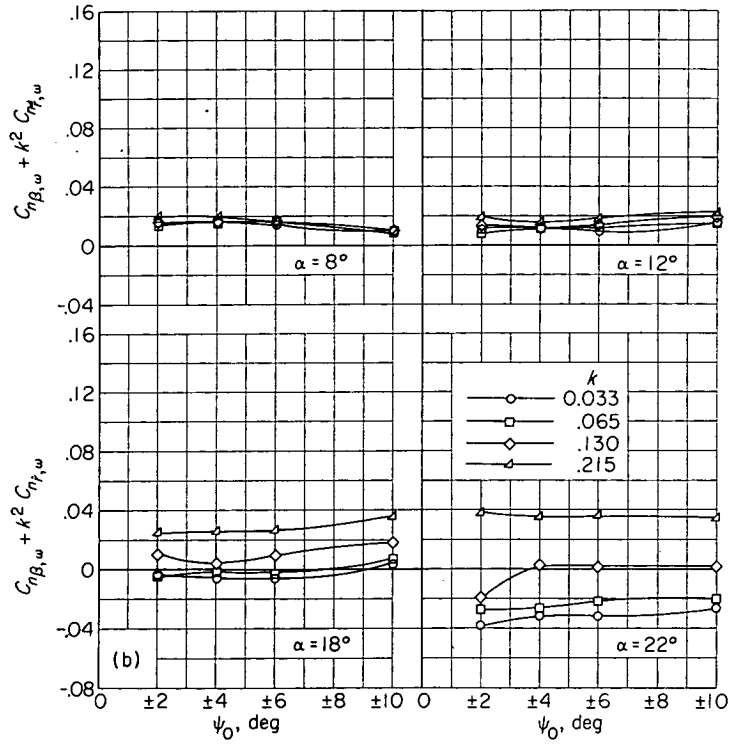

FIGURE 16.—Concluded.

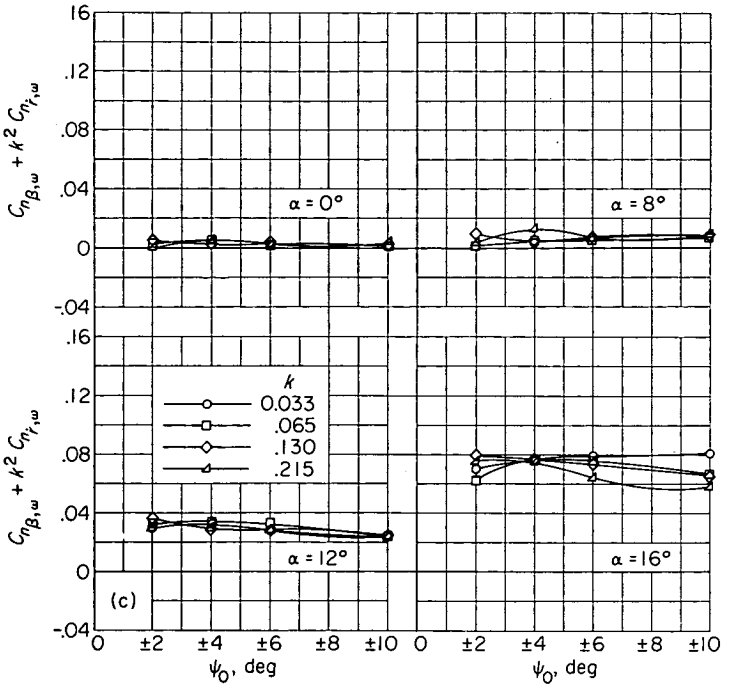
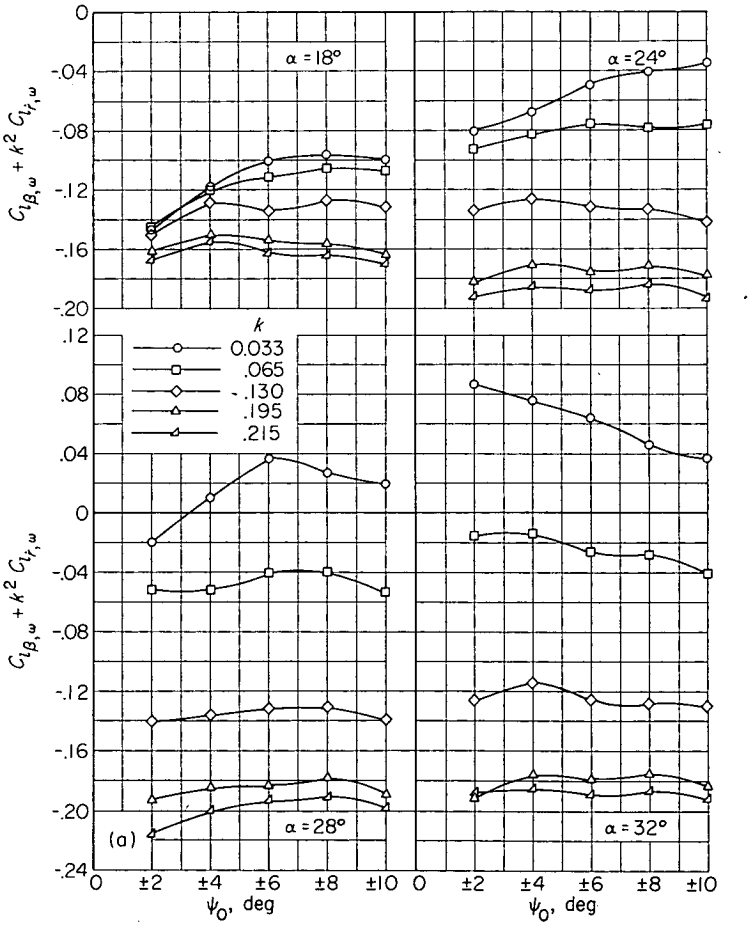
Directional stability.—The variation of the directional-stability derivative $C_{n_{\beta,\omega}}+k^2C_{n_{\dot{r},\omega}}$ with amplitude is shown in figure 17. The delta wing (fig. 17 (a)) exhibits amplitude effects for all frequencies of oscillation at $\alpha=28°$ and $\alpha=32°$ which are about equal in magnitude but opposite in direction. At $\alpha=28°$, an increase in amplitude generally reduces the derivative, whereas at $\alpha=32°$, an increase in amplitude increases the positive values of the derivative.



(a) Delta wing.

FIGURE 17.—The effect of amplitude on directional-stability derivative.

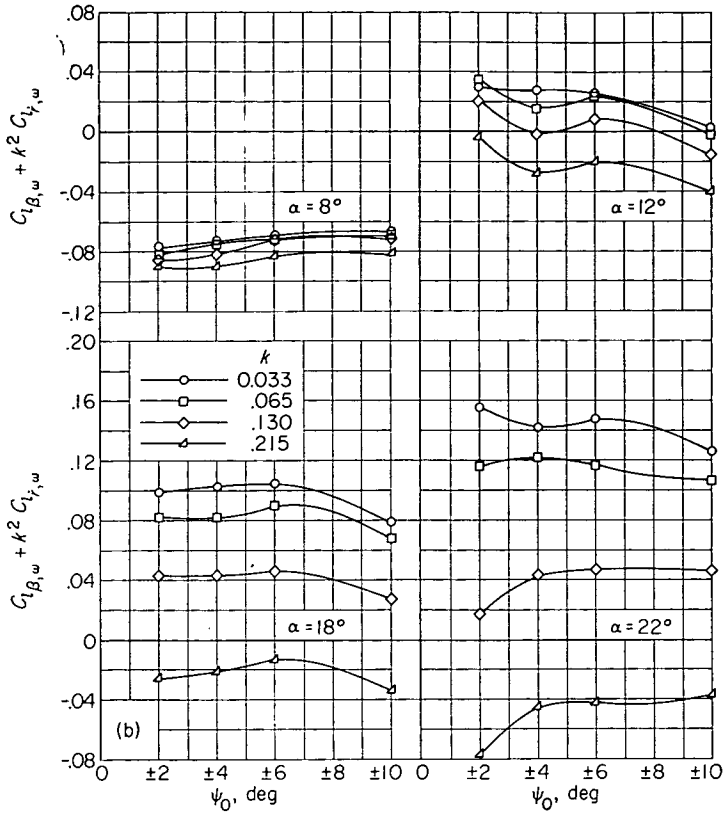


(b) Swept wing.

FIGURE 17.—Continued.

(c) Unswept wing.

FIGURE 17.—Concluded.

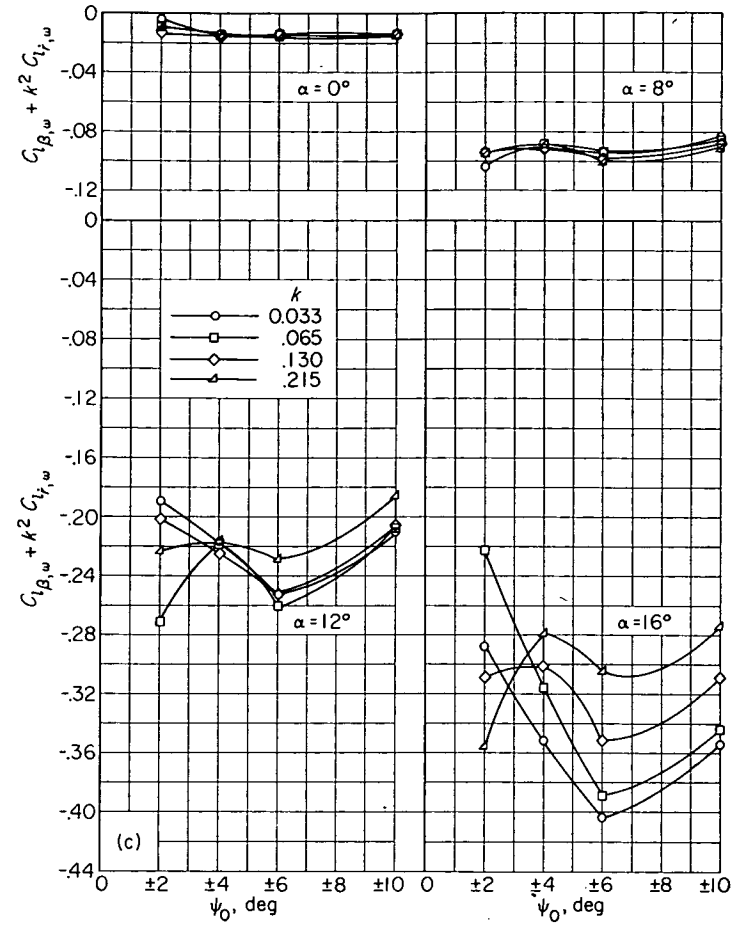


(a) Delta wing.

FIGURE 18.—The effect of amplitude on effective-dihedral derivative.

For the swept wing at $\alpha=22°$ (fig. 17 (b)), an increase of amplitude gives slightly higher positive values of the derivative for the lowest frequency; for the highest frequency a reverse effect, although slight, is indicated.

Effective dihedral.—The effect of amplitude on the effective-dihedral parameter $C_{l_{\beta,\omega}}+k^2C_{l_{\dot{r},\omega}}$ is shown in figure 18. For the delta wing at $\alpha=18°$, and for the lowest frequency of oscillation, an increase in amplitude reduces the magnitude of the derivative at low amplitudes, whereas at the higher amplitudes, the magnitude of the derivative remains about constant with amplitude. At $\alpha=24°$, for the lowest frequency ($k=0.033$), increasing the amplitude reduces the derivative. A reversal in the variation with amplitude is



(b) Swept wing.
FIGURE 18.—Continued.

indicated at $\alpha=28°$ for this frequency; and at $\alpha=32°$ the derivative increases in magnitude throughout the amplitude range.

The data for the swept wing at $\alpha=22°$ (fig. 18 (b)) shows a reversal in trend with amplitude between the lowest and highest frequencies of oscillation. The derivative for the unswept wing at the higher angles of attack (fig. 18 (c)) exhibits large variations due to amplitude and reversals in trend between the low and high amplitudes of oscillation. These variations with amplitude are strongly dependent upon frequency.

COMPARISON OF EXPERIMENTAL DERIVATIVES AND ADDITION OF COMPONENT DERIVATIVES

The derivatives $C_{n_{r,\omega}}$, $C_{n_{\dot{r},\omega}}$, $C_{l_{r,\omega}}$, and $C_{l_{\dot{r},\omega}}$ were measured at $k=0.22$ and at an amplitude $\psi_0=8°$ for the investigation of reference 1. The derivatives $C_{n_{\beta,\omega}}$, $C_{n_{\dot{\beta},\omega}}$, $C_{l_{\beta,\omega}}$, and $C_{l_{\dot{\beta},\omega}}$ were determined by a series of tests similar to those of reference 2. The latter were forced-oscillation tests with $k=0.22$ and an amplitude of sideslip $\beta_0=6°$. These individual derivatives, and the appropriate algebraic additions thereof, are compared in figures 19 to 22 with the corresponding combination derivatives measured in the present investigation for $k=0.22$ and $\psi_0=6°$. In general, the comparisons are good. In figure 19, the experimentally combined damping-in-yaw derivative for the delta wing is just a little smaller than the sum of the individual derivatives through the angle-of-attack range. The comparisons for the swept and unswept wings are also generally in good agreement. Figure 19 indicates for these wings that the $C_{n_{\dot{\beta},\omega}}$ derivative

(c) Unswept wing.
FIGURE 18.—Concluded.

is larger in absolute magnitude than the $C_{n_{r,\omega}}$ derivative at high angles of attack and therefore is the major contributor to the damping in yaw as determined in these tests.

For the delta wing, the algebraic sum of the individual derivatives $C_{l_{r,\omega}}$ and $C_{l_{\dot{\beta},\omega}}$ (fig. 20) appears to have somewhat higher positive values by an almost constant increment through the angle-of-attack range than the experimentally obtained combination derivative. For the swept wing, the added derivatives also have higher positive values than the experimental derivatives up to $\alpha=16°$, and for the unswept wing at all angles of attack greater than zero. Figure 20 indicates that, at least for the delta and swept wings, $C_{l_{\dot{\beta},\omega}}$ contributes a greater portion to the combination derivative than does $C_{l_{r,\omega}}$.

The algebraically added derivatives $C_{n_{\beta,\omega}}$ and $k^2C_{n_{\dot{r},\omega}}$ are presented in figure 21 as a function of angle of attack and are compared with the experimental combination derivatives. Although $C_{n_{\dot{r},\omega}}$ can have large magnitudes of its own, as demonstrated by the investigation of reference 1, the multiplication of this derivative by k^2 would be expected to reduce the significance of this term in the determination of the directional stability parameter except for, perhaps, extremely large values of the reduced frequency or the derivative $C_{n_{\dot{r},\omega}}$. Figure 21 shows this $k^2C_{n_{\dot{r},\omega}}$ contribution to be small relative to the large $C_{n_{\beta,\omega}}$ contributions for the delta and the

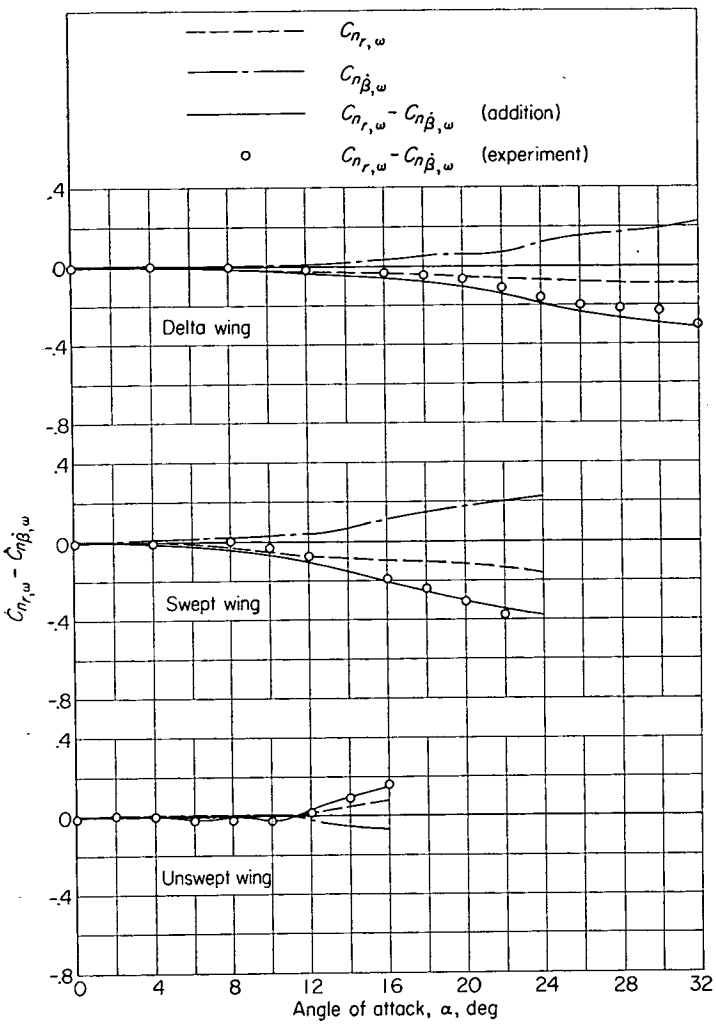


FIGURE 19.—Comparison of the component and the combination derivatives making up the damping in yaw. $k=0.22$; $\psi_0=\pm 6°$ or $\pm 8°$.

unswept wings at high angles of attack. The swept wing has relatively small values of $C_{n_{\beta,\omega}}$ which are of about the same magnitude as $k^2C_{n_{\dot r,\omega}}$ for most of the high-angle-of-attack range.

The contribution of $k^2C_{l_{\dot r,\omega}}$ to the effective dihedral derivative is also small relative to $C_{l_{\beta,\omega}}$ for the delta and the unswept wings (fig. 22). At lower frequencies of oscillation, the $k^2C_{l_{\dot r,\omega}}$ contribution to the derivative would be of less significance still, since the k^2 factor would reduce to relative unimportance even $C_{l_{\dot r,\omega}}$ derivatives of very large magnitude as k approached zero. The nonlinear variation with angle of attack shown by $C_{l_{\beta,\omega}}+k^2C_{l_{\dot r,\omega}}$ for the swept wing can be attributed to the $C_{l_{\beta,\omega}}$ portion of the derivative.

The particular model yawing motion employed for these tests was such that the amplitude of the sideslipping motion was the negative of the amplitude of the yawing motion so that $\beta_0/\psi_0=-1$. Airplane lateral motions may be made up of any ratio of these amplitudes, although motions wherein $\beta_0/\psi_0\approx -1$ occur quite frequently. When this ratio is close to -1 and when the phase relationship between the separate motions is small, then the stability derivatives may be combined in the airplane lateral equations of motion in the forms

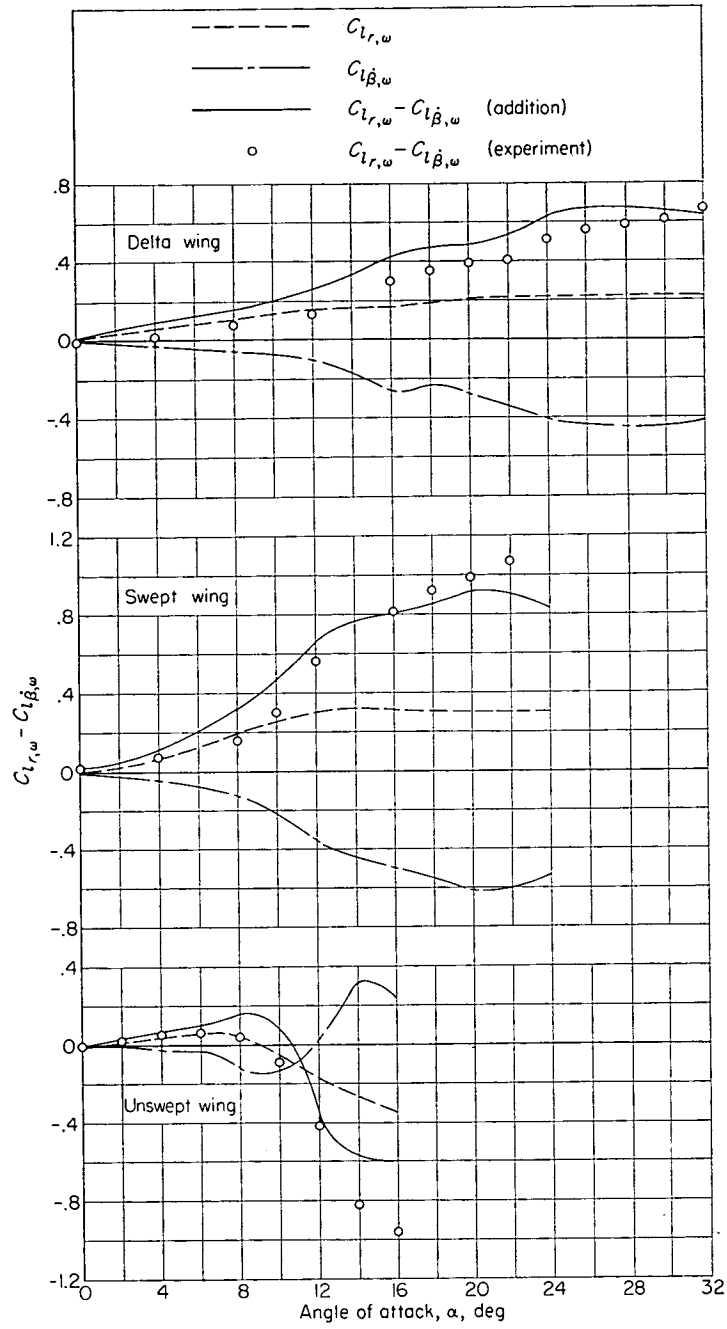

FIGURE 20.—Comparison of the component and the combination derivatives making up the rolling moment due to yawing. $k=0.22$; $\psi_0=\pm 6°$ or $\pm 8°$.

used herein. The resulting agreement between the addition of the separately determined β and ψ derivatives and the combination derivatives measured herein indicates that for $\beta_0/\psi_0=-1$, at least, and for $k=0.22$, the aerodynamic phenomena responsible for the individual derivatives are linear to a large degree in that the individual derivatives are approximately additive. For low values of the reduced frequency, however, it is possible that the individual derivatives may not add up quite as well as at the high reduced frequency because of the large effects of frequency and amplitude which exist at low frequencies and which indicate lessening linearity.

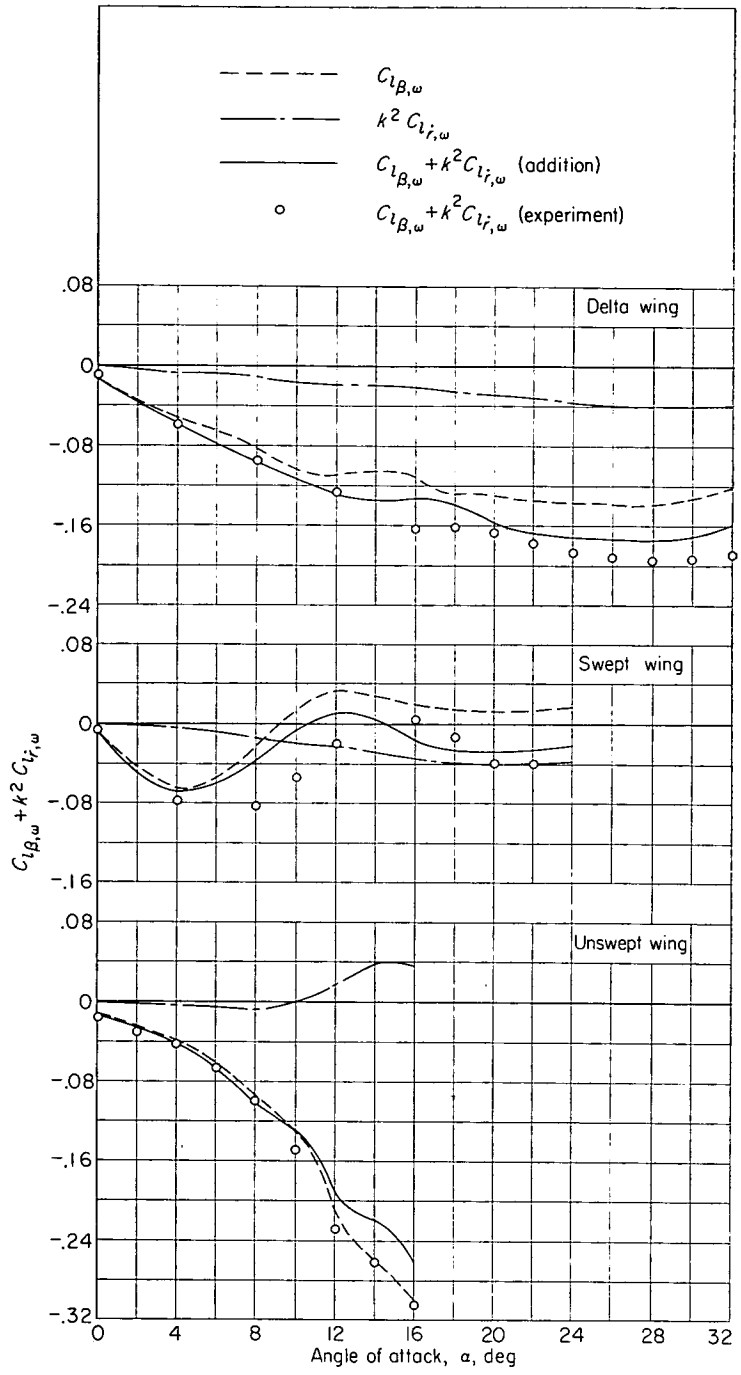

FIGURE 22.—Comparison of the component and the combination derivatives making up the effective dihedral. $k=0.22$; $\psi_0=\pm 6°$ or $\pm 8°$.

CONCLUSIONS

A delta wing, a swept wing, and an unswept wing were oscillated in yaw about their quarter-chord points in order to determine the separate effects of frequency and amplitude on the combination lateral stability derivatives resulting from this motion. The results of this investigation indicate the following conclusions:

1. The frequency of oscillation had a determining influence on the lateral stability derivatives for the delta wing at high angles of attack. The largest changes in the variations of the derivatives with angle of attack took place for the lowest frequencies of oscillation; as the frequency increased, the effects of frequency became smaller, and the curves of the derivatives plotted against angle of attack became more linear. Similar effects of frequency, but to a smaller extent, were shown for the derivatives of the swept wing. The derivatives for the unswept wing were apparently influenced only slightly by frequency.

2. The effect of amplitude of oscillation on the lateral stability derivatives appears to depend substantially upon the angle of attack of the wing and upon the frequency of oscillation. Some large effects of amplitude were shown on

the derivatives for the delta wing at high angles of attack and for the lowest frequency of oscillation. As the frequency was increased to its highest value, these effects of amplitude, in general, disappeared. Similar amplitude effects were indicated for the swept wing to a lesser degree, but, in general, did not appear for the unswept wing.

3. A comparison of the present results with the results of previous investigations for a corresponding frequency and amplitude indicated that the derivatives taken with respect to sideslip angular velocity $\dot{\beta}$ are somewhat larger in absolute magnitude than the derivatives taken with respect to yawing angular velocity r, with which they are generally combined. The derivatives taken with respect to yawing angular acceleration $\dot{r}$, although of large magnitude themselves, lose significance when combined with the derivatives taken with respect to sideslip β because of their multiplication by the square of the reduced-frequency parameter. Hence, in the range of frequencies being considered, the in-phase stability derivatives are determined primarily by the β derivatives. As the frequency of oscillation became smaller, the combination in-phase derivatives approached the static (zero frequency) β derivatives.

4. The algebraic addition of the component derivatives gave results which were generally in good agreement with the derivatives obtained in combination for the present investigation. These results indicate that the aerodynamic phenomena responsible for these derivatives are linear to a large degree.

REPORT 1358

ON FLOW OF ELECTRICALLY CONDUCTING FLUIDS OVER A FLAT PLATE IN THE PRESENCE OF A TRANSVERSE MAGNETIC FIELD [1]

By VERNON J. ROSSOW

SUMMARY

The use of a magnetic field to control the motion of electrically conducting fluids is studied. The incompressible boundary-layer solutions are found for flow over a flat plate when the magnetic field is fixed relative to the plate or to the fluid. The equations are integrated numerically for the effect of the transverse magnetic field on the velocity and temperature profiles, and hence, the skin friction and rate of heat transfer.

It is concluded that the skin friction and the heat-transfer rate are reduced when the transverse magnetic field is fixed relative to the plate and increased when fixed relative to the fluid. The total drag is increased in all of the cases studied.

INTRODUCTION

It has been said that a fluid at a very high temperature is like a universal solvent which cannot be contained. A possible method of containing this fluid is suggested when it is noted that at such a high temperature it would surely contain ions and quite probably also free electrons. The fluid would then be an electrical conductor. The invisible hand of electrical and magnetic fields can then be used to induce forces on the fluid such that it is prevented from coming in direct contact with a wall which it would dissolve.

A somewhat similar technique has been in use for some time in the metal purification industry. It employs a high-frequency magnetic field which causes eddy currents in a lump of molten metal which in turn react with the imposed magnetic field. The metal is thereby suspended in space if the imposed magnetic field is made strong enough.

Another example is the so-called "perhapsatron" described briefly in reference 1. A gas in a doughnut shaped container is heated to a high temperature by an electrical current discharge. Through the use of the interaction of the resulting ion current and a magnetic field, the hot gas is prevented from coming in contact with the surface of the vessel. An application of similar principles was used in thermonuclear fusion experiments in the Soviet Union. The techniques and results described very briefly in reference 2 indicate that it was possible to keep the hot fluid from the walls and to concentrate the hot gases quickly so as to generate a focusing shock wave.

These examples indicate the possibilities which may be realized through the use of a magnetic-field force on a flowing conducting fluid. A number of situations exist in aerodynamics wherein a magnetic or electrical field might be used to alleviate high convective heat-transfer rates to a wall. Such problems arise in the flow of air in the boundary layer and in the vicinity of stagnation regions of an aircraft moving at very high speeds. If the velocity is high enough the air is ionized and, therefore, electrically conducting. See, for example, references 3 and 4. Other examples are those associated with the flow of the combustion products (which are hot and generally electrically conducting, refs. 5 through 7) in the propulsion units of aircraft.

The extent to which a given heating problem can be alleviated is as yet difficult to determine. It would be well if a few theoretical results were available to evaluate the effect of a magnetic field on the drag and heat-transfer rate. An attempt to include all the aerodynamic features of the flow of air over or inside an aircraft plus the magneto-hydrodynamic (or more correctly, magneto-aerodynamic) effects would render the problem so complicated as to make its solution difficult if not impossible. It is felt that a few simple basic theoretical solutions would point out the advantages or disadvantages and yield a rough estimate of the various quantities entering the problem. It is the purpose of this report to present the results of several such solutions which, it is hoped, will extend the information already available so that such estimates can be made. Several applications of the results are indicated.

PRINCIPAL SYMBOLS

HISTORICAL REVIEW OF MAGNETO-HYDRODYNAMICS

The earliest known published works treating a problem in the flow of an electrically conducting fluid through a magnetic field are those of Hartmann and of Hartmann and Lazarus in references 8 and 9. Since that time a number of theoretical and experimental studies have been carried out. Some of these pertain to the flow of a conducting fluid but a larger number relate to the dynamics of ionized clouds or stars. No attempt will be made here to include a complete discussion of the latter group. However, much can be learned by studying the papers on the flow of conducting fluids. These papers will be divided into several groups according to the type of problem treated.

1. Flow in a channel (refs. 8 through 19).
2. Flow about bodies of various shapes (refs. 20 through 22).
3. Related papers on astronomy (refs. 23 through 26).

The various papers will be reviewed briefly on a group basis and reference to particular papers given only in special instances.

FLOW IN CHANNEL

Following his invention of the electromagnetic pump [2] in 1918, Hartmann, reference 8, developed equations which describe the steady-state flow inside a channel in the presence of a magnetic field or a magnetic and electrical field. Interest was stimulated in problems of this type when it was found in reference 9 that a turbulent stream could be stabilized to the extent that it could be forced to return to a laminar flow. Such a sequence of events is opposite to the usual form of transition when a magnetic field is not present. Further investigations by other authors, references 10 through 19, substantiated these results and led to the introduction of terms such as "magnetic viscosity," $\lambda=\frac{1}{4\pi\sigma\overline{\mu}}$, "magnetic Hartmann number," $\overline{M}=Bl\sqrt{\frac{\sigma}{\mu}}$ and $Q=\frac{\sigma B^2 l}{\rho U}$.

A rigidity of the fluid is brought about by a coplanar magnetic field so that stabilization is achieved because the conducting fluid experiences a force which resists the motion across the magnetic lines of force (ref. 13). For example, if the main fluid flow direction is parallel to the magnetic lines of force, no interaction takes place unless some deviation or instability arises. In this event, a restraining force will be induced which is proportional and opposite to the velocity component perpendicular to the lines of force, tending to damp out the initial instability.

When the magnetic field is perpendicular to the flow direction, a change is brought about in the velocity distribution. This may make the fluid flow more stable or unstable to transition to turbulence. In the case of flow of an electrically conducting fluid through a transverse magnetic field in a two-dimensional channel (refs. 9 and 14), the change in the velocity profile had a very favorable effect on transition. Such is not always expected to be the case in other flow problems.

[2] Electromagnetic pumps are used in atomic energy plants to transfer radioactive solutions from one place to another (e. g., see p. 32 of Atomic Power—a Scientific American book, Simon and Schuster Inc., New York, 1955).

These two techniques which increase the stability of fluid flowing in a two-dimensional channel were studied theoretically in references 13 and 14. The transition boundaries are given in graphical form for a range of the magnetic parameter. It was observed that a considerable increase in laminar run could be achieved at the higher values of the magnetic parameter.

FLOW ABOUT BODIES OF VARIOUS SHAPES

The papers describing the external flow of a conducting fluid about bodies are small in number. The three references listed, 20 through 22, describe the flow of a conducting fluid around a circular cylinder and a sphere in the presence of a magnetic field; the third paper treats the stability of the flow between rotating cylinders. Streamlines are shown in the first two cases and the stability boundary for the latter case. Problems in this category are naturally more difficult than the unidirectional channel flow problems discussed in the previous section.

RELATED PAPERS ON ASTRONOMY

A need for understanding the motion of electrically conducting fluids (ionized clouds) has been felt by astronomers for some time. The dimensions and quantities considered are generally not reproducible in the laboratory or in the earth's atmosphere; however, some of the equations and results may be applied to aerodynamic problems.

In reference 23, Batchelor investigated the possibility of spontaneous magnetic fields arising in a conducting medium as a result of turbulence. He found that unless $4\pi\bar{\mu}\sigma\nu > 1$ such fields cannot occur. In all foreseeable problems in aerodynamics $4\pi\bar{\mu}\sigma\nu$ is many orders of magnitude less than 1, ruling out spontaneous magnetic fields in a fluid due to turbulence.

The manner and velocity at which pressure waves are propagated in an ionized fluid and other cosmic problems are treated in references 24 through 26. The results of these studies on wave propagation may be useful in studying interference problems on high-velocity aircraft.

MAGNETO-AERODYNAMIC EQUATIONS

The equations which describe the flow of an electrically conducting fluid in the presence of magnetic and electrical fields will now be discussed. The equations are simplified to the extent that the flow is assumed to be incompressible and to have constant properties (C_p, μ, k) throughout the flow field. In all cases except one, the electrical conductivity of the fluid is assumed to be constant.

MOMENTUM-TRANSPORT EQUATIONS

The momentum-transport equations for the flow of a viscous incompressible fluid consist of a combination of the force terms arising from the excess charge density θ, and induced magnetic effect due to the motion of the conducting fluid through magnetic lines of force (see, e. g., refs. 23 and 27) and the usual Navier-Stokes relations (see, e. g., ref. 28). In equation form, these force terms are,

$$\vec{F}=\theta\vec{E}+\vec{j}\times\vec{B}$$

where the term $\theta\vec{E}$ results from the electrostatic force on the excess charges due to the presence of an imposed electric field $\vec{E}$. The second term describes the force on the fluid due to the interaction of the electric current, $\vec{j}$, in the fluid and the magnetic induction $\vec{B}$. The differential equation can be written in vector notation as

$$\frac{D\vec{U}}{Dt}=\frac{\theta\vec{E}}{\rho}+\frac{\bar{\mu}}{\rho}\vec{j}\times\vec{H}+\frac{1}{\rho}\text{grad}\,p=\nu\nabla^2\vec{U} \tag{1}$$

where ρ is the fluid density, θ is the excess charge density, and $\bar{\mu}$ is the magnetic permeability. The substantial derivative D/Dt is associated with the use of spatial coordinates. A simplified version of Maxwell's equations appropriate for the present problem is

$$\text{div}\,\vec{H}=0;\ \text{div}\,\vec{J}=0;\ \bar{\mu}\vec{H}=\vec{B} \tag{2a}$$

$$\text{curl}\,\vec{H}=4\pi\vec{J} \tag{2b}$$

A reduced form of the generalized Ohm's law is, from reference 29,

$$\vec{j}=\sigma(\vec{E}+\bar{\mu}\vec{U}\times\vec{H}) \tag{2c}$$

The more complete form given as equation 2–22 in reference 29 includes additional terms accounting for gravity and pressure gradient effects. Both of these factors will be assumed negligible in this analysis. It will also be assumed that the conductivity, σ, does not have directional properties.

The continuity equation is

$$\text{div}\,\vec{U}=0 \tag{3}$$

Equation (2b) expresses the relation between the magnetic intensity $\vec{H}$ and the total electric current density $\vec{J}$. The distinction between the current densities $\vec{j}$ and $\vec{J}$ lies in their location and action. Consider first the situation when the fluid is stationary and the electric field intensity $\vec{E}$ is zero. The current density in the fluid is then zero. The magnetic field strength $\vec{H}_o$ or magnetic induction $\vec{B}_o=\mu\vec{H}_o$ is a result of an electric current $\vec{J}_o$ outside of the fluid. The current density $\vec{J}_o$ could be thought of as an electric current in a coil or electromagnet outside the flow region producing a magnetic field of a given number of lines of force per unit area. The relation between $\vec{J}_o$ and $\vec{H}_o$ is given by equation (2b). The basic magnetic field strength will be designated as $\vec{H}_o$.

When a conducting fluid moves through the magnetic lines of force, $\vec{B}_o$, the positive and negative charges are each accelerated in such a way that their average motion gives rise to an electric current $\vec{j}=\sigma\vec{U}\times\vec{B}$, where $\vec{B}=\vec{B}_o+\vec{b}$. The quantity $\vec{b}$ is the magnetic induction resulting from the electric current $\vec{j}$ in the fluid. In this analysis $\vec{b}$ will be con-

sidered as a perturbation on the basic field strength and negligible in comparison with $\vec{B}_o$; that is, from equation (2b),

$$\text{curl } (\vec{B}_o+\vec{b})=4\pi\bar{\mu}(\vec{J}_o+\vec{j})=4\pi\bar{\mu}\vec{J}$$

or

$$\text{curl } \vec{B}_o=4\pi\bar{\mu}\vec{J}_o$$

$$\text{curl } \vec{b}=4\pi\bar{\mu}\vec{j}$$

where $\vec{B}_o \gg \vec{b}$.

If an electric potential $\vec{E}$ were to be imposed across the flow field, the current density would be changed by $\vec{j}=\sigma\vec{E}$. However, the boundary conditions will be taken so that the impressed potential, $\vec{E}$, is zero. Therefore, $\vec{j}=\sigma\vec{U}\times\vec{B}_o$; that is, the electric current is proportional to the voltage generated by the relative motion of the fluid and magnetic field.

The fluid is assumed to be ionized and thereby an electrical conductor. However, within any small but finite volume the number of particles with positive and negative charges are nearly equal. The total excess charge, θ, in this small but finite volume will be taken as equal to zero. It has been shown in reference 17 that a very small increase in viscosity is realized due to the increased ordered-migration velocities of positive and negative ions in the presence of the electric field. This effect will be neglected and the electrostatic force term, $\theta\vec{E}$ will be assumed to be identically zero.

The induced electromagnetic force term, $\vec{j}\times\vec{B}_o$ will now be related to the local velocity vector. The procedure used in references 10, 19, and 22 which results in the magnetic parameter $\frac{\bar{\mu}H^2}{\rho U^2}$ (ratio of electromagnetic and inertia forces) and the magnetic viscosity $\lambda=\frac{1}{4\pi\sigma\bar{\mu}}$ will not be used. Instead a procedure will be followed which will lead to the magnetic parameter, $Q=\frac{\sigma B^2 l}{\rho U}$, used by references 7, 9, 11, 12, and 13.

A relation between $\vec{j}\times\vec{B}$ and the velocity is obtained from equation (2). It will be assumed that:

(1) Magnetic field lines are perpendicular to free-stream velocity.

(2) Permeability $\bar{\mu}$ is constant throughout the fluid.

(3) The assumptions already made are that the excess charge density θ and imposed electric field intensity $\vec{E}$ are assumed to be zero.

(4) Induced magnetic field $\vec{b}$ is negligible, linearizing the induced magnetic force term.

The first assumption is not highly restrictive since the perpendicular component of the magnetic field is the only part contributing a force which will change the laminar velocity profile. The other assumptions are reasonable physical approximations.

If these assumptions are used together with equation (2c), the induced magnetic force term becomes

$$-\frac{\vec{j}\times\vec{B}_o}{\rho}=-\frac{\sigma}{\rho}\left(\vec{U}\times\vec{B}_o\right)\times\vec{B}_o \tag{5}$$

From vector relations,

$$-\frac{\vec{j}\times\vec{B}_o}{\rho}=-\frac{\sigma}{\rho}\left(\vec{U}\times\vec{B}_o\right)\times\vec{B}_o=\frac{\sigma}{\rho}\left[\vec{U}\left(\vec{B}_o\cdot\vec{B}_o\right)-\vec{B}_o\left(\vec{B}_o\cdot\vec{U}\right)\right]$$

However, it has been assumed that $\vec{B}_o$ is perpendicular to the free-stream velocity $\vec{U}_\infty$ (assumption (1)). In the problems treated, the local velocity direction differs a negligible amount from the free-stream direction so that $\vec{B}_o\cdot\vec{U}=0$ and the linearized magneto-hydrodynamic force term becomes

$$-\frac{\vec{j}\times\vec{B}_o}{\rho}=\frac{\sigma B_o^2\vec{U}}{\rho}=mU_\infty\vec{U} \tag{6}$$

The parameter [3] m is related to the viscous Reynolds number and the Hartmann number of references 8 through 12 by

$$ml=\frac{\sigma B_o^2 l}{\rho U_\infty}=\frac{\sigma B_o^2 l^2}{\mu}\frac{1}{\frac{\rho U_\infty l}{\mu}}=\frac{\overline{M}^2}{Re}$$

Equation (1) may then be written as

$$\frac{D\vec{U}}{Dt}+\frac{\sigma B_o^2}{\rho}\vec{U}+\frac{1}{\rho}\text{grad } p=\nu\nabla^2\vec{U} \tag{7}$$

In the development of equation (7), it was assumed that the velocity of the magnetic field is zero. Since only the inductive force is being considered, the second term becomes $\frac{\sigma B_o^2}{\rho}\left(\vec{U}-\vec{U}_B\right)$ for a magnetic field in uniform translation, where $\vec{U}_B$ is the velocity of the magnetic field.

When electrical currents flow in a plasma it is well to define the conditions at the solid boundaries of the flow field. The problems treated are assumed to be two-dimensional with the electric current flowing from and to infinity parallel to a flat plate and perpendicular to the stream direction. The configuration may also be thought to consist of flow in a wide channel with the two side walls as conductors connected by a conductor of negligible resistance located outside of the influence of the flow field. The flow in the middle of such a channel should approximate the two-dimensional type of flow being analyzed. Such phenomena as charge accumulation and boundary effects at the walls will be assumed negligible.

THERMAL ENERGY TRANSPORT EQUATION

The differential equation describing the relationship between the convection and conduction of thermal energy and the work done on an electrically conducting fluid in the presence of a magnetic field is found by considering the

---

[3] From electric motor equations, it can be shown that

$$\sigma B_o^2=\frac{\text{force}}{j^3\times\text{velocity}}$$

and therefore

$$\frac{\sigma B_o^2 l}{\rho U_\infty}=\left(\frac{\bar{\mu}H_o^2}{\rho U_\infty^2}\right)(\sigma\bar{\mu}U_\infty l)=\left(\frac{\text{magnetic pressure}}{\text{dynamic pressure}}\right)\left(\text{magnetic Reynolds number}\right)$$

energy entering and leaving an elementary cubic box. The result is given by

$$\rho C_p \frac{DT}{Dt}=k\nabla^2 T+\frac{j^2}{\sigma}+\frac{Dp}{Dt}+\mu\left\{2\left[\left(\frac{\partial u}{\partial x}\right)^2+\left(\frac{\partial v}{\partial y}\right)^2+\left(\frac{\partial w}{\partial z}\right)^2\right]+\left(\frac{\partial v}{\partial x}+\frac{\partial u}{\partial y}\right)^2+\left(\frac{\partial w}{\partial y}+\frac{\partial v}{\partial z}\right)^2+\left(\frac{\partial u}{\partial z}+\frac{\partial w}{\partial x}\right)^2\right\} \quad (8)$$

The derivation of equation (8), with the exception of the second term on the right of the equal sign, can be found, for example, in reference 28. The term on the left of the equal sign takes account of the enthalpy transported by the motion of the fluid or by convection. The first term on the right represents heat conducted from one element of fluid to the next by molecular motion. The expression, j^2/σ, is the heat added by the electrical current produced by the motion of the fluid through magnetic lines of force or by an imposed electrical field (see eq. (2c)). The remaining terms arise when work is done on the fluid by either pressure or shear forces. The symbol D/Dt is the substantial derivative of the particular quantity and ∇^2 denotes the Laplacian.

If the general expression for the electric current density, as given by equation (2c), is inserted into the expression for the heat added by electrical means, the result is

$$\frac{j^2}{\sigma}=\sigma\left(\vec{E}+\vec{U}\times\vec{B}\right)^2 \quad (9)$$

It has been assumed that the electric field $\vec{E}$ is zero and that the magnetic field lines are perpendicular to the free-stream direction. To a good approximation in the problems to be considered, equation (9) can then be written as

$$\frac{j^2}{\sigma}=\sigma U^2 B_o^2 \quad (10)$$

where U^2 must be written as $(U-U_B)^2$ when relative motion exists between the magnetic field and the plate. Equation (8) is then

$$\rho C_p \frac{DT}{Dt}=k\nabla^2 T+\sigma U^2 B_o^2+\frac{Dp}{Dt}+\mu\left\{2\left[\left(\frac{\partial u}{\partial x}\right)^2+\left(\frac{\partial v}{\partial y}\right)^2+\left(\frac{\partial w}{\partial z}\right)^2\right]+\left(\frac{\partial v}{\partial x}+\frac{\partial u}{\partial y}\right)^2+\left(\frac{\partial w}{\partial y}+\frac{\partial v}{\partial z}\right)^2+\left(\frac{\partial u}{\partial z}+\frac{\partial w}{\partial x}\right)^2\right\} \quad (11)$$

IMPULSIVE MOTION OF A FLAT PLATE

The impulsive motion of an infinite flat plate [4] in a viscous fluid serves as a model for the boundary layer on a semi-infinite flat plate. The advantages of working the problem of the impulsive motion of a flat plate are that it is simple enough to yield a result in closed form and suggests the proper choice of parameters to be used on the more complicated problem of a semi-infinite flat plate.

The velocity profiles will be found for two cases. In the first it will be assumed that the magnetic lines of force are fixed relative to the plate, and the second relative to the fluid. In both cases the fluid is of uniform density and viscosity, and has the same electrical conductivity throughout. A third case, in which the magnetic field is fixed on the plate and a compensating pressure gradient exists in the fluid, will be shown to be equivalent to the case wherein the magnetic field is fixed relative to the fluid. The problem wherein the fluid conductivity varies will not be considered. The fluid and plate will be assumed to be initially at rest. At time $t=0$, the plate will move impulsively with a given velocity.

MAGNETIC FIELD FIXED RELATIVE TO THE PLATE

At time $t<0$, the fluid, plate, and magnetic field are assumed to be everywhere stationary. At time $t=0$ and for all later times the plate and magnetic field are moving at velocity $u=u_\infty$ (fig. 1). The problem is to find the velocity-time history of the fluid.

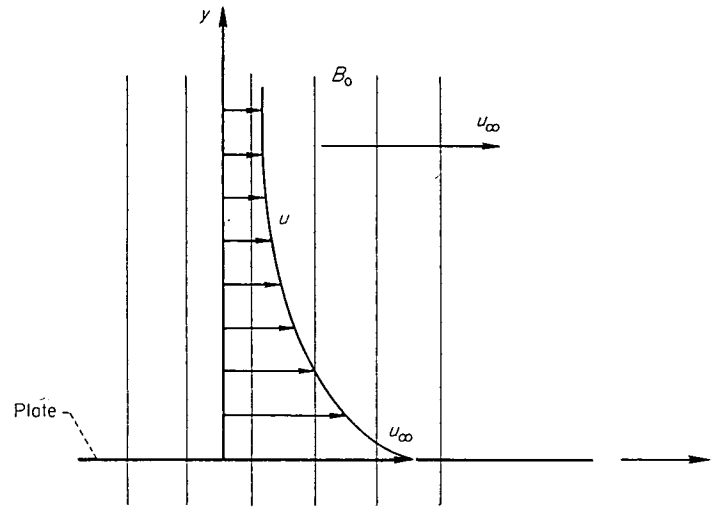

FIGURE 1.—Flat plate moving impulsively through a fluid in the presence of a transverse magnetic field.

The velocity in a given y=constant plane does not change with x. It can then be reasoned that the vertical, v, and transverse, w, velocities are zero or negligible together with the pressure gradients in all directions. Equation (7) then reduces to

$$\frac{\partial u}{\partial t}+\frac{\sigma B_o^2}{\rho}u=\nu\frac{\partial^2 u}{\partial y^2} \quad (12)$$

Since the magnetic field is moving and the fluid is initially at rest the relative motion must be accounted for. Equation (12) is then

$$\frac{\partial u}{\partial t}+\frac{\sigma B_o^2}{\rho}(u-u_\infty)=\nu\frac{\partial^2 u}{\partial y^2} \quad (13)$$

The boundary conditions are

$$u=u_\infty,\ y=0,\ t\geq 0$$

$$u=0,\quad y>0,\ t=0$$

The Laplace transform of the velocity u is defined as

$$\bar{u}=\int_0^\infty e^{-st}u\,dt \quad (14)$$

[4] This problem is often referred to as the "Rayleigh problem" when the fluid is incompressible and nonconducting.

Applying the Laplace transformation (see, e. g., refs. 30 and 31) to the first term in equation (13) gives

$$L\left(\frac{\partial u}{\partial t}\right)=\int_0^\infty e^{-st}\frac{\partial u}{\partial t}dt=+ue^{-st}\Big|_0^\infty+s\int_0^\infty e^{-st}u\,dt$$

$$\equiv s\bar{u}$$

If the other terms of equation (13) are treated similarly, the transformed equation is

$$s\bar{u}=\nu\frac{d^2\bar{u}}{dy^2}+\frac{m_1u_\infty}{s}-m_1\bar{u}$$

or

$$\frac{d^2\bar{u}}{dy^2}=\bar{u}\left(\frac{s+m_1}{\nu}\right)-\frac{m_1u_\infty}{\nu s} \tag{15}$$

The solution to equation (15) is the sum of the solution of the homogeneous equation plus the particular solution, that is,

$$\bar{u}=\frac{m_1u_\infty}{s(s+m_1)}+\frac{m_1u_\infty}{s(s+m_1)}\left[C_1(s)e^{-y\sqrt{\frac{s+m_1}{\nu}}}+C_2e^{+y\sqrt{\frac{s+m_1}{\nu}}}\right]$$

The constant C_2 is chosen equal to zero to fit the boundary condition that $\bar{u}$ must be finite at $y=\infty$. The integration constant $C_1(s)$ is found from the boundary condition at $y=0$; that is, on the plate

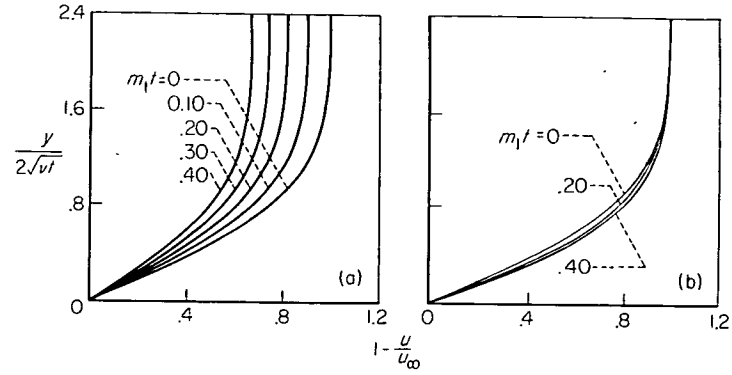
$$u_{y=0}=u_\infty$$

The Laplace transform of u_∞ is u_∞/s. Therefore

$$C_1(s)=\frac{s}{m_1}$$

and

$$\bar{u}=\frac{m_1u_\infty}{s(s+m_1)}+\frac{u_\infty}{s+m_1}e^{-y\sqrt{\frac{s+m_1}{\nu}}} \tag{16}$$



Equation (16) can be inverted with the aid of reference 30. Combining several terms gives

$$u=u_\infty\left(1-e^{-m_1t}erf\frac{y}{2\sqrt{\nu t}}\right) \tag{17}$$

The symbol *erf* denotes the error function of the argument. The error function is discussed in reference 31 and tabulated extensively in reference 32. Typical velocity profiles are shown in figure 2 (a). If m_1 is set equal to zero, equation (17) reduces to the result for the Rayleigh problem; that is,

$$u=u_\infty\left(1-erf\frac{y}{2\sqrt{\nu t}}\right)$$

The velocity is a function of $y/2\sqrt{\nu t}$ only and therefore a single profile suffices. However, when a magnetic field is acting on the fluid, the velocity profiles are not similar because they change with time according to e^{-m_1t}. The fluid at infinity is accelerated by the magnetic field so that the entire mass of fluid is accelerated by the magnetic field. It is, in fact, accelerated more rapidly than when the only force is the viscous action between layers.

(a) Magnetic field fixed relative to plate. (b) Magnetic field fixed relative to fluid.

FIGURE 2.—Boundary-layer velocity profiles on a flat plate set into motion impulsively.

The skin-friction coefficient is expressed as

$$c_f=\frac{\mu(\partial u/\partial y)|_{y=0}}{\rho u_\infty{}^2/2} \tag{18}$$

so that, from equation (17),

$$c_f=\frac{2\nu}{u_\infty\sqrt{\pi\nu t}}e^{-m_1t} \tag{19a}$$

Values of c_f are shown in graphical form in figure 3. When m_1 is zero, equation (19a) reduces to the skin friction for the nonelectromagnetic Rayleigh problem.

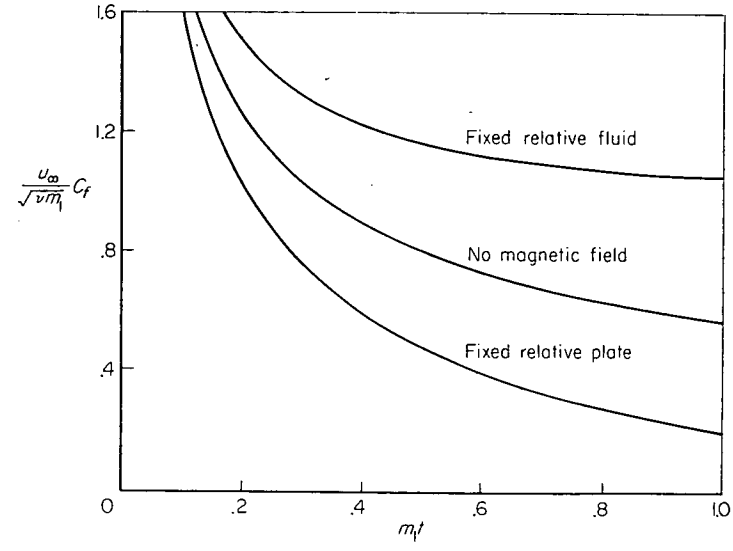


FIGURE 3.—Skin friction parameter as a function of a magnetic parameter.

The change in the velocity profile is a result of the force exerted by the magnetic field on the fluid. The reaction on the unit generating the magnetic field is expressed as

$$F/\text{unit area}=\int\sigma B_o{}^2(u_\infty-u)\,dy=\sigma B_o{}^2e^{-m_1t}\int_0^{y\to\infty}erf\frac{y}{2\sqrt{\nu t}}dy \tag{19b}$$

The force per unit area goes to infinity as the upper limit of integration goes to infinity because the magnetic field extends

undiminished an infinite distance from the plate. Thereby, an infinite amount of fluid is accelerated, resulting in an infinite force.

MAGNETIC FIELD FIXED RELATIVE TO THE FLUID

At all times less than zero the fluid, magnetic field, and plate are assumed to be at rest. At time $t=0$ the plate begins moving with velocity $u=u_\infty$ but the magnetic field remains at rest. The differential equation is the same as equation (12) because there is no relative motion between the fluid at $y=\infty$ and the magnetic field.

$$\frac{\partial u}{\partial t}+m_1 u=\nu\frac{\partial^2 u}{\partial y^2} \tag{20}$$

The boundary conditions are

$$u=u_\infty \quad \text{at } y=0\ t\geq 0$$

$$u=0 \quad \text{at } y>0\ t=0$$

Applying the Laplace transformation to equation (20), as was done in the previous section, yields the transformed equation

$$\nu\frac{d^2\bar{u}}{dy^2}=\bar{u}(s+m_1)$$

The solution to this ordinary differential equation is

$$\bar{u}=C_1(s)e^{-y\sqrt{\frac{s+m_1}{\nu}}}+C_2 e^{+y\sqrt{\frac{s+m_1}{\nu}}}$$

where the constant C_2 is set equal to zero because of the requirement of a finite velocity at $y=\infty$. The integration constant, $C_1(s)$, is found from the boundary condition at $y=0$, $t\geq 0$, as

$$C_1(s)=\frac{u_\infty}{s}$$

Equation (20) can be written as

$$\bar{u}=\frac{u_\infty}{(s+m_1)-m_1}e^{-\sqrt{s+m_1}\frac{y}{\sqrt{\nu}}}$$

This equation can be inverted with the aid of reference 30 as

$$u=\frac{u_\infty}{2}\left[e^{-y\sqrt{\frac{m_1}{\nu}}}erfc\left(\frac{y}{2\sqrt{\nu t}}-\sqrt{m_1 t}\right)+e^{+y\sqrt{\frac{m_1}{\nu}}}erfc\left(\frac{y}{2\sqrt{\nu t}}+\sqrt{m_1 t}\right)\right] \tag{21}$$

The symbol *erfc* denotes the complementary error function defined as $1-erf$ (see, e. g., p. 370 of ref. 31). The velocity is once again dependent on more than one parameter so that a single similar profile cannot be drawn. Several profiles are shown in figure 2 (b). The fluid at $y=\infty$ is not disturbed in this case because the velocity across the magnetic lines is zero. In the vicinity of the plate the induced magnetic force counteracts the acceleration force of viscosity resulting in an increased rate of shear at the walls as expressed by the skin-friction coefficient.

$$c_f=\frac{2\nu}{u_\infty}\left(\sqrt{\frac{m_1}{\nu}}\,erf\sqrt{m_1 t}+\frac{e^{-m_1 t}}{\sqrt{\pi\nu t}}\right) \tag{22}$$

Even at time, $t=\infty$, a friction force acts on the plate—a situation contrary to the previous case and the Rayleigh problem. Values computed by equation (22) are shown in figure 3.

The force on the magnetic field is given by

$$F/\text{unit area}=\int_0^\infty \sigma B_o^2 u\,dy \tag{23}$$

where u is given by equation (21). The force is finite in this case.

Another case which may be of interest arises when the magnetic field is fixed on the plate but a pressure gradient compensates for the action of the magnetic field at $y=\infty$. A flow of this character may be imagined to exist in the early stages of boundary-layer formation on the walls of a two-dimensional channel. The conducting fluid is assumed to be pumped through a channel containing a stationary transverse magnetic field. A pressure gradient arises automatically to compensate for the resistance of the magnetic field. The equations then describe the boundary layer as a function of time, after the pump has started. For this case equation (7) reduces to

$$\frac{\partial u}{\partial t}+m_1(u-u_\infty)+\frac{1}{\rho}\frac{\partial p}{\partial x}=\nu\frac{\partial^2 u}{\partial y^2}$$

The pressure gradient $\frac{1}{\rho}\frac{\partial p}{\partial x}$ is found by examining the boundary condition mentioned above at $y=\infty$. At $y=\infty$

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial y^2}=u=0$$

Therefore, at $y=\infty$,

$$-m_1 u_\infty+\frac{1}{\rho}\frac{\partial p}{\partial x}=0$$

and the above equation becomes equation (12). Since the boundary conditions are the same as when the magnetic field was fixed relative to the fluid, the results shown in figures 2 (b) and 3 apply here also.

BOUNDARY LAYER ON A SEMI-INFINITE FLAT PLATE

In the analysis of the boundary layer on a flat plate moving impulsively, it was found that the shape of the boundary-layer velocity profile changes with time, necessitating a new calculation at each instant. Therefore, a simple transformation of the coordinates would not yield a similar solution wherein all profiles could be drawn as one. It is then to be expected that in the flow of an incompressible fluid over a semi-infinite flat plate in the presence of a magnetic field, a similar solution will not exist. Since the boundary-layer solution of Blasius is not known in closed form and the velocity profiles at two different stations along the plate are not similar, a numerical solution to a series expansion is found by the method used in reference 33. The first or zero-order term is found to be the same as the Blasius solution which is well known and is tabulated, for example, on page 103 of reference 28. The first nonzero term will be calculated for the cases studied here.

The boundary-layer velocity and temperature profiles will be found for three cases. The conductivity of the fluid is assumed to be uniform throughout the flow field in the first

and second cases. A particular variation is assumed in the third case. The magnetic field is fixed relative to the plate in the first and third cases and relative to the fluid in the second case. A fourth case is shown to be equivalent to the second. In all cases the fluid will be assumed to be incompressible and to have a Prandtl number of 1.[5]

MAGNETIC FIELD FIXED RELATIVE TO THE PLATE

Velocity profile.—The magnetic field lines of force are assumed to be perpendicular to the free-stream direction and to begin at the leading edge of the plate as indicated in figure 4. An experimental setup may be imagined to consist of a wing or flat plate in a stream of conducting fluid such as mercury, sodium, or salt water. A magnetic field is impressed across the flow field using either a permanent or electromagnet.

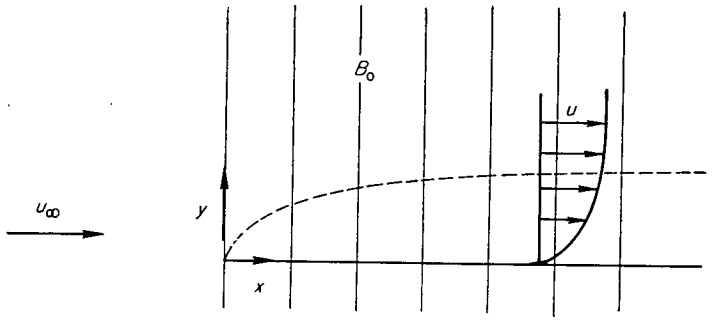

FIGURE 4.—Fluid flowing past a semi-infinite flat plate in the presence of a transverse magnetic field.

On the basis of the usual boundary-layer assumptions, equation (7) reduces to

$$u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+m_1u=\nu\frac{\partial^2 u}{\partial y^2} \tag{24}$$

The boundary conditions are that $u=0$ at $y=0$ and $u=u_\infty$ upstream of the plate. At $y=\infty$, $\partial u/\partial y=0$ and $\partial u/\partial x=-m_1$. Outside of the boundary layer the continuity equation requires that $\partial v/\partial y=m_1$; therefore, $v\to\infty$ as $y\to\infty$. If the flow field is restricted to the vicinity of the surface of the flat plate, no real difficulty arises. In an actual problem the magnetic field will not extend uniformly to large distances from the plate. At the location where the magnetic field strength dies out another viscous layer will develop. This slip layer will be ignored. Equation (24) is the same as the incompressible boundary-layer equation except for the additional term m_1u. As was done in the Blasius boundary-layer solution, the transformation,

$$\left.\begin{aligned}\xi&=x\\ \eta&=y\sqrt{\frac{u_\infty}{\nu x}}\end{aligned}\right\} \tag{25}$$

is introduced. The stream function, ψ, is defined as

$$\psi=\sqrt{u_\infty\nu x}\,[f_o+\sqrt{mx}f_1+mxf_2+(mx)^{3/2}f_3+(mx)^2f_4\ \ldots] \tag{26}$$

where the functions f_o, f_1, f_2, . . . are functions of η only. The series expansion in $\sqrt{mx}$ is suggested by equation (21), where the exact form of m is yet to be determined. If the expression (21) is expanded in a power series in m_1t, the odd power terms contributed by the first and second parts cancel each other. Also, if these terms are carried along in the following analysis, the corresponding functions are found to be zero. Therefore, only whole powers of mx will be considered in what follows.

The velocity components and their derivatives are found from equations (25) and (26) as

$$u=\frac{\partial\psi}{\partial y}=\frac{\partial\psi}{\partial\xi}\frac{\partial\xi}{\partial y}+\frac{\partial\psi}{\partial\eta}\frac{\partial\eta}{\partial y}$$

$$u=u_\infty\,[f_o'+mxf_2'+(mx)^2f_4'\ \ldots] \tag{27}$$

$$v=-\frac{\partial\psi}{\partial x}=-\frac{\partial\psi}{\partial\xi}\frac{\partial\xi}{\partial x}-\frac{\partial\psi}{\partial\eta}\frac{\partial\eta}{\partial x}$$

$$v=\frac{1}{2}\sqrt{\frac{u_\infty\nu}{x}}\,[f_o'+mxf_2'+(mx)^2f_4'+\ \ldots]-$$

$$\frac{1}{2}\sqrt{\frac{u_\infty\nu}{x}}\,[f_o+3mxf_2+5(mx)^2f_4+\ \ldots] \tag{28}$$

Similarly,

$$\frac{\partial u}{\partial x}=-\frac{\eta}{2}\frac{u_\infty}{x}\,[f_o''+mxf_2''+(mx)^2f_4''+\ \ldots]+$$

$$\frac{u_\infty}{2x}\,[2mxf_2'+4(mx)^2f_4'+\ \ldots] \tag{29a}$$

$$\frac{\partial u}{\partial y}=u_\infty\sqrt{\frac{u_\infty}{\nu x}}\,[f_o''+mxf_2''+(mx)^2f_4''+\ \ldots] \tag{29b}$$

$$\frac{\partial^2 u}{\partial y^2}=\frac{u_\infty^2}{\nu x}[f_o'''+mxf_2'''+(mx)^2f_4'''+\ \ldots] \tag{29c}$$

When equations (27) through (29) are substituted into equation (24) and the like powers of

$$mx=\frac{\sigma B_o^2}{\rho u_\infty}x=\frac{\overline{M}^2}{Re_x} \tag{30}$$

are equated, the following differential equations result:

$$2f_o'''=-f_o''f_o \tag{31}$$

$$f_2'''=f_o'f_2'-\frac{1}{2}f_of_2''-\frac{3}{2}f_2f_o''+f_o' \tag{32a}$$

$$f_4'''=2f_o'f_4'+f_2'f_2'-\frac{1}{2}f_of_4''-\frac{3}{2}f_2f_2''-\frac{5}{2}f_4f_o''+f_2' \tag{32b}$$

etc.

The boundary conditions are

$$f_o=f_2=f_4=\ \ldots\ =0 \text{ at } \eta=0$$

$$f_o'=f_2'=f_4'=\ \ldots\ =0 \text{ at } \eta=0$$

$$f_o'=1 \text{ and } f_2'=-1 \text{ at } \eta=\infty$$

$$f_4'=f_6'=\ \ldots\ =0 \text{ at } \eta=\infty$$

[5] Recent theoretical computations by Hansen (ref. 34) indicate that when the air is ionized up to 20 or 25 percent, a more realistic value for the Prandtl number would be about 0.3. When the gas becomes fully ionized, the Prandtl number drops off to the order of 0.01.

The differential equations for f_2 and f_4 are linear ordinary differential equations with variable coefficients. Since the coefficients (Blasius solution) are not known in closed form, the equations must be integrated numerically. Only the functions f_2 and f_4 of the series will be found because the work involved is sizable and it is the intent of this study to find the over-all trends and gross effects rather than precise results.

The Runge-Kutta method was used to integrate both the homogeneous and nonhomogeneous forms of equations (32a) and (32b). The integration is started at the surface of the plate using two boundary conditions and then assuming a value for f_2'' and f_4''. The correct solution is found by a proper combination of the numerical solutions to the homogeneous and nonhomogeneous equations. The factor by which the homogeneous equation is to be multiplied is found from the boundary condition at $\eta=\infty$. The numerical results for f_2 and f_4 are tabulated in table I (a). The velocity profiles shown in figure 5 (a) indicate that the flow separation at $mx=0.5$ will probably not be predicted if a sufficient number of terms are taken in the series (27). The first three terms (f_o', f_2', and f_4') describe the velocity in the boundary layer quite well up to at least $mx=0.2$.

The skin-friction coefficient and the displacement δ^* of an incoming streamline are

$$c_f=\frac{0.664-1.789\ mx+0.706\ m^2x^2-\ \cdots\ +\ \cdots}{\sqrt{Re_x}} \tag{33a}$$

$$\delta^*=mxy+(1.73+0.54\ mx+1.34\ m^2x^2+\ \cdots\ )\sqrt{\frac{\nu x}{u_\infty}} \tag{33b}$$

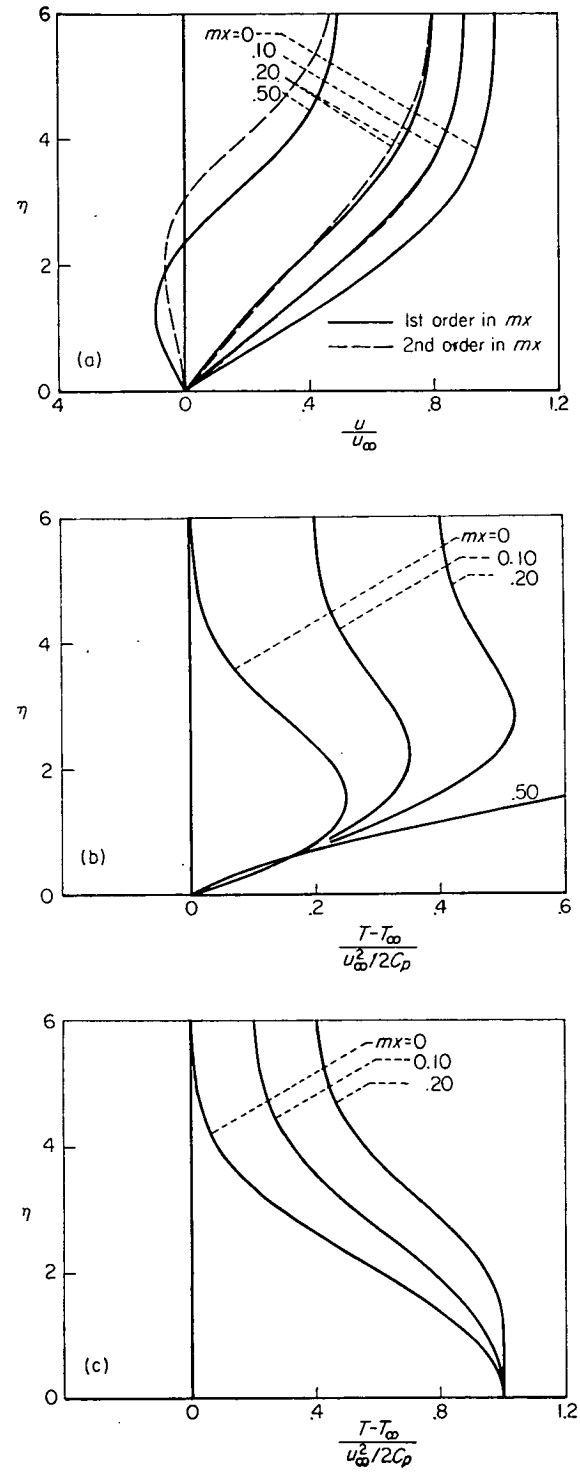
The unit generating the magnetic field is assumed to be carried by the aircraft. The drag on this unit caused by the magnetic-field-fluid interaction is

$$F/\text{unit area}=\int_0^{y\to\infty}\sigma B_o^2 u\,dy$$

Substituting equation (27),

$$F/\text{unit area}=\sigma B_o^2\sqrt{u_\infty \nu x}\int_0^{\eta\to\infty}(f_o'+mxf_2'+\ \cdots\ )d\eta$$

$$=\sigma B_o^2\sqrt{u_\infty \nu x}\,(f_o+mxf_2+\ \cdots\ )_0^{\eta\to\infty} \tag{33c}$$



The force is finite only for a conducting layer of finite thickness.

Temperature profile.—When the pressure gradients are reasoned to be everywhere zero and the usual two-dimensional boundary-layer assumptions are made, equation (11) reduces to

$$\rho u C_p\frac{\partial T}{\partial x}+\rho v C_p\frac{\partial T}{\partial y}-\sigma B_o^2u^2=\frac{C_p\mu}{Pr}\frac{\partial^2 T}{\partial y^2}+\mu\left(\frac{\partial u}{\partial y}\right)^2 \tag{34}$$

If total energy is defined as

$$E=C_pT+\frac{u^2}{2} \tag{35}$$

(a) Velocity.
(b) Temperature distribution for a cool wall, $T_w=T_\infty$.
(c) Temperature distribution for an insulated wall.

FIGURE 5.—Boundary-layer profiles for fluid flowing over a semi-infinite flat plate with a transverse magnetic field fixed relative to the plate.

equations (24) and (34) can be combined to yield a differential equation for the transport of total energy E; that is, if equation (24) is multiplied by u, added to equation (34), and the Prandtl number, Pr, is assumed to be 1,

$$u\frac{\partial E}{\partial x}+v\frac{\partial E}{\partial y}=\nu\frac{\partial^2 E}{\partial y^2} \tag{36}$$

Although the temperature distribution is altered by the presence of the magnetic field because u and v are affected, the total energy of the conducting fluid is not. The kinetic energy removed by the force of the magnetic field is exactly equal to the heat generated by the electric current, independent of the field strength B_o and the conductivity σ. An analogy may be drawn by considering a similar situation for an electric motor. Assume the motor to be rotating at a given speed. The power is then turned off and the armature is short-circuited. The motor will decelerate at a given rate depending on the field strength, resistance of the circuit, and rotational speed, just as in the fluid flow problem. The temperature rise of the wires, insulation, etc., however, depends only on the initial kinetic energy of the rotor. If the conductivity of the wires (or fluid) is reduced, the time required to stop the motion will be increased but the total j^2/σ or joule heat is not changed.

A first-order estimate of the influence of the magnetic field on the temperature profile can be found from equation (34) together with equations (25) through (29) and table I (a). Assume that

$$T=T_o(\eta)+T_2(\eta)mx+T_4(\eta)m^2x^2+\ldots \tag{37}$$

where, T_2, T_4, . . . are functions only of $\eta=y\sqrt{\frac{u_\infty}{\nu x}}$ and $T_1=T_3=T_5\ldots=0$ as in the part of the problem dealing with the velocity profile. The derivatives of the temperature with respect to x and y are found as

$$\frac{\partial T}{\partial x}=\frac{\partial T}{\partial \xi}\frac{\partial \xi}{\partial x}+\frac{\partial T}{\partial \eta}\frac{\partial \eta}{\partial x}$$

$$\left.\begin{aligned}\frac{\partial T}{\partial x}&=\frac{1}{x}\left[mxT_2+2m^2x^2T_4+\ldots-\right.\\&\qquad\left.\frac{\eta}{2}(T_o'+mxT_2'+m^2x^2T_4'+\ldots)\right]\\\frac{\partial T}{\partial y}&=\frac{\partial T}{\partial \eta}\frac{\partial \eta}{\partial y}=\sqrt{\frac{u_\infty}{\nu x}}(T_o'+mxT_2'+m^2x^2T_4'+\ldots)\end{aligned}\right\} \tag{38}$$

When the various expressions are inserted into equation (34) and terms containing like powers of mx are equated, the differential equations for T_o and T_2 are

$$\frac{T_o''}{Pr}+\frac{T_o'f_o}{2}+\frac{u_\infty^2(f_o'')^2}{C_p}=0 \tag{39}$$

$$\frac{T_2''}{Pr}+\frac{T_2'f_o}{2}-f_o'T_2+\frac{3}{2}f_2T_o'+\frac{u_\infty^2}{C_p}(f_o'^2+2f_o''f_2'')=0 \tag{40}$$

The boundary conditions are

$$\begin{aligned}T_o&=T_w &&\text{at } \eta=0\\T_o&=T_\infty &&\text{at } \eta=\infty\\T_2''&=T_2'=0 &&\text{at } \eta=\infty\\T_2&=0 &&\text{at } \eta=0\end{aligned}$$

The solution to equation (39) was first found by Pohlhausen and is discussed on page 246 ff. of reference 28. The function $T_o(\eta)$ is the temperature profile for a boundary layer on a flat plate and is given by (assuming $Pr=1$)

$$T_o=T_\infty+\left(T_w-T_\infty-\frac{u_\infty^2}{2C_p}\right)(1-f_o')+\frac{u_\infty^2}{2C_p}(1-f_o'^2) \quad (41)$$

The derivative of T_o to be inserted into equation (40) becomes

$$T_o'=-f_o''\left(T_W-T_\infty-\frac{u_\infty^2}{2C_p}+\frac{u_\infty^2}{C_p}f_o'\right) \quad (42)$$

For simplicity, the temperature of the plate will be assumed to be the same as that of the fluid far from the plate; that is, $T_W=T_\infty$. Equation (40) then becomes ($Pr=1$)

$$T_2''+\frac{f_o}{2}T_2'-f_o'T_2+\frac{u_\infty^2}{C_p}\left[\frac{3}{2}f_2f_o''\left(\frac{1}{2}-f_o'\right)+(f_o')^2+2f_o''f_2''\right]=0 \quad (43)$$

Equation (43) was integrated numerically by the same method used for equation (32a) and the results are tabulated in table I (b). Several temperature profiles are shown in figure 5 (b). The quantity of heat transferred to the plate per unit time is

$$q=k\left(\frac{\partial T}{\partial y}\right)_{y=0} \quad (44a)$$

The local convective heat-transfer rate is ($Pr=1$)

$$h=\frac{q}{u_\infty^2/2C_p}=\frac{\rho u_\infty C_p}{2\sqrt{Re_x}}(0.664-0.704\,mx-\ \ldots\ +\ \ldots) \quad (44b)$$

In the limit as the conductivity or field strength vanishes ($m\to 0$), equation (44b) reduces to

$$h)_{m=0}=\frac{f_o''u_\infty\rho C_p}{\sqrt{Re_x}} \quad (45a)$$

or by virtue of equation (33a)

$$h)_{m=0}=\frac{1}{2}c_f\rho u_\infty C_p \quad (45b)$$

Equation (45b) is often identified as Reynolds analogy. A similar relation of equal simplicity was not found for the problems treated in this paper.

The differential equation for flow over an insulated plate is obtained from equation (40) by introducing the proper expression for T_o'. The solution of equation (39) for the insulated plate case is (see, e. g., ref. 28)

$$T_o=T_\infty+\frac{u_\infty^2}{2C_p}(1-f_o'^2) \quad (46a)$$

and therefore,

$$T_o'=-\frac{u_\infty^2}{C_p}f_o'f_o'' \quad (46b)$$

Equation (40) then becomes, for the insulated plate case ($Pr=1$),

$$T_2''+\frac{T_2'f_o}{2}-f_o'T_2-\frac{u_\infty^2}{C_p}\left[\frac{3}{2}f_2f_o'f_o''-(f_o')^2-2f_o''f_2''\right]=0 \quad (46c)$$

The temperature profiles (table I (c)) for several values of mx are shown in figure 5 (c). It is to be noted that the recovery temperature is not altered by the magnetic field. Such a result is to be expected since the magnetic field and the fluid at the wall do not interact.

MAGNETIC FIELD FIXED RELATIVE TO THE FLUID

Velocity profile.—In this case the magnetic lines of force move past the plate at the free-stream velocity. The fluid, which is decelerated by the viscous action of the plate, receives a push from the magnetic field which counteracts the viscous effect. Such a situation exists when a plate, vane, or wing moves through a stationary electrically conducting fluid and magnetic field. The boundary layer on a wing of an aircraft flying in the ionosphere over the magnetic poles of the earth could be considered to correspond to this case. Under these circumstances, equation (7) reduces to

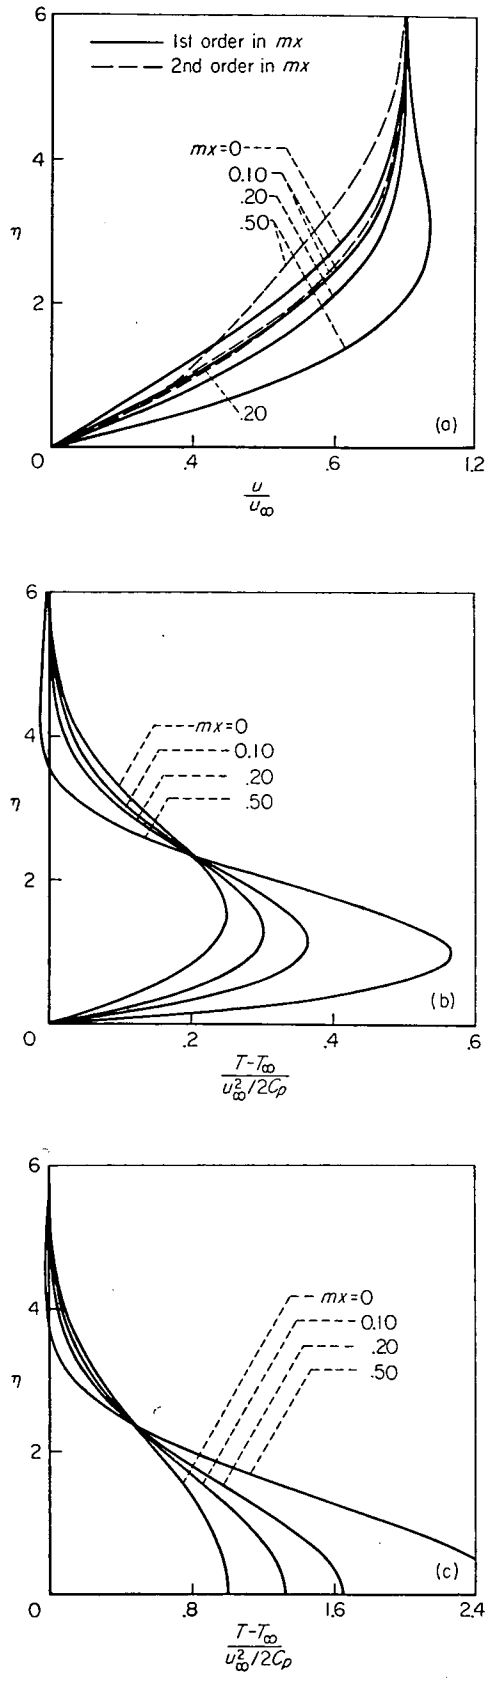
$$u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+\frac{\sigma B_o^2}{\rho}(u-u_\infty)=\nu\frac{\partial^2 u}{\partial y^2} \quad (47)$$

If the transformation of coordinates and the stream function described by equations (25) and (26) are introduced into equation (47), a set of ordinary linear differential equations with variable coefficients is found for f_2, f_4, . . .

$$f_2'''=f_o'f_2'-\frac{1}{2}f_o'f_2''-\frac{3}{2}f_2f_o''+f_o'-1 \quad (48a)$$

$$f_4'''=2f_o'f_4'+f_2'f_2'-\frac{1}{2}f_of_4''-\frac{3}{2}f_2f_2''-\frac{5}{2}f_4f_o''+f_2' \quad (48b)$$

The boundary conditions are



$$f_o=f_2=f_4=\ \ldots\ =0 \qquad \text{at } \eta=0$$

$$f_o'=f_2'=f_4'=\ \ldots\ =0 \qquad \text{at } \eta=0$$

$$f_o'=1 \text{ and } f_2'=f_4'=\ \ldots\ =0 \text{ at } \eta=\infty$$

The integration for f_2 and f_4 was carried out by the same method described in the previous section and the results are tabulated in table II (a). Several velocity profiles are shown in figure 6 (a). The difference between the first- and second-order curves is small at small values of mx. However, the separation of the $mx=0.5$ curves indicates that the series expression (27) does not converge rapidly. More than two terms in the series must then be used if the velocity profile is to be predicted accurately at values of mx higher than about 0.2. The local skin-friction coefficient is

$$c_f=\frac{0.664+2.293\,mx-2.768\,m^2x^2+\ \ldots\ -\ \ldots}{\sqrt{Re_x}} \quad (49a)$$

(a) Velocity.
(b) Temperature distribution for a cool wall, $T_w = T_\infty$.
(c) Temperature distribution for an insulated wall.

FIGURE 6.—Boundary-layer profiles for fluid flowing over a semi-infinite flat plate with a transverse magnetic field fixed relative to the fluid.

and the displacement thickness is

$$\delta^* = (1.73 - 2.21\,mx + 5.22\,m^2x^2 - \ldots + \ldots)\sqrt{\frac{\nu x}{u_\infty}} \tag{49b}$$

The disturbance caused by viscous action on the plate results in a force on the magnetic field, which is given by

$$F/\text{unit area} = \int_0^{y\to\infty} \sigma B_o^2 (u_\infty - u)\,dy$$

From equations (27), (66), and table II (a),

$$\left.\begin{aligned} F/\text{unit area} &= \sigma B_o \sqrt{u_\infty \nu x} \int_0^{\eta\to\infty} (1 - f_o' - mx f_2' - \ldots)\,d\eta \\ &= (1.73 - 2.21\,mx + 5.22\,m^2x^2 - \\ &\quad \ldots + \ldots)\sigma B_o^2 \sqrt{u_\infty \nu x} \\ &= \sigma u_\infty \delta^* B_o^2 \end{aligned}\right\} \tag{49c}$$

The force would appear as a reaction on the unit generating the magnetic field and not on the model which disturbs the fluid.

Equation (47) is identical with the differential equation for the case when the magnetic field is fixed with respect to the plate and a pressure gradient exists just strong enough to compensate for the electromagnetic effects at $\eta = \infty$. The boundary conditions and, hence, also the numerical results of table II (a) and figure 6 (a) can be applied to this problem.

Temperature profile.—Since the magnetic field lines are now moving relative to the plate, the expression for the electric current in the fluid is

$$j = \sigma B_o (u - u_\infty)$$

The equation for the transport of thermal energy in the boundary layer then becomes

$$\rho u C_p \frac{\partial T}{\partial x} + \rho v C_p \frac{\partial T}{\partial y} - \sigma B_o^2 (u - u_\infty)^2 = \frac{\mu C_p}{Pr} \frac{\partial^2 T}{\partial y^2} + \mu \left(\frac{\partial u}{\partial y}\right)^2 \tag{50}$$

If equations (47) and (50) are combined to describe the transport of total energy in the boundary layer ($Pr = 1$)

$$\rho u \frac{\partial E}{\partial x} + \rho v \frac{\partial E}{\partial y} + u_\infty (u - u_\infty)\sigma B_o^2 = \mu \frac{\partial^2 E}{\partial y^2} \tag{51}$$

where, as before, $E = C_p T + \frac{u^2}{2}$. It is seen that the presence of the magnetic field adds energy to the local element by doing work on the fluid retarded by viscosity. The magnitude of the work depends on the velocity, electrical conductivity, and field strength.

When the transformation of coordinates, equation (25), and the series expansion, equation (37), are inserted into equation (50), a set of differential equations is obtained for T_o, T_2, T_4, . . . The relation for T_o is the same as equation (39) and that for T_2 is

$$\frac{T_2''}{Pr} + \frac{f_o}{2} T_2' - f_o' T_2 + \frac{3}{2} f_2 T_o' + \frac{u_\infty^2}{C_p} [(1 - f_o')^2 + 2 f_o'' f_2''] = 0 \tag{52a}$$

8.6	2.213	0	0	−5.224	0	0	0	0	0	0

When the expression (42) is inserted into equation (52a) and it is assumed that $T_w=T_\infty$ and $Pr=1$, the result is

$$T_2''+\frac{f_o}{2}T_2'-f_o'T_2+\frac{u_\infty^2}{C_p}\left[\frac{3}{2}f_2f_o''\left(\frac{1}{2}-f_o'\right)+(1-f_o')^2+2f_o''f_2''\right]=0 \tag{52b}$$

The boundary conditions are

$$T_2=0 \text{ at } \eta=0$$

$$T_2=0 \text{ at } \eta=\infty$$

The numerical integration of equation (52b) was carried out by the method used earlier and the results are tabulated in table II (b). The temperature profiles shown in figure 6 (b) correspond to the same values of mx shown for the velocity profiles in figure 6 (a). The temperature gradient and the heat transfer to the wall are, respectively,

$$\left(\frac{\partial T}{\partial y}\right)_{y=0}=\frac{u_\infty^2}{2C_p}\sqrt{\frac{u_\infty}{\nu x}}\,(0.332+2.022\,mx+\ldots)$$

$$h=\frac{q}{u_\infty^2/2C_p}=\frac{\rho u_\infty C_p}{2\sqrt{Re_x}}\,(0.664+4.044\,mx+\ldots) \tag{53}$$

The recovery temperature for an insulated plate is altered by the relative motion between the magnetic field and the fluid at the plate. The differential equation for the perturbation profiles are obtained by inserting equation (46b) into equation (52a).

$$T_2''+\frac{f_o}{2}T_2'-f_o'T_2-\frac{3u_\infty^2}{2C_p}f_2f_o'f_o''+\frac{u_\infty^2}{C_p}[(1-f_o')^2+2f_o''f_2'']=0 \tag{54a}$$

Several typical temperature profiles (table II (c)) are shown in figure 6 (c). The recovery temperature at the wall is changed due to the j^2/σ or joule heating caused by the relative motion between the magnetic field and the fluid at the plate; that is, the recovery temperature at the wall is given by

$$T_r)_{y=0}=T_o+1.614\,\frac{u_\infty^2}{C_p}\,mx+\ldots-\ldots$$

$$T_r)_{y=0}=T_\infty+\frac{u_\infty^2}{2C_p}\,(1+3.228\,mx+\ldots-\ldots) \tag{54b}$$

The heat transferred to the plate may also be written as $q=h(T_r-T_w)$, where T_r is the recovery temperature given by equation (54b) and T_w is the wall temperature. Since the magnetic field increases T_r as well as τ, the heat-transfer rate is increased in two ways.

MAGNETIC FIELD FIXED RELATIVE TO PLATE—FLUID OF VARIABLE CONDUCTIVITY

Velocity profile.—Numerous problems in fluid dynamics exist wherein the electrical conductivity of the fluid or the strength of the magnetic field changes with distance from

the surface. The magnetic field strength can be varied somewhat by the design of the apparatus. It is possible to adjust not only the strength of the field but also the variation with distance from or along the surface within certain physical limits. A first approximation to the shape and magnitude of most magnetic fields would be a uniform magnetic field of constant magnitude throughout the flow field. Such a magnetic system will once again be chosen for this case.

The electrical conductivity of the fluid would be expected to vary in a complicated manner in directions along and perpendicular to the surface and from one situation to the next. The constant value chosen for the conductivity in the two previous cases is not realistic. The conductivity will vary under actual conditions of flow in a boundary layer. This will surely change the skin friction and heat transfer from that found in the last two cases. A logical variation will be studied in this section to see how large an effect a variable conductivity will have on c_f and h.

It is to be expected that the conductivity will vanish at the outer edge of the boundary layer and reach a maximum somewhere near the surface. The equations which can be used to determine the number of ions (and hence conductivity) in a stream at high temperature or under circumstances wherein combustion is taking place, are cumbersome. Therefore, a simple, approximate, analytical relation for the electrical conductivity as a function of temperature between the plate and outer edge of the boundary layer was not found. The conductivity of air after the passage of a normal shock wave has been measured in a shock tube and reported on page 339 of reference 3. The conductivity is reproduced in figure 7. At Mach numbers above 20, the results are approximated by a straight line.

In view of the lack of knowledge of the variation of σ in the boundary layer, a linear relation between the velocity

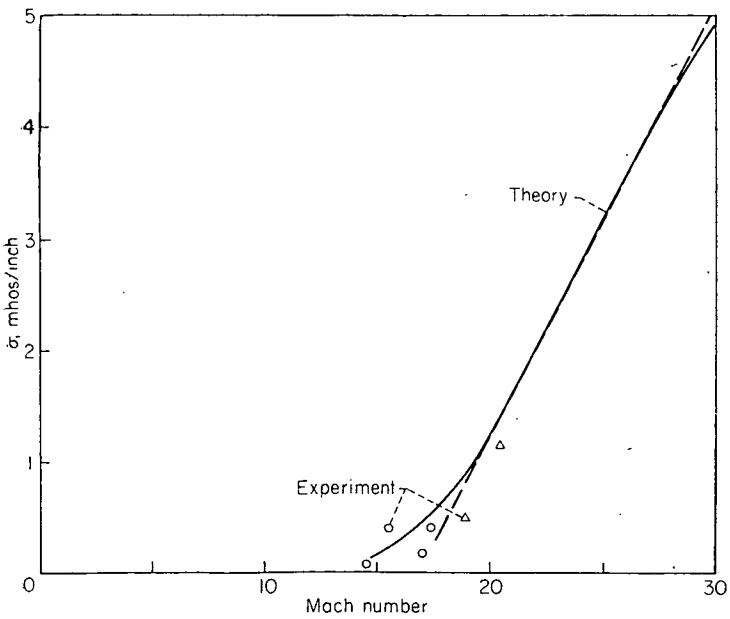

FIGURE 7.—Electrical conductivity of air as a function of shock wave Mach number as found in reference 3.

decrement and the conductivity will be chosen for this case. Therefore, it will be assumed that

$$\sigma=\sigma_o\left(\frac{u_\infty-u}{u_\infty}\right) \tag{55}$$

where σ_o is the conductivity at the surface, where $u=0$. Whether equation (55) is realistic is uncertain. Inserting the expression (55) into equation (24) gives

$$u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+\frac{m_1 u}{u_\infty}(u_\infty-u)=\nu\frac{\partial^2 u}{\partial y^2} \tag{56}$$

As before, an ordinary differential equation for each of the functions $f_2, f_4, \ldots$ results when the variables in equations (25) and (26) are inserted into equation (56) and like powers of mx are equated.

$$f_2'''=f_o'f_2'-\frac{3}{2}f_2f_o''-\frac{1}{2}f_of_2''+f_o'(1-f_o') \tag{57a}$$

$$f_4'''=2f_o'f_4'+f_2'f_2'-\frac{1}{2}f_of_4''-\frac{3}{2}f_2f_2''-\frac{5}{2}f_4f_o''+f_2'-2f_2'f_o' \tag{57b}$$

The boundary conditions are,

$f_o=f_2=f_4=\ldots=0$ when $\eta=0$

$f_o'=f_2'=f_4'=\ldots=0$ when $\eta=0$

$f_o'=1, f_2'=f_4'=\ldots=0$ when $\eta=\infty$

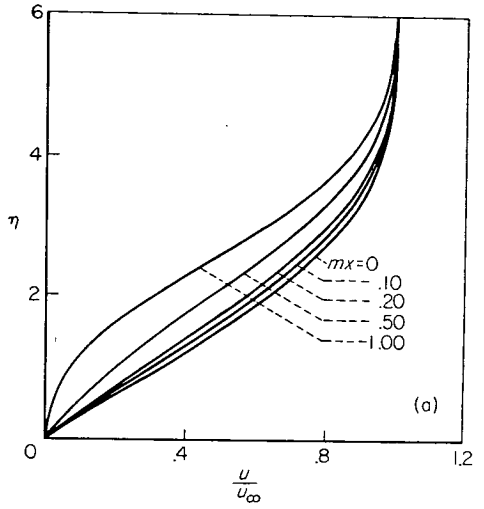
The numerical integration of equation (57a) was carried out for f_2 by the method used in the other cases and the results are tabulated in table III(a). Typical boundary-layer velocity profiles are shown in figure 8(a). The local skin-friction coefficient is

$$c_f=\frac{0.664-0.627\,mx\pm\ldots}{\sqrt{Re_x}} \tag{58a}$$

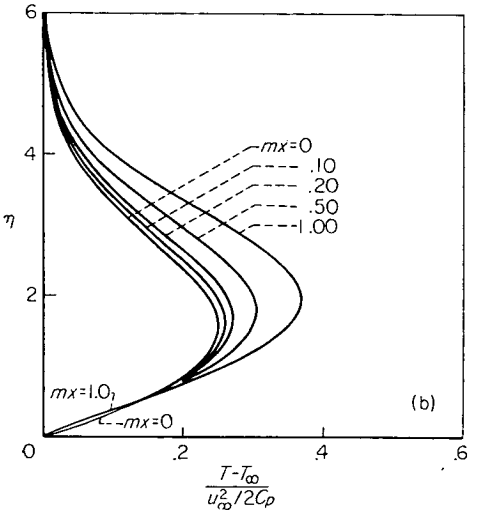
and the displacement thickness is

$$\delta^*=(1.73+0.97\,mx+\ldots)\sqrt{\frac{\nu x}{u_\infty}} \tag{58b}$$

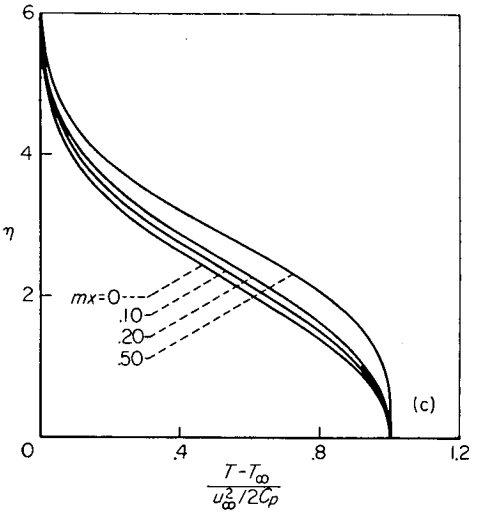
The force on the unit generating the magnetic field is expressed by



$$F=\sigma B_o^2\sqrt{u_\infty\nu x}\int_0^{\eta\to\infty}(1-f_o'-mxf_2'-\ldots)(f_o'+mxf_2'+\ldots)d\eta/\text{unit area}$$



The integral is evaluated through the use of equation (57a) and table III (a) as



$$F=\sigma B_o^2\sqrt{u_\infty\nu x}\,(0.664+0.649\,mx+\ldots)\text{lb/unit area} \tag{59a}$$

or, integrating from the leading edge to x,

$$F=\frac{2}{3}x\sigma_o B_o^2\sqrt{u_\infty\nu x}\,(0.664+0.390\,mx+\ldots)\text{lb/unit width} \tag{59b}$$

(a) Velocity.
(b) Temperature distribution for a cool wall, $T_w = T_\infty$.
(c) Temperature distribution for an insulated wall.

FIGURE 8.—Boundary-layer profiles for fluid flowing over a semi-infinite flat plate with a transverse magnetic field fixed relative to the plate-fluid of variable conductivity.

Equation (59a) or (59b) expresses a drag force on the plate which is to be added to the friction drag. In coefficient form, the local drag per unit area on the plate due to the magnetic field is

$$c_B = \frac{mx}{\sqrt{Re_x}} (1.328 + 1.299\, mx + \ldots) \tag{60a}$$

When equations (58a) and (60a) are added, the net local force coefficient to a first order in mx is

$$c_D = \frac{1}{\sqrt{Re_x}} (0.664 + 0.701\, mx + \ldots) \tag{60b}$$

The interference of the magnetic field reduces the skin friction at the expense of a higher drag.

Temperature profile.—The thermal-energy transport equation is reduced in the manner used in the previous cases. The electrical or joule heating is now described by

$$\frac{j^2}{\sigma} = \sigma_o B_o^2 \left(\frac{u_\infty - u}{u_\infty}\right) u^2$$

Equation (11) is then

$$\rho C_p u \frac{\partial T}{\partial x} + \rho v C_p \frac{\partial T}{\partial y} - \frac{\sigma_o B_o^2}{u_\infty}(u_\infty - u)u^2 = \frac{\mu C_p}{Pr}\frac{\partial^2 T}{\partial y^2} + \mu \left(\frac{\partial u}{\partial y}\right)^2 \tag{61}$$

If equation (56) is multiplied by u and added to equation (61), the resulting equation for the transport of total energy is identical with equation (36). Once again, the temperature distribution is changed but the total energy of the fluid is not altered by the presence of a magnetic field.

The change of variables ξ, η, the stream function, ψ, and temperature expansion given by equations (25), (26), and (37), respectively, are now introduced into equation (61). A set of linear ordinary differential equations for T_o, T_2, T_4, . . . is obtained for this case when like powers of mx are equated. The expression for T_o is once again the same as equation (39). The differential equation for T_2 is

$$\frac{T_2''}{Pr} + \frac{f_o T_2'}{2} - f_o' T_2 + \frac{3}{2} f_2 T_o' + \frac{u_\infty^2}{C_p}[(1 - f_o')f_o'^2 + 2f_o'' f_2''] = 0 \tag{62}$$

If it is assumed that $Pr = 1$ and the expression for T_o' is inserted into equation (62), the result is

$$T_2'' + \frac{f_o T_2'}{2} - f_o' T_2 + \frac{u_\infty^2}{C_p}\left[\frac{3}{2} f_2 f_o''\left(\frac{1}{2} - f_o'\right) + (1 - f_o')f_o'^2 + 2f_o'' f_2''\right] = 0 \tag{63}$$

Numerical integration of equation (63) was carried out by the method used for the previous cases. The results are presented in table III (b) and several temperature profiles are shown in figure 8 (b). The coefficient for the convective heat-transfer rate is given by

$$h = \frac{\rho u_\infty C_p}{2\sqrt{Re_x}} (0.664 - 0.206\, mx - \ldots + \ldots) \tag{64}$$

The influence of the magnetic field on the heat-transfer rate and skin friction is not so large in this case as in either of the two previous cases (eqs. (33a), (44b), (49a), and (53)). From these results it is apparent that the change in the heat-transfer rate and the skin friction is strongly dependent on the manner in which the conductivity (or magnetic field strength) vary through the boundary layer. A magnetic field which changes in strength with distance from the surface and a variable conductivity are to be expected in the real physical situation.

The differential equation for flow over an insulated plate is obtained by substitution of equation (46b) into equation (62).

$$T_2''+\frac{f_o T_2'}{2}-f_o' T_2-\frac{3u_\infty^2}{2C_p} f_2 f_o' f_o''+\frac{u_\infty^2}{C_p}\left[(1-f_o')f_o'^2+2f_o''f_2''\right]=0$$

The temperature profiles for several values of mx are shown in figure 8 (c) and tabulated in table III (c). As would be expected, the recovery temperature at the wall is not altered by the magnetic field because there is no relative motion between the fluid at the wall and the magnetic field.

MAGNETIC PARAMETER

UNITS

The importance of the magneto-hydrodynamic effect depends on the size of the magnetic parameter $m=\sigma B_o^2/\rho u_\infty$. The usual engineering units are: σ in mhos/inch; B_o in lines/square inch; ρ in slugs/cubic foot; and u_∞ in feet/second. If each of these quantities is expressed as such, the parameter mx will be dimensionless only if multiplied by a factor which relates the various dimensional quantities. When the correct conversion factors are inserted, reference 27,

$$m=1.529\times10^{-12}\frac{\sigma\left(\frac{\text{mhos}}{\text{in.}}\right)\left[B_o\left(\frac{\text{lines}}{\text{in.}^2}\right)\right]^2}{\rho\left(\frac{\text{slugs}}{\text{ft}^3}\right)u_\infty\left(\frac{\text{ft}}{\text{sec}}\right)}\text{ per inch} \quad (65a)$$

or

$$m=6.432\times10^{-10}\frac{\sigma\left(\frac{\text{mhos}}{\text{in.}}\right)\left[B_o\left(\frac{\text{lines}}{\text{in.}^2}\right)\right]^2}{\left(\frac{\rho}{\rho_o}\right)u_\infty\left(\frac{\text{ft}}{\text{sec}}\right)}\text{ per inch} \quad (65b)$$

where $\rho_o=0.002378$ slugs/ft^3 is the air density at sea level.

Another method of finding the conversion factor for m is to combine the electric motor equations (ref. 35)

$$F=8.8507\times10^{-8}B_o l i \text{ lb} \quad (66a)$$

$$E=B_o l u\times10^{-8}\text{ volts}=\frac{i}{\sigma l} \quad (66b)$$

so that

$$\frac{\text{Force}}{ul^3}=8.8507\times10^{-16}\sigma B_o^2\frac{\text{lb sec}}{\text{in.}^4}$$

or

$$m=\frac{\text{force}/l^3}{\rho_o(\rho/\rho_o)u^2}=\frac{(8.8507)(1728)10^{-16}}{0.002378}\frac{\sigma B_o^2}{(\rho/\rho_o)u}\text{ per inch}$$

$$=6.432\times10^{-10}\frac{\sigma B_o^2}{(\rho/\rho_o)u_\infty}\text{ per inch}$$

In words, the parameter m expresses the ratio of electromagnetic force density to dynamic pressure.

The value of m can easily vary over many orders of magnitude. However, the density ρ and velocity u associated with a particular vehicle are generally fixed within relatively narrow limits. It remains, then, to adjust the conductivity and magnetic field strength so that the desired characteristics are achieved. The limits for the magnetic field strength lie between zero and a maximum (discounting astrophysical possibilities) of about 10^5 lines/sq in. The electrical conductivity depends on the fluid considered and can vary over wide limits from very small values for insulators to approximately 10^5 mhos/inch for metals. The results of several investigations of the conductivity of gases will be discussed in the next section.

ELECTRICAL CONDUCTIVITY

The information on the electrical conductivity[6] of gases under the special conditions of this report is not large. However, it is known that the air around a missile will be a conductor if: (1) the energy imparted to the air is great enough to ionize it; (2) metal is ablated from the missile; (3) the missile is in the ionosphere where the air is ionized by radiation from the sun; or (4) other special devices are used to ionize the air, such as irradiation by high energy particles.

The electrical conductivity of air behind a normal shock wave has been measured in a shock tube and is reported on page 339 of reference 3. The results, replotted in figure 7, indicate conductivities of the order of 1 to 5 mhos/inch for air behind strong shock waves.

Firings of ultraspeed pellets, references 36 through 39, indicate that another phenomenon will enter the problem of conductivity. Photographs and spectrographs taken with special cameras show that metal is eroded or ablated from the pellet and swept off the model into the wake where it burns. Since the metal is in a liquid spray or vapor form while it is in the vicinity of the pellet, the conductivity there would be increased by a sizable amount. It would be difficult to estimate the orders of magnitude to be expected. The tests show that the air can be made a conductor by ionization of its molecules and atoms and/or by metal vapor or spray eroded from the surface of the vehicle. It is pointed out in reference 40 that the latter effect predominates when meteors enter the earth's atmosphere.

The air in the ionosphere is partially ionized by radiation from the sun so that it is a conductor without addition of energy from the aircraft. The amount of ionization at various altitudes and the total number of particles are listed in tables 2 and 9 of reference 41. A rough estimate of the conductivity is found from reference 7 as

$$\sigma=\frac{ne^2l_e}{m_eU_e}\approx 3\times 10^{-16}\, n\,\frac{N_o}{N}\ \text{mhos/inch} \qquad (67)$$

[6] Good electrical conductors are always good heat conductors. The ratio may be expressed approximately as (ref. 7),

$$\frac{k}{\sigma T}=\frac{\pi^2}{3}\left(\frac{\kappa}{e}\right)^2$$

where k is the coefficient of thermal conductivity, κ is Boltzmann's constant, and e is the charge on an electron

where e, l_e, m_e, and U_e are the charge, mean free path length, mass, and velocity, respectively, of the electron and N_o and N are the particle density at sea level and the altitude in question. The factor n is the electron density. The values for σ range from 10^{-4} mhos/in. at 62 miles altitude to about 32 mhos/in. at 250 miles altitude.

The large variety in fuels makes it difficult to bracket the magnitude of the conductivity of combustion products but information is available for several cases. It was reported in reference 5 that the conductivity of the jet from a 50-pound thrust acid-aniline rocket motor was measured as being about 10^{-6} mhos/in. It was added, however, that the addition of a small amount of an impurity such as sodium would strikingly increase the electron density.

A discussion is given in reference 6 of similar experiments and theory on the combustion of hydrocarbon fuels. The experimental evidence required that the number of electrons in the combustion products (10^{11} to 10^{14} per cc) be several orders of magnitude greater than predicted theoretically (10^8 to 10^9 per cc). The maximum conductivity can be estimated by equation (67) to be roughly 10^{-2} mhos/inch.

Although the conductivities discussed are low compared with those of metals, they appear to be large enough so that appreciable magneto-hydrodynamic forces can be exerted. If the conductivity is too low for a specific case, it may be possible that alkaline salts or some other additive can be used to increase the number of free electrons and ions.

APPLICATIONS

The possibility of using a magnetic field to prevent a hot fluid from coming in contact with a wall which it would dissolve or destroy was discussed in the introduction. The extent to which this can be accomplished is measured directly by the parameter $m=(\sigma B_o^2/\rho u_\infty)$. The larger the parameter m is, the more effectively the "fluid suspension" process can be carried out. The influence of the magnetic field on the fluid is expressed in equations (33), (44), (49), (53), (58), . . . by the product mx. The distance x represents an "adjustment distance" required before the fluid responds a given amount or adjusts to the magnetic lines of force. If the magnetic parameter is very large, the adjustment distance will be very small and the fluid will follow the magnetic lines of force quite closely as indicated in figure 9. The magnetic force restrains any motion across the lines of force because the inertia forces are insignificant in comparison. In this limit the magnetic lines of force are the same as invisible solid boundaries.

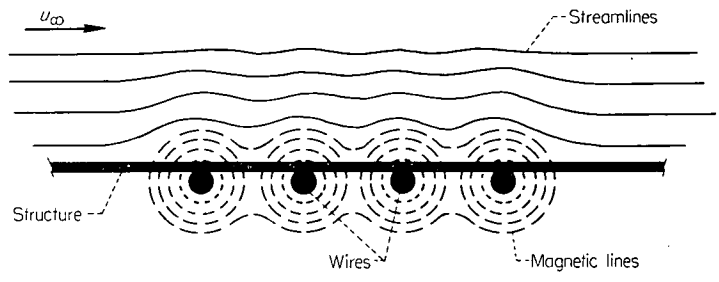

FIGURE 9.—Sketch of fluid of high electrical conductivity flowing over a surface.

If the parameter m is very small the adjustment distance x becomes very large and the influence of the magnetic field becomes negligible.

The numbers quoted in the last section for the conductivity and field strength indicate that most of the applications will lie between the two extreme limits.

FLOW OVER A HIGH-SPEED VEHICLE

Magneto-aerodynamic effects may be used to alter the external flow over aircraft. Examples which illustrate the changes in the boundary layer will now be discussed. It will be pointed out that the skin friction on an aircraft might be reduced by judicious use of a magnetic field either to inhibit transition to turbulent flow or to alter the boundary-layer profile.

It has been shown in reference 13 that the Reynolds number of transition is raised when a coplanar magnetic field is applied. The results of reference 13 can be used as a rough estimate for flows of the boundary-layer type when the particular velocity distribution may be approximated by a parabolic profile. This is permissible since a coplanar magnetic field does not change the velocity profile, which is not so for the cases considered in this paper.

The results of reference 14 for a transverse magnetic field apply to a two-dimensional channel and should not be used for flows of the boundary-layer type because of the change induced by the magnetic field on the velocity profile. For the flow in the two-dimensional channel the change in the velocity profile was largely responsible for the resistance to turbulence. The same will not always be true for other types of flow fields. It will then in general be necessary to carry out a stability calculation in order to determine whether a transverse magnetic field tends to stabilize or destabilize the boundary layer. A situation wherein the magnetic field destabilizes the flow field is presented in reference 26, warning one that the presence of a magnetic field does not always decrease the likelihood of transition.

The numerical results of table I and the equations (33) and (44) may be used to estimate the effects of a magnetic field attached to an aircraft on boundary layers of uniform electrical conductivity. The model analyzed theoretically will probably never be duplicated in a physical situation. However, circumstances may arise wherein the conductivity and magnetic field are such that they vary only slightly or are almost uniform in a layer of finite depth. This might occur, for example, (1) in the boundary layer of high-speed aircraft; (2) in the region between the surface of a blunt body and its shock wave; (3) in local regions near an aircraft when material is being ablated from the surface; or (4) in the ionosphere wherein air is ionized by radiation from the sun (ref. 41) and is then a uniform conductor, provided the influence of the aircraft is small. The fact that the layer is of finite thickness causes the equations to be in error at the interface. However, if the conducting layer is relatively thick the equations would serve as a good estimate in the vicinity of the surface.

The second semi-infinite flat plate case which was analyzed, equations (49) and (53), could be thought to correspond to flight over the magnetic poles of the earth or through some other magnetic field. The electrically conducting fluid could come about by the same processes mentioned in the previous paragraph. As before, the magnetic field strength and electrical conductivity will probably not correspond exactly to the model analyzed. A close approximation is obtained when an aircraft flies through the ionosphere over one of the magnetic poles of the earth (provided the influence of the aircraft on the electrical conductivity of the air and on the magnetic field is small). Since the earth's magnetic field is small ($B_o \approx 4$ lines/sq in. from ref. 42), effects of this type are generally negligible in the lower reaches of the ionosphere. At the higher altitudes the magnetic parameter is large enough to cause a change in the heat-transfer rate but at those altitudes the mean free path is so large that the continuum flow analysis of this report is no longer applicable.

If the air in the boundary layer is ionized by frictional heating, the conductivity of the air will change with distance from the surface (fig. 10). The actual variation to be expected would be difficult to predict theoretically. The

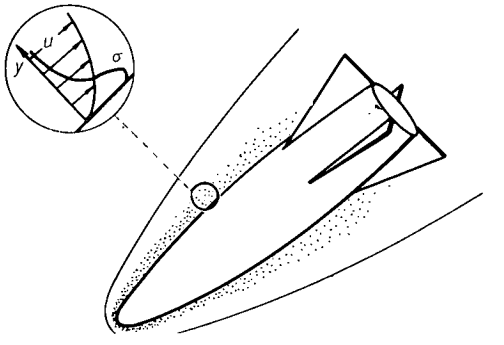

FIGURE 10.—Aircraft moving through the atmosphere at high speed.

solution for a boundary layer with variable electrical conductivity found in a previous section of this paper (eqs. (58), (59), (60), and (64)) and tabulated in table III can be used as an approximate answer. Equation (58) shows that the skin friction can be reduced by a sizable amount at the expense of increased total drag (see eq. (60)). The advantages of using a magnetic field lie in the possibility of reducing the aerodynamic heating, as expressed by equation (64).

The preceding discussion dealt with the advantages that may be achieved by reducing the skin friction, heat transfer, or turbulence. Favorable effects may also be obtained by increasing the displacement thickness of the boundary layer. Such a device, figure 11, could be used on the lower surface of a wing or body to induce forces for lift, control purposes, or drag. The magnitude of these forces is easily changed by increasing or decreasing the field strength which in turn increases or decreases the displacement thickness.

Several additional problems arise when magneto-hydrodynamic effects are used. The system generating the magnetic field will need to be cooled since its parts will dissipate power. Also, the weight of the unit required to generate a magnetic field of sufficient strength may be too large to consider, or of such a size that any advantages are nullified. If the slow moving fluid is hot enough to radiate energy, a sizable quantity of heat may be transferred even though the hot fluid is not in contact with the surface. An

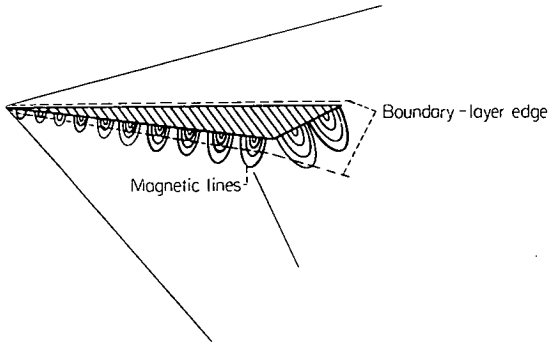

FIGURE 11.—Schematic diagram indicating use of magnetic field to build up the boundary layer on a wing for lift or control purposes.

evaluation of this effect would require a more complete analysis than the solutions developed in this paper.

Whether the applications just discussed can actually be made depends on the magnitude of the quantities entering the parameter m. Consider, for example, an aircraft moving through the upper atmosphere at 25,000 feet per second. From figure 7, a conductivity of not over 5 mhos/inch is to be expected. If ρ/ρ_o is taken as 10^{-4}, and the above values are inserted into equation (65b),

$$m=6.43\times10^{-10}\frac{5B_o^2}{2.5}\approx10^{-9}B_o^2$$

In figures 5, 6, and 8, it is seen that the product mx should be of the order of 0.1 for a notable magneto-aerodynamic effect to be brought about. If x is taken as about 100 inches, the magnetic field strength, B_o, should be around 1000 lines per square inch so that the product mx is equal to 0.1. A magnetic field of such a strength is not unreasonable.

FLOW IN PROPULSION UNITS

The discussion on the reduction of skin friction and heat-transfer rate to the walls of an aircraft by electromagnetic forces applies as well to the internal flow of reaction engines. It may be added that a uniform magnetic field across the jet stream corresponds to the channel flow problems studied in references 8 to 12 and 14. In general, imposing such a field increases the skin friction, equation (49a), and lowers the thrust because of the interference of the magnetic field. A compensating influence is realized through a reduction in turbulence in the stream (see, e. g., refs. 9 and 14) which lowers the skin friction, heat transfer, and probably the noise level of jet engines. Shallow magnetic fields appear to be the most promising for reducing the heat transfer if the flow is nearly laminar.

The cases and illustrations considered so far have assumed that an electric potential E has not been applied across the fluid. To do so would add another force term (see eq. (2)) to equations (7) and (11). If a source of power is available, a combined electric and magnetic field can be used to maneuver the fluid. A possible application would be to use the combined fields to induce an electric motor action to obtain very high exhaust velocities.

CONCLUDING REMARKS

The laminar boundary-layer solutions presented in this paper for the flow of an incompressible electrically conducting fluid over a flat plate indicate the changes that will be brought about by a transverse magnetic field. It has been found that the skin friction and heat-transfer rate are reduced if there is no relative motion between the plate and the magnetic field. The skin friction and heat-transfer rate increased in the case where relative motion was assumed. In all the cases studied the total drag was increased.

The product of the magnetic parameter m and an adjustment distance x is the quantity which determines the effectiveness of the magnetic field to change the heat-transfer rate. Other studies have shown that a magnetic field will in certain cases inhibit transition to turbulent flow and thereby retain a lower heat-transfer rate.

All the cases studied, except one, assume that the conductivity and magnetic field did not change with distance from the surface. A more realistic case of a variable conductivity was considered in one example where a special variation was chosen. The reduction in heat-transfer rate and skin friction for a given value of mx was not as large as when the conductivity was constant. This points out the importance of considering the way in which the conductivity and magnetic field strength change with distance from the surface.

REPORT 1359

THIN AIRFOIL THEORY BASED ON APPROXIMATE SOLUTION OF THE TRANSONIC FLOW EQUATION [1]

By JOHN R. SPREITER and ALBERTA Y. ALKSNE

SUMMARY

The present paper describes a method for the approximate solution of the nonlinear equations of transonic small disturbance theory. Although the solutions are nonlinear, the analysis is sufficiently simple that results are obtained in closed analytic form for a large and significant class of nonlifting airfoils. Application to two-dimensional flows with free-stream Mach number near 1 leads, for instance, to general expressions for the determination of the pressure distribution on an airfoil of specified geometry and for the shape of an airfoil having a prescribed pressure distribution and gives, furthermore, the correct variation of pressure with Mach number at Mach number 1. For flows that are subsonic everywhere, the method yields a pressure-correction formula that is more accurate than the Prandtl-Glauert rule and compares favorably with existing higher approximations. For flows that are supersonic everywhere, the method yields the equivalent, in transonic approximation, of simple wave theory. Results obtained by application of these general expressions are shown to correspond closely to existing solutions and to experimental data for a wide variety of airfoils.

INTRODUCTION

The difficulty of solving the nonlinear equations of motion of a compressible inviscid gas has led to widespread use of approximate methods in the practical solution of the problems of airfoil theory. The simplest and most versatile approximate method is that based on a complete linearization of the equations and stems from the pioneering work of Munk, Prandtl, Glauert, Ackeret, and others (see refs. 1 and 2 for a résumé). Although this linear theory of compressible flow has been extensively developed in recent years and is widely used in aeronautical applications, it has two limitations that are of significance in the present discussion. First, linearized theory gives only a first approximation that is correct for airfoils of small thickness ratio. This limitation is, in some respects, of continually diminishing significance as the aeronautical engineer is forced to use thin wings and slender bodies to avoid heavy penalties in wave drag. If the airfoil is not sufficiently thin, however, corrections are necessary and higher order theories have been developed to fill the need (see ref. 3 for a résumé). Second, and more important for the present discussion, linearized theory requires, in general, that the Mach number be sufficiently removed from unity that the flow is either purely subsonic or purely supersonic. If both subsonic and supersonic velocities occur in different parts of a single flow field, the flow is said to be transonic and the results of neither linear theory nor the existing higher order theories are, even qualitatively, in agreement with the experimentally observed flows.

Transonic flows have been studied successfully by consideration of a simplified, although still nonlinear, theory that was originally conceived in an effort to provide a useful first approximation for the pressures and forces on thin wings and slender bodies in inviscid flows with free-stream Mach number very near unity (see ref. 4 for a short résumé). More recent developments described in references 5, 6, 7, 8, and elsewhere have shown that the useful range of this theory can be extended to include subsonic and supersonic flows if slightly different approximations are employed in the derivation of the fundamental equations. Although the resulting theory is commonly designated as transonic small disturbance theory, or more briefly as transonic flow theory, it is actually a unified theory for subsonic, supersonic, or transonic flow around thin wings and slender bodies, and is moreover, the simplest theory proposed to date that is capable of yielding reliable results throughout that Mach number range.

This formulation of transonic flow theory provides a set of equations that differs from that of linear theory by the addition of one nonlinear term in the differential equation for the perturbation potential and in the shock relation. If the flow is purely subsonic or purely supersonic, solutions of the equations of transonic flow theory can be sought by application of existing methods for approximating the solutions of the exact equations of compressible inviscid flow. If the flow is transonic, however, the results obtained by application of these methods are at wide variance with those observed experimentally and it is necessary to devise new and appropriate methods of solution. Although methods of the successive approximation type have recently been developed that can be applied to transonic flows (e. g., refs. 9 and 10), the principal method that has been employed in the theoretical analysis of such flows involves the use of the hodograph transformation by means of which the nonlinear equation for the perturbation potential is transformed into a linear differential equation of mixed elliptic-hyperbolic type, the Tricomi equation. Although the resulting boundary-value problem is still very difficult to solve, this method has been applied with considerable success in the study of transonic flow around wedge and flat-plate airfoils and a

[1] Supersedes NACA TN 3970 by John R. Spreiter and Alberta Y. Alksne, 1957.

number of specific results have been given in recent years by Guderley and Yoshihara, Vincenti and Wagoner, Cole, and others (see ref. 11 for a résumé). Extension of this method to permit calculation of transonic flows around arbitrary airfoils with curved boundaries appears, however, to be a difficult task.

The present analysis is based on a novel method of approximation that avoids most of the difficulties of existing procedures while still preserving much of the nonlinear effects in the solution. Sufficient simplicity is gained by restricting attention to surface pressures and to flows that are either purely subsonic, purely supersonic, or have a free-stream Mach number near 1, that results can be obtained in closed analytical form for both the direct problem of calculating the pressure distribution on an airfoil of given shape, and the inverse problem of calculating the shape of an airfoil associated with a given pressure distribution. Inasmuch as the magnitude of the errors introduced by use of the approximation procedures is not evaluated in all cases by mathematical considerations, the usefulness and accuracy of the results are demonstrated by the calculation of the pressure distribution and drag for many different airfoil shapes and by comparison with existing theoretical and experimental results.

Of the theoretical results available for comparison, only two are exact. They are the simple-wave solution for supersonic flows without shock waves, and the variation of pressure with Mach number at Mach number 1. The present method yields both of these results exactly within the framework of transonic small disturbance theory.

Although the existing results mentioned above for wedge airfoils at Mach number 1 contain certain approximations beyond those implicit in the use of the equations of transonic flow theory, the influence of these approximations appears to be minor and the results are generally considered to be very nearly exact solutions of these equations. The present method produces results for this case that are in substantial agreement with these previous theoretical results. In contrast to the hodograph methods, the necessary steps are sufficiently simple, moreover, that results can also be obtained for sonic and near sonic flow around arbitrary airfoils with curved boundaries. Since previous theoretical information for such cases is meager, comparisons are made with a large number of experimental results. In general, the theoretical results found by application of the present method lie within the range of experimental scatter of the data.

In the subsonic range, no exact solutions are available for flow around a thin airfoil. Comparisons are made, therefore, with pressure correction formulas, such as that of Kármán-Tsien, and with higher approximations obtained by iteration methods.

A simple heuristic account of the general method and extensive discussion of the results are contained in the main text. Additional details concerning the underlying basis for the general procedures are contained in the Appendix.

PRINCIPAL SYMBOLS

a	speed of sound
a_∞	speed of sound in the free stream
C_p	pressure coefficient, $\frac{p-p_\infty}{\frac{\rho_\infty}{2}U_\infty^2}$
$\overline{C}_p$	$\frac{[M_\infty^2(\gamma+1)]^{1/3}}{\tau^{2/3}}C_p$
c	chord
c_d	section pressure drag coefficient, $\frac{d}{\frac{\rho_\infty}{2}U_\infty^2 c}$
$\bar{c}_d$	$\frac{[M_\infty^2(\gamma+1)]^{1/3}}{\tau^{5/3}}c_d$
d	pressure drag
k	$\frac{M_\infty^2(\gamma+1)}{U_\infty}$
M	local Mach number
M_∞	free-stream Mach number
n	exponent in the relations for airfoil ordinates given by equations (56) and (61)
p	static pressure
p_∞	free-stream static pressure
q	resultant local velocity
t	maximum thickness of profile
U_∞	free-stream velocity
u,w	perturbation velocity components parallel to x and z axes, respectively
u_E	value of u obtained by solution of equation (21)
u_H	value of u obtained by solution of equation (8)
u_P	value of u obtained by solution of equation (39)
X	value of x at which parabolic and hyperbolic solutions are joined
x,z	Cartesian coordinates where x extends in the direction of the free-stream velocity
x^*	value of x at which the local velocity is sonic
Z	ordinates of the upper surface of the airfoil
Γ	gamma function
γ	ratio of specific heats, for air $\gamma=1.4$
θ	semiapex angle of wedge airfoil
Λ	pressure gradient, $\frac{dC_p}{d(x/c)}$
λ_E	$1-M_\infty^2-ku$
λ_H	M_∞^2-1+ku
λ_P	$k\frac{\partial u}{\partial x}$
ξ_∞	$\frac{M_\infty^2-1}{[M_\infty^2(\gamma+1)\tau]^{2/3}}$
ρ_∞	free-stream density of air
τ	thickness ratio, t/c
φ	perturbation velocity potential

SUBSCRIPTS

cr	values associated with critical Mach number
i	values associated with incompressible flow or with $M_\infty=0$
L	values given by linearized compressible flow theory

$M_\infty=1$ values associated with $M_\infty=1$

$\xi_\infty=0$ values associated with $\xi_\infty=0$, or with $M_\infty=1$

FUNDAMENTAL EQUATIONS AND BOUNDARY CONDITIONS

Consider the steady flow of an inviscid compressible gas past an arbitrary thin symmetrical nonlifting airfoil, and introduce Cartesian coordinates x and z with the x axis parallel to the direction of the free-stream, as illustrated in figure 1.

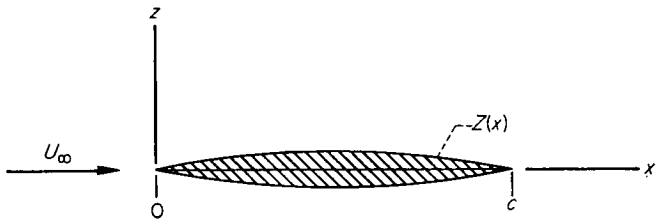

FIGURE 1.—View of airfoil and coordinate system.

Let the free-stream velocity and density be U_∞ and ρ_∞, the perturbation potential be φ, and the perturbation velocity components parallel to the x and z axes be φ_x, or u, and φ_z, or w, where the subscript indicates differentiation. The boundary conditions require that the perturbation velocities vanish at infinity, and that the flow be tangential to the wing surface. The first condition indicates that φ is constant at infinity. The latter condition can be approximated for thin wings by

$$(\varphi_z)_{z=0}=U_\infty \frac{dZ}{dx} \tag{1}$$

where Z represents the ordinates of the airfoil upper surface. The pressure coefficient C_p is likewise approximated to first order by

$$C_p\equiv\frac{p-p_\infty}{\frac{\rho_\infty}{2}U_\infty^2}=-2\frac{\varphi_x}{U_\infty}=-2\frac{u}{U_\infty} \tag{2}$$

These relations are familiar from linear theory, but apply equally for transonic thin airfoil theory. The differential equation for φ is not the same as in linear theory, however, but is

$$\left(1-M_\infty^2-M_\infty^2\frac{\gamma+1}{U_\infty}\varphi_x\right)\varphi_{xx}+\varphi_{zz}=0 \tag{3}$$

where M_∞ is the Mach number of the undisturbed flow and γ is the ratio of specific heats (1.4 for air). It is useful to note that the coefficient of φ_{xx} corresponds, in the present approximation, to $1-M^2$ where M is the local Mach number.

Knowledge of methods for obtaining solutions of equation (3) is meager, not only because the equation is nonlinear, but because it can change type (elliptic, hyperbolic), depending on the value of M_∞ and φ_x. This change of type is an essential feature of transonic flow, since subsonic flows are represented by elliptic equations and supersonic flows by hyperbolic equations. If both types of flow occur in a single flow field, it is apparent that the differential equation must change type. In the present case, the type of the equation is recognized by the sign of the total coefficient of φ_{xx}, as follows:

$$1-M_\infty^2-M_\infty^2\frac{\gamma+1}{U_\infty}\varphi_x\begin{cases}>0 & \text{elliptic (subsonic)}\\ <0 & \text{hyperbolic (supersonic)}\end{cases} \tag{4}$$

An important quantity in the discussion of compressible flows is the critical pressure coefficient $C_{p_{cr}}$ associated with the local occurrence of sonic velocity. The appropriate relation is found by combination of equation (2) and the relation obtained by equating the coefficient of φ_{xx} in equation (3) to zero, and is

$$C_{p_{cr}}=-\frac{2(1-M_\infty^2)}{M_\infty^2(\gamma+1)} \tag{5}$$

In transonic and supersonic flows, it is also necessary, in general, to provide an additional equation for the discontinuous changes in velocity that occur at shock surfaces. The necessary equations, when simplified to the form consistent with the approximations of transonic flow theory, reduce to

$$\left.\begin{aligned}&\left[1-M_\infty^2-M_\infty^2\frac{\gamma+1}{U_\infty}\left(\frac{u_a+u_b}{2}\right)\right](u_a-u_b)^2+(w_a-w_b)^2=0\\ &\varphi_a=\varphi_b\end{aligned}\right\} \tag{6}$$

where the subscripts a and b refer to the values on the two sides of the shock surface. With the exception of the Appendix and minor references in the main text, equation (6) is not employed explicitly in the following analysis and discussion because attention is confined to (a) purely subsonic flows in which no shocks occur, (b) purely supersonic flows in which shock waves can be approximated with good accuracy by isentropic compressions, and (c) flows with free-stream Mach number near 1 in which the shock waves are situated either downstream or far upstream of the airfoil.

The remainder of the present paper is concerned with the approximate solution of the preceding equations and with comparison of the results obtained in specific applications with existing theoretical and experimental results. Purely supersonic flows are discussed first because the method of approximation yields the exact equivalent, in transonic approximation, of simple wave theory. Purely subsonic flows are discussed next because of the close relationship between the results for this and the preceding case. Flows with free-stream Mach number near 1 are treated last.

SUPERSONIC FLOWS

APPROXIMATE SOLUTION OF EQUATIONS

It is convenient in the analysis of supersonic flows to introduce the symbol λ_H as an abbreviation for the negative of the coefficient of φ_{xx}

$$\lambda_H=M_\infty^2-1+M_\infty^2\frac{\gamma+1}{U_\infty}\varphi_x=M_\infty^2-1+ku>0 \tag{7}$$

and rewrite equation (3) in the form:

$$-\lambda_H\varphi_{xx}+\varphi_{zz}=0 \tag{8}$$

It is now assumed that λ_H is neither zero nor infinite and that it varies sufficiently slowly that its derivatives can be disregarded so that it can be considered, temporarily, as a constant. At this stage, the problem is equivalent to that encountered in linearized supersonic airfoil theory (it is identical if λ_H is replaced by M_∞^2-1) and the solution u_H at the airfoil surface is

$$u_H=-\frac{U_\infty}{\sqrt{\lambda_H}}\frac{dZ}{dx} \tag{9}$$

Differentiation yields

$$\frac{du_H}{dx}=-\frac{U_\infty}{\sqrt{\lambda_H}}\frac{d^2Z}{dx^2} \tag{10}$$

If, now, M_∞^2-1+ku is restored in place of λ_H so that, in effect, the local value for λ_H is used at each point and the subscript H on u is dropped, equation (10) becomes

$$\frac{du}{dx}=-\frac{U_\infty}{\sqrt{M_\infty^2-1+ku}}\frac{d^2Z}{dx^2} \tag{11}$$

It is immediately apparent that a certain degree of arbitrariness is displayed in the preceding steps and that different results will be obtained depending, for instance, on whether M_∞^2-1+ku is substituted for λ_H in equation (10) as above, or in equation (9), or in other equations obtained by further differentiation or integration of equation (9). It is shown in the Appendix, however, that the error involved in the preceding steps can be assessed exactly by examination of the remainder terms that have been omitted in writing equations (9) and (10). The advisability of using equation (11) is assured by the fact that the error is shown to vanish, in the absence of shock waves, if λ_H is replaced by M_∞^2-1+ku in equation (10), but not in equation (9). This conclusion becomes immediately evident, furthermore, upon recognition of the fact that equation (11) is the counterpart, in transonic small disturbance theory, of a fundamental differential equation that occurs in the analysis of Prandtl-Meyer and simple wave flows (see, e. g., ref. 12, p. 87 or ref. 13, pp. 190 and 212). Equation (11) is a nonlinear ordinary differential equation for u that can be solved easily by separation of variables. The result is

$$\frac{2}{3k}\left(M_\infty^2-1+ku\right)^{3/2}=-U_\infty\frac{dZ}{dx}+C \tag{12}$$

where C is a constant of integration. In applications of equation (12) to flows that are supersonic everywhere, perhaps the most logical method for the evaluation of this constant is to use the expression between u and dZ/dx provided at the leading edge by the transonic approximation to the shock relation, that is by equation (6) with u_a and w_a equated to zero, u_b to $(u)_{x=0}$, and w_b to $U_\infty(dZ/dx)_{x=0}$. The result given by equation (12) with C evaluated in this way corresponds, to the degree of approximation afforded by use of transonic small disturbance theory, to shock-expansion theory. An alternative procedure that leads to a somewhat simpler result possessing very nearly equal accuracy is to evaluate C by use of the result indicated by equation (9) that $u=0$ where $dZ/dx=0$ for any nonsingular λ_H thus

$$C=\frac{2}{3k}(M_\infty^2-1)^{3/2} \tag{13}$$

whence

$$u=\frac{1}{k}\left\{-(M_\infty^2-1)+\left[(M_\infty^2-1)^{3/2}-\frac{3}{2}kU_\infty\frac{dZ}{dx}\right]^{2/3}\right\} \tag{14}$$

The corresponding relation for the pressure coefficient C_p is obtained by combination of equations (2) and (14), and is

$$C_p=\frac{2}{M_\infty^2(\gamma+1)}\left\{(M_\infty^2-1)-\left[(M_\infty^2-1)^{3/2}-\frac{3}{2}M_\infty^2(\gamma+1)\frac{dZ}{dx}\right]^{2/3}\right\} \tag{15}$$

It should be noted that the restriction to supersonic flow imposed in the evaluation of C and in the inequality of equation (7) requires that equation (15) is to be applied only to cases for which the quantity in square brackets, that is, $[(M_\infty^2-1)^{3/2}-(3/2)M_\infty^2(\gamma+1)\ (dZ/dx)]$, is positive.

COMPARISON WITH EXISTING HIGHER APPROXIMATIONS

Equation (15) is recognized, by comparison with equation (3-15) of reference 3, page 387,[2] as the precise equivalent, in the transonic small disturbance approximation, of simple wave theory for the surface pressure on an airfoil in supersonic flow. Exact simple wave theory is known, moreover, to be perfectly adequate for all practical purposes up to a Mach number of 3, which is considerably in excess of the present range of interest. Within this Mach number range, the results obtained by use of simple wave theory are almost identical with those obtained by use of shock-expansion theory. Comparisons of the variations of C_p with dZ/dx indicated by exact simple wave theory and by equation (15) are shown in figure 2 for several Mach numbers from 1 to 2. As might be anticipated, the two sets of results are in close agreement for Mach numbers near 1, and differ by an increasing amount with increasing Mach number.

Although the necessary calculations are very easy to accomplish in any given case, simple wave theory is not always used in actual practice. Many calculations are based on linear theory or Busemann's second-order theory. Consequently, an additional set of graphs is shown in figure 3 in which the curves of figure 2 are repeated together with the corresponding curves calculated by use of first- and second-order theory. No comparisons are shown for $M_\infty=1$ because the latter theories indicate infinite pressures. It can be seen that equation (15) furnishes a better approximation than linear theory throughout the entire range of variables shown on figure 3 and a better approximation than second-order theory for Mach numbers less than about 1.4. It can be

[2] Comparison discloses that the quantity $M_\infty^2(\gamma+1)$ that appears in equation (15) is represented by $\gamma+1$ in equation (3-15) of reference 3. The difference is associated with a corresponding difference in the coefficient k of the nonlinear term of equation (3). Although the two coefficients are identical at $M_\infty=1$, and might appear to be equally consistent with the other assumptions of transonic flow theory, it has been shown in references 5, 6, 7, 8, and elsewhere that the approximation obtained by use of $M_\infty^2(\gamma+1)$ is much the better of the two for Mach numbers other than 1.

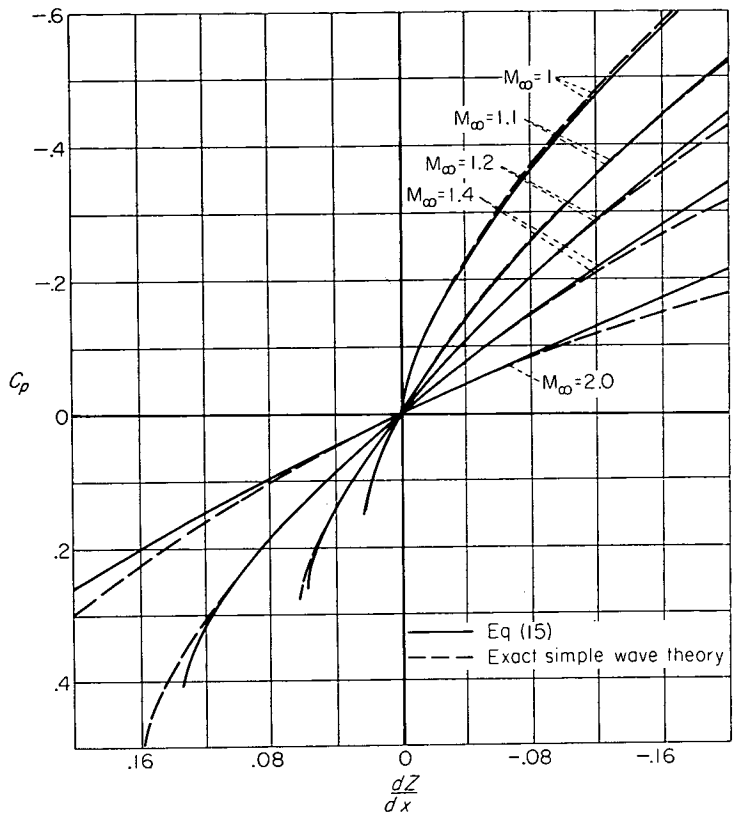

FIGURE 2.—Comparison of results indicated by present theory and by exact simple wave theory.

seen that second-order theory furnishes a very poor approximation for C_p at Mach numbers approaching unity.

In order to explore this behavior further, two additional curves labeled "third order" and "fourth order," calculated using the formulas of references 14 and 15,[3] are included on the graph of figure 3, even though they must be interpreted in a somewhat more restricted sense than the other curves. To be more precise, the third-order curve is restricted to airfoils for which dZ/dx is zero at the leading edge, and the fourth-order curve to airfoils for which both dZ/dx and d^2Z/dx^2 are zero there. It is clear from this sketch that the accuracy of second-order theory at Mach numbers near unity is not improved by addition of higher order terms. The explanation resides in the fact that the larger values of $|dZ/dx|$ shown on the graphs of figure 3 exceed the radius of convergence of the power series expansion for C_p for all but the highest Mach number shown. With the noted restrictions on the leading edge, the higher order results of figure 3 are equivalent to the first few terms of a power series expansion, in terms of dZ/dx, of the expression for C_p indicated by exact simple wave theory. The radius of convergence of the series depends, of course, on the Mach number and is given by the value of $|dZ/dx|$ associated with the occurrence of sonic flow or, in terms of the curves shown on figures 2 and 3, with the termination of the left end of the exact curve. The failure of higher order theories at negative dZ/dx is thus of purely mathematical origin and has no direct physical significance.

[3] Attention of those who refer to reference 15 is called to the fact that the first term appearing in the fourth-order coefficient a_4 of equation (29) should be 2/3 rather than 1/3. This term is written correctly in the numerical example given in equation (135).

ADDITIONAL PROPERTIES OF APPROXIMATE SOLUTION

Equation (15) has some additional interesting properties worth noting. Of the two major components of the right-hand side, the first is recognized upon comparison with equation (5) as the expression for $C_{p_{cr}}$. Since the remaining term is zero when $C_p=C_{p_{cr}}$, it follows that the expression for the critical value for dZ/dx associated with the occurrence of sonic velocity at a given Mach number M_∞ is

$$\left(\frac{dZ}{dx}\right)_{cr}=\frac{2(M_\infty^2-1)^{3/4}}{3M_\infty^2(\gamma+1)} \tag{16}$$

It follows, furthermore, that a curve representing the variation of C_p with M_∞ for a given dZ/dx, and hence a given point on the airfoil, approaches infinite slope as C_p approaches $C_{p_{cr}}$.

An alternative form for equation (15) that is useful for some purposes is the following which expresses C_p in terms of the linear-theory solution C_{p_L} rather than dZ/dx.

$$C_p=\frac{2(M_\infty^2-1)}{M_\infty^2(\gamma+1)}\left\{1-\left[1-\frac{3}{4}\frac{M_\infty^2(\gamma+1)}{M_\infty^2-1}C_{p_L}\right]^{4/3}\right\} \tag{17}$$

where

$$C_{p_L}=\frac{2}{\sqrt{M_\infty^2-1}}\frac{dZ}{dx}$$

This relation can be written in somewhat more concise form if expressed in terms of the transonic similarity parameters $\overline{C}_p$ and ξ_∞, thus

$$\overline{C}_p=2\xi_\infty\left[1-\left(1-\frac{3}{4}\frac{\overline{C}_{p_L}}{\xi_\infty}\right)^{4/3}\right] \tag{18}$$

where

$$\overline{C}_p\equiv\frac{[M_\infty^2(\gamma+1)]^{1/4}}{\tau^{3/4}}C_p, \qquad \xi_\infty\equiv\frac{M_\infty^2-1}{[M_\infty^2(\gamma+1)\tau]^{2/3}}$$

and τ refers to the thickness ratio. Critical values for $\overline{C}_p$ and $\overline{C}_{p_L}$ corresponding to the local occurrence of sonic velocity are easily recognized to be the following:

$$\overline{C}_{p_{cr}}=2\xi_\infty, \qquad \overline{C}_{p_{L_{cr}}}=\frac{4}{3}\xi_\infty \tag{19}$$

SUBSONIC FLOWS

APPROXIMATE SOLUTION OF EQUATIONS

The procedure described in the preceding section will now be applied to the analysis of subsonic flows. Thus, introduce the symbol λ_E as an abbreviation for the coefficient of φ_{xx}

$$\lambda_E=1-M_\infty^2-M_\infty^2\frac{\gamma+1}{U_\infty}\varphi_x=1-M_\infty^2-ku>0 \tag{20}$$

and rewrite equation (3) as follows:

$$\lambda_E\varphi_{xx}+\varphi_{zz}=0 \tag{21}$$

If it is again assumed that λ_E is neither zero nor infinite and that it varies sufficiently slowly that its derivatives can be disregarded, the problem is equivalent to that encountered

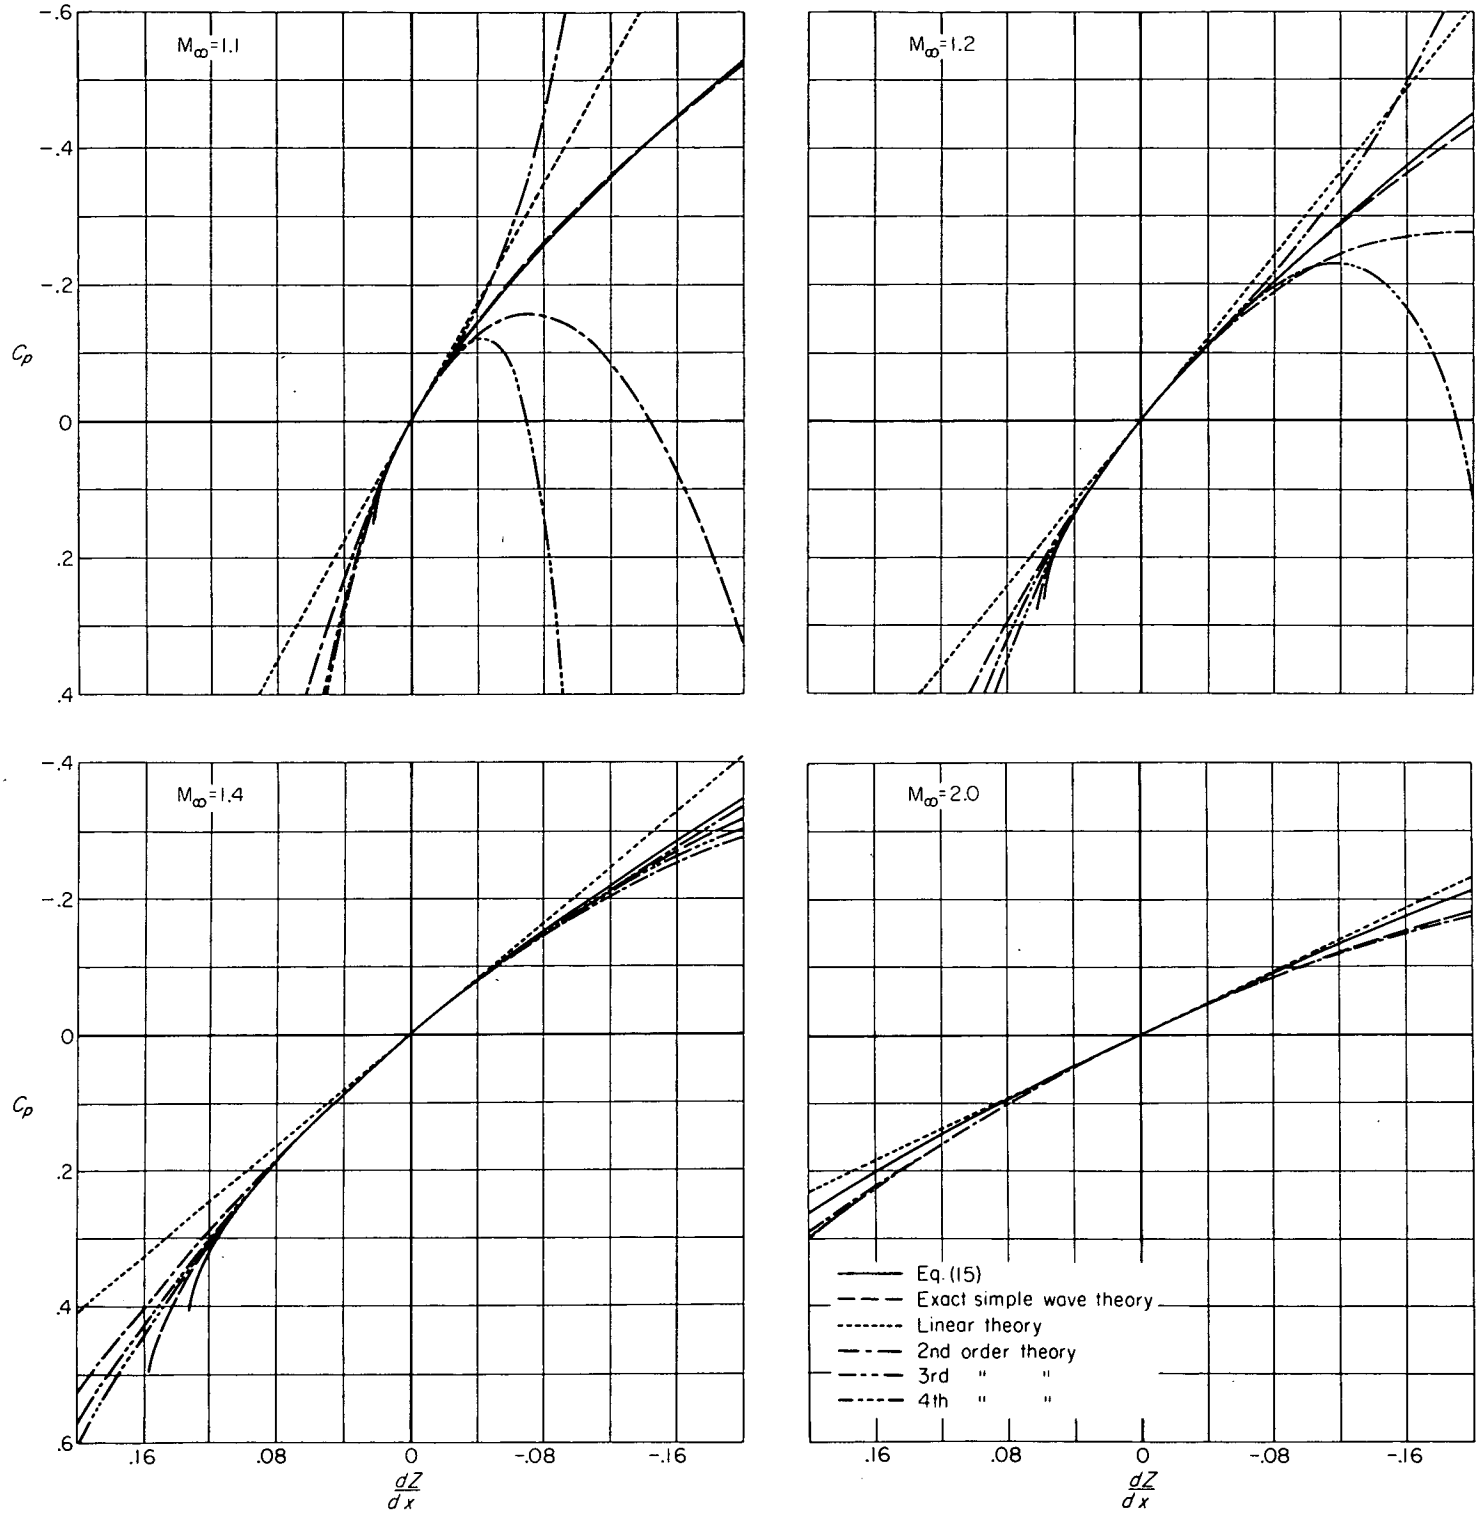

FIGURE 3.—Comparison of results indicated by present theory and by the method of successive approximations for supersonic flow.

in linearized subsonic airfoil theory and the solution u_E at the airfoil surface is

$$u_E=\frac{U_\infty}{\pi\sqrt{\lambda_E}}\int_0^c \frac{dZ/d\xi}{x-\xi}\,d\xi=\frac{u_i}{\sqrt{\lambda_E}} \tag{22}$$

where the subscript i refers to the values for $M_\infty=0$. Differentiation yields

$$\frac{du_E}{dx}=\frac{1}{\sqrt{\lambda_E}}\frac{du_i}{dx} \tag{23}$$

If, in the same manner as described for the supersonic case, $1-M_\infty{}^2-ku$ is restored in place of λ_E so that, in effect, the local value for λ_E is used at each point, and the subscript E on u is dropped, equation (23) becomes

$$\frac{du}{dx}=\frac{1}{\sqrt{1-M_\infty{}^2-ku}}\frac{du_i}{dx} \tag{24}$$

As in the previous discussion of supersonic flows, the error terms are omitted in writing the preceding relations, but are included in a more complete presentation of the equations

given in the Appendix. Once again, the resulting relation is a nonlinear ordinary differential equation that can be solved readily by separation of variables

$$-\frac{2}{3k}(1-M_\infty^2-ku)^{3/2}=u_i+C \tag{25}$$

In applications to flows that are subsonic everywhere, the constant of integration C is evaluated by use of the result indicated by equation (22) that $u=0$ where $u_i=0$ for any nonsingular λ_E, thus

$$C=-\frac{2}{3k}(1-M_\infty^2)^{3/2} \tag{26}$$

In this way, the following relation is obtained between u and u_i

$$u=\frac{1}{k}\left\{1-M_\infty^2-\left[(1-M_\infty^2)^{3/2}-\frac{3}{2}ku_i\right]^{2/3}\right\} \tag{27}$$

The corresponding relation for the pressure coefficient C_p is obtained by combination of equations (2) and (27) and is [4]

$$C_p=-\frac{2}{M_\infty^2(\gamma+1)}\left\{(1-M_\infty^2)-\left[(1-M_\infty^2)^{3/2}+\frac{3}{4}M_\infty^2(\gamma+1)C_{p_i}\right]^{2/3}\right\} \tag{28}$$

where

$$C_{p_i}=-2\frac{u_i}{U_\infty}=-\frac{2}{\pi}\int_0^c\frac{dZ/d\xi}{x-\xi}d\xi$$

In the same way as noted for supersonic flows following equation (15), the restriction to subsonic flow imposed in the evaluation of C and by the inequality of equation (20) requires that equation (28) be applied only to cases where the quantity in the square bracket is positive.

This result possesses several simple, but interesting, properties. First of all, the leading term of an expansion of equation (28) in a series involving ascending powers of C_{p_i} is precisely the familiar Prandtl-Glauert rule of linearized subsonic compressible flow theory

$$C_{p_L}=\frac{C_{p_i}}{\sqrt{1-M_\infty^2}} \tag{29}$$

The coefficients of succeeding terms, however, do not agree with those given by the method of successive approximation. Next, the first of the two major components of the right-hand member of equation (28) is recognized, just as in the supersonic case, as the expression for the critical pressure coefficient $C_{p_{cr}}$. Since the remaining term is zero when $C_p=C_{p_{cr}}$, it follows that the expression for the critical value for C_{p_i} associated with the occurrence of sonic velocity at a given Mach number M_∞ is

$$C_{p_{i_{cr}}}=-\frac{4}{3}\frac{(1-M_\infty^2)^{3/2}}{M_\infty^2(\gamma+1)} \tag{30}$$

[4] Attention is called to the fact that this same relation, except for replacement of $M_\infty^2(\gamma+1)$ by $\gamma+1$ for the same reasons as noted in footnote 2, has been found independently by Kusukawa by application of the WKB method of approximation to the equations of transonic flow theory. This result, together with a number of applications, is published in the September 1957 issue of the Journal of the Physical Society of Japan.

It may be noted that this value is just two-thirds of that obtained by use of equation (5) together with the Prandtl-Glauert rule. It follows, furthermore, that a curve illustrating the variation of C_p with M_∞ for a given C_{p_i}, and hence a given point on the airfoil surface, approaches infinite slope as C_p approaches $C_{p_{cr}}$. This latter behavior signifies that a power series expansion of the result will only converge for Mach numbers less than the critical. Last, the following result is obtained if equation (28) is expressed in terms of the subsonic linear theory solution C_{p_L} rather than C_{p_i}

$$C_p=\frac{-2(1-M_\infty^2)}{M_\infty^2(\gamma+1)}\left\{1-\left[1+\frac{3}{4}\frac{M_\infty^2(\gamma+1)}{1-M_\infty^2}C_{p_L}\right]^{2/3}\right\} \tag{31}$$

where

$$C_{p_L}=\frac{C_{p_i}}{\sqrt{1-M_\infty^2}}$$

Note that the relation between C_p and C_{p_L} indicated by equation (31) for subsonic flows is precisely the same as given by equation (17) for supersonic flows. It follows immediately that the corresponding expression in terms of the transonic similarity parameters $\overline{C}_p$ and ξ_∞ given by equation (18) applies to subsonic, as well as supersonic flows. In order to illustrate the nature of the results indicated by equation (18), a plot of the variation of $\overline{C}_p$ with ξ_∞ for various $C_{p_L}\sqrt{|\xi_\infty|}$ is shown in figure 4. Although the remarkable symmetry about $\xi_\infty=0$ is a consequence of expressing the results in terms of the transonic similarity parameters, the general symmetry remains, although in somewhat distorted form, when C_p is plotted as a function of M_∞ for constant $C_{p_L}\sqrt{|1-M_\infty^2|}$. Such a plot is shown in figure 5.

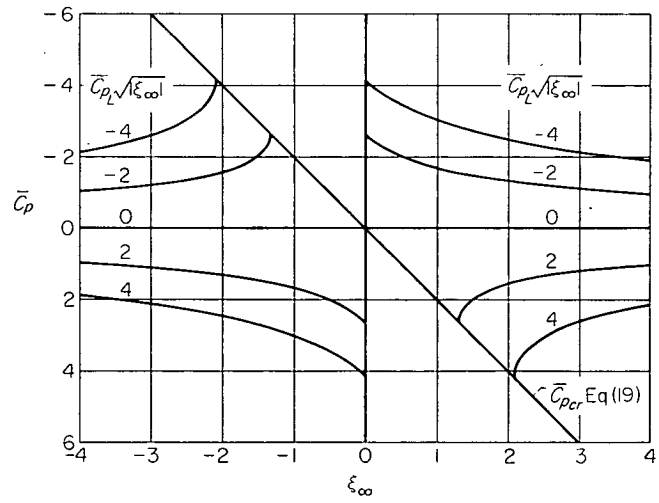

FIGURE 4.—Variation of reduced pressure coefficient, $\overline{C}_p$, with the similarity parameter, ξ_∞, for various values of $\overline{C}_{p_L}\sqrt{|\xi_\infty|}$.

COMPARISON WITH EXISTING HIGHER APPROXIMATIONS

The remainder of the present section on subsonic flows is concerned with an evaluation of the degree of accuracy achieved by use of equation (28). This discussion is handicapped somewhat by the fact that all other theories for subsonic flows around airfoils are also approximate and that no exact solutions are known. Perhaps the most widely

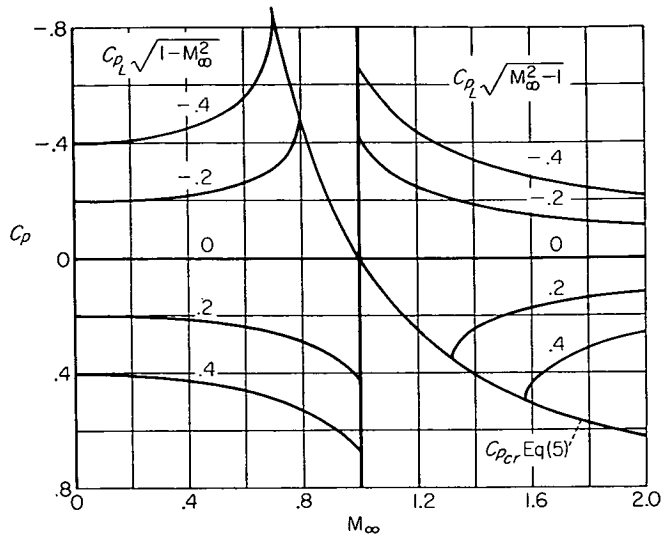

FIGURE 5.—Variation of C_p with M_∞ for various values of $C_{p_L}\sqrt{|M_\infty^2-1|}$.

used higher approximation is the Kármán-Tsien rule. (See refs. 3 and 16 for a résumé.) Although the traditional derivation of the Kármán-Tsien rule is based on the hodograph method, it is not without interest to observe that the Kármán-Tsien rule can be obtained by use of the present procedures together with the three assumptions introduced in the original derivation. These are: (a) that γ can be approximated by -1 in the expression for the speed of sound, (b) that the perturbation velocities are small, and (c) that the Mach number can be considered small in the evaluation of additional effects of compressibility beyond those indicated by linear theory. The starting point is equation (3) with the coefficient of φ_{xx} replaced by the approximate relation for $1-M^2$, where M is the local Mach number, afforded by use of assumptions (a) and (b). The necessary relation can be derived from the energy equation

$$\frac{a^2}{\gamma-1}+\frac{q^2}{2}=\frac{a_\infty^2}{\gamma-1}+\frac{U_\infty^2}{2} \tag{32}$$

where

$$q^2=(U_\infty+u)^2+w^2$$

by setting $\gamma=-1$, whence

$$a^2=a_\infty^2-U_\infty^2+q^2$$

and

$$1-M^2=1-\frac{q^2}{a^2}=\frac{1-M_\infty^2}{1-M_\infty^2+M_\infty^2(q^2/U_\infty^2)}\approx\frac{1-M_\infty^2}{1+2M_\infty^2(u/U_\infty)} \tag{33}$$

Note that this approximation does not permit the attainment of $M=1$ with finite q/U_∞ and with M_∞ different from unity. Substitution of this relation for $1-M^2$ in place of λ_E in equation (23) and integration yields

$$\sqrt{1+2M_\infty^2(u/U_\infty)}=\frac{M_\infty^2}{\sqrt{1-M_\infty^2}}\frac{u_i}{U_\infty}+C \tag{34}$$

The constant of integration is again evaluated by setting $u=0$ where $u_i=0$, whence C equals unity. Solution for u and introduction of the relation between u and C_p given by equation (2) yields

$$C_p=\frac{C_{p_i}}{\sqrt{1-M_\infty^2}}\left(1-\frac{M_\infty^2}{4\sqrt{1-M_\infty^2}}C_{p_i}\right)\approx\frac{C_{p_i}}{\sqrt{1-M_\infty^2}+(1/4)M_\infty^2C_{p_i}} \tag{35}$$

Replacement of M_∞^2 in the second term in the denominator by $2(1-\sqrt{1-M_\infty^2})$ is consistent with assumption (c) and leads directly to the familiar expression for the Kármán-Tsien rule

$$C_p=\frac{C_{p_i}}{\sqrt{1-M_\infty^2}+(1-\sqrt{1-M_\infty^2})(C_{p_i}/2)} \tag{36}$$

This rule, in common with the Prandtl-Glauert rule and the present result given in equation (28), is termed a pressure correction formula because C_p is given in terms of C_{p_i} and M_∞ with no further dependence on airfoil shape. A comparison of the variations of C_p with M_∞ indicated by these three relations is shown in figure 6. A great many other pressure-correction formulas having widely varying properties have also been proposed in recent years. One that yields results in closer agreement with equation (28) than the Prandtl-Glauert or the Kármán-Tsien rule has been given by Garrick and Kaplan in reference 17. A curve illustrating their results is included on figure 6.

A second important method that has been used to obtain higher approximations for subsonic pressure distributions on thin airfoils is the method of successive approximation in which the solution is expressed in a power series in thickness ratio. In this method, the first term is the result given by linear theory, and the coefficients of successive terms are determined by iteration. Higher approximations cannot be expressed in terms of C_{p_i} and M_∞ in such a simple and uni-

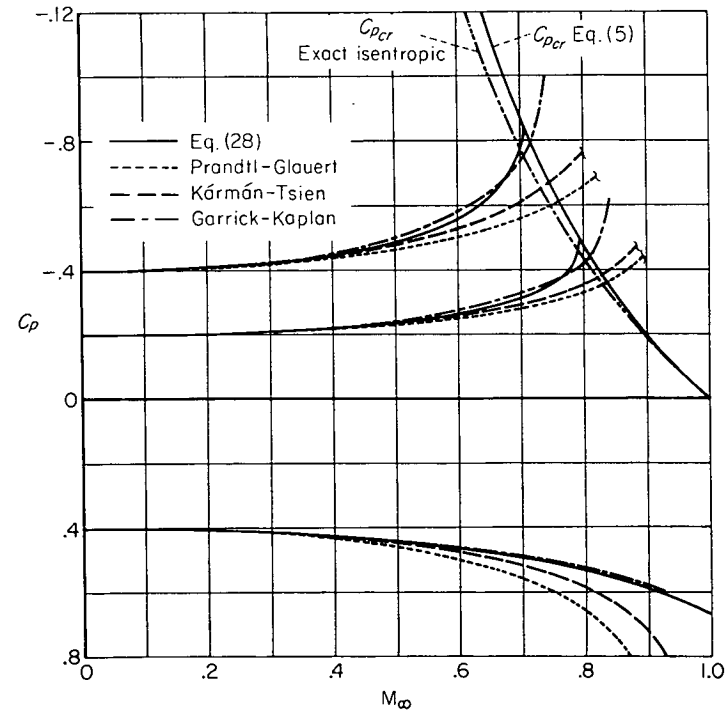

FIGURE 6.—Comparison of results indicated by present theory and by various pressure correction formulas for subsonic flow.

versal manner as with the pressure-correction formulas, but depend on the airfoil shape in a more explicit manner. Although a relatively simple and general procedure for the evaluation of the second approximation has recently been given by Van Dyke (ref. 18), the determination of the third approximation has been accomplished for only a few special shapes. One of these is the nonlifting symmetrical circular-arc section for which the second approximation has been given by Hantzsche and Wendt (ref. 19) and the third approximation by Asaka (refs. 20, 21, and 22).[5] Figure 7 shows a comparison of the variations of C_p with M_∞ at the midpoint of such an airfoil having a thickness ratio τ of 0.10, as indicated by equation (28) and by the first, second, and third approximations. It can be seen that the results obtained by use of equation (28) are identical to those given by the first approximation (or linear theory) for small Mach numbers, but depart therefrom with increasing Mach number and are much closer to the higher approximations for Mach numbers near the critical. It should be noted that the curves labeled first, second, and third order represent the results indicated by successive approximations to the solution of the exact equation for inviscid compressible flow. It is also of interest to compare the results indicated by equation (28) with those indicated by successive approximations to the solution of the simplified equations of transonic small disturbance theory. The latter results can be calculated by use of the following expression, which is readily derived from Asaka's result by taking the limiting form consistent with the approximations of transonic flow theory:

$$C_p=-\frac{8}{\pi}\frac{\tau}{\sqrt{1-M_\infty^2}}-\left(\frac{10}{\pi^2}-\frac{1}{2}\right)\frac{(\gamma+1)M_\infty^2}{(1-M_\infty^2)^2}\tau^2-\left[\frac{1}{\pi}\left(-\frac{281}{108}+\frac{7}{6}ln2\right)+\frac{1}{\pi^3}\left(\frac{292}{9}+4.908\right)\right]\frac{(\gamma+1)^2M_\infty^4}{(1-M_\infty^2)^{7/2}}\tau^3+\ldots$$

$$=-2.5465\frac{\tau}{\sqrt{1-M_\infty^2}}-0.5132\frac{(\gamma+1)M_\infty^2}{(1-M_\infty^2)^2}\tau^2-0.6339\frac{(\gamma+1)^2M_\infty^4}{(1-M_\infty^2)^{7/2}}\tau^3+\ldots \quad (37)$$

It can be seen that the curve in figure 8 indicated by equation (28) is somewhat higher than even that representing the third approximation, but evaluation of its accuracy remains difficult because neither the exact solution nor an upper bound for the results is provided by the classical method of successive approximation. Attention is called to the fact that recent developments in transonic flow theory permit the establishment of an upper bound by application of an alternative method of successive approximation that involves the solution of quadratic, rather than linear, equations at each step of the iteration process. This process, based on the methods employed in reference 9. is described in the Appendix, and additional results are given for the specific case considered in figure 8.

[5] The results for the third approximation given in the present report differ from those obtainable directly from the expressions given in either reference 20 or 21 and 22 due to the correction of some misprints. These corrections have been verified by correspondence with the author, and are published in the January 1958 issue of the Journal of the Physical Society of Japan.

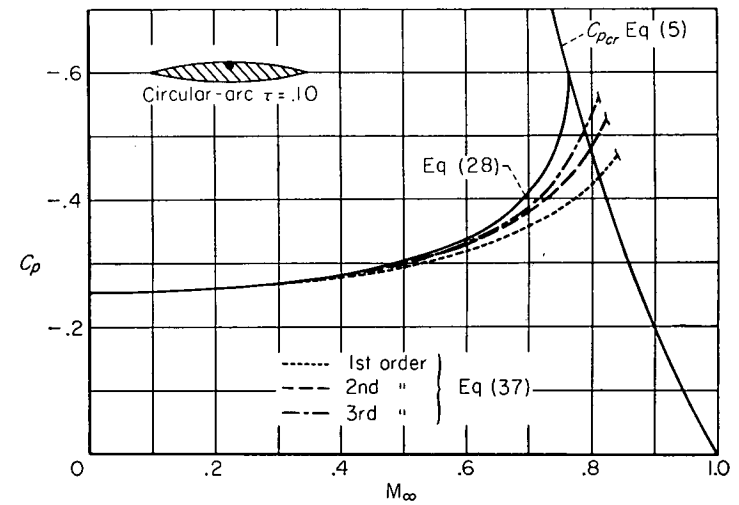

FIGURE 8.—Comparison of the variation of C_p with M_∞ at the midpoint of a circular-arc airfoil in subsonic flow, as indicated by present theory and by application of the method of successive approximations to the transonic equation.

FLOWS WITH FREE-STREAM MACH NUMBER NEAR 1

The analyses of supersonic and subsonic flows given in the preceding sections have started by introduction of a symbol λ for the coefficient of φ_{xx} and the assumption that λ is nonsingular and varies sufficiently slowly that it can be regarded as a constant in the initial stages of the analysis. Since the results so obtained terminate if $\lambda=0$, or physically if sonic velocity occurs in the flow field, it is immediately clear that some change is necessary to study flows with free-stream Mach number near 1 where the transition from subsonic to supersonic flow is an essential feature. The technique adopted is to introduce the symbol λ_P as an abbreviation for the coefficient of φ_x rather than φ_{xx}, thus

$$\lambda_P=M_\infty^2\frac{\gamma+1}{U_\infty}\varphi_{xx}=k\frac{\partial u}{\partial x} \quad (38)$$

whence equation (3) may be written as follows:

$$\varphi_{zz}-\lambda_P\varphi_x=-(1-M_\infty^2)\varphi_{xx}=f_P \quad (39)$$

If attention is confined to flows with free-stream Mach number 1 so that the right-hand side of equation (39) vanishes and if λ_P is replaced by a constant, the resulting relation given by equation (39) is a linear partial differential equation of parabolic type that is familiar from the study of one-dimensional unsteady conduction of heat. If approximate solutions for flows with free-stream Mach number 1 are sought in this way, the analysis proceeds through considerations that are generally applied to parabolic differential equations, and is, in some sense, intermediate between the mixed elliptic-hyperbolic type of the transonic equation. The idea of using the equation for heat conduction for the study of transonic flows in this way is not new, but apparently originated with Oswatitsch, who suggested it to Behrbohm for the analysis of internal flows of nozzles (refs. 23 and 24) The same idea has been applied more recently by Oswatitsch and Keune (refs. 25, 26, and 27) to calculate the flow around the forepart of slender bodies of revolution at free-stream Mach number 1, and they have shown that the results are in remarkable agreement with those measured on the front half of a circular-arc body of revolution. Although the parameter λ_P is regarded throughout as a constant, and various means are proposed for the selection of an appropriate value, it develops that the numerical result for the pressures on the forward part of typical smooth bodies of revolution depends so slightly on the actual choice that almost any reasonable value can be used for λ_P.

If flows with free-stream Mach number different from unity are considered so that the right-hand side of equation (39) remains, and if λ_P is again replaced by a constant, the resulting differential equation is linear and is of elliptic or hyperbolic type depending on whether the free-stream Mach number, rather than the local Mach number, is less than or greater than unity. Maeder and Thommen (ref. 28) have suggested that this linearized equation, or its counterpart in three dimensions, be applied, together with a new and arbitrary rule for the selection of a value for λ_P, to calculate the pressure distribution on complete bodies of revolution and on airfoils in two-dimensional flows. The selection of an appropriate value for λ_P is much more critical for these problems than for those discussed originally by Oswatitsch and Keune, however, and the replacement of λ_P by a constant results not only in serious loss of accuracy in many applications, but also in loss of certain essential general features of the solution. In general, results obtained by replacing λ_P, or $\partial u/\partial x$, with a constant appear to be remarkably accurate if the resulting values calculated for $\partial u/\partial x$ are, indeed, nearly constant over most of the chord. If, on the other hand, $\partial u/\partial x$ varies substantially over the chord, no choice of a single value for λ_P will suffice to provide a useful result. This point is developed further in the course of the following discussion and in the Appendix. Some criticisms of the above procedure, although principally from a different point of view, have appeared in a note by Miles (ref. 29).

In the present analysis, it is assumed once again that λ_P is nonsingular and that it varies sufficiently slowly that it can be considered as a constant in the initial stages of the analysis in which a nonlinear ordinary differential equation is established for u on the airfoil surface. The final result for u is determined by integration of this differential equation and restores, to a large degree, the effects of the variation of λ_P along the chord. The result for the first stage of the analysis requires the solution of equation (39) subject to the boundary conditions given in equation (1) and can be obtained by application of standard procedures. The solution has two distinct forms depending on the sign of λ_P. The form associated with positive λ_P is appropriate for application to regions where the flow is accelerating, whereas that associated with negative λ_P may be appropriate for application to regions where the flow is decelerating. The analysis of accelerating flow will be developed first. The direct problem in which the airfoil shape is specified and the pressure distribution is sought, and the inverse problem in which the pressure distribution is specified and the associated airfoil shape is sought are discussed for each case.

ACCELERATING FLOWS, DIRECT PROBLEMS

Approximate solution of equations for arbitrary airfoil shape.—A relation for u at the airfoil surface derived by consideration of equation (39) with positive λ_P, the boundary conditions stated in equation (1), and the form of Green's theorem associated with the left side of equation (39) (see Appendix) is

$$u_P=-\frac{U_\infty}{\sqrt{\pi\lambda_P}}\frac{d}{dx}\int_0^x\frac{dZ/d\xi}{\sqrt{x-\xi}}d\xi-\frac{1}{\lambda_P}\frac{\partial}{\partial x}\int_{-\infty}^{+\infty}d\zeta\int_{-\infty}^{x}\sigma_P f_P d\xi$$

$$=-\frac{U_\infty}{\sqrt{\pi\lambda_P}}\left[\left(\frac{dZ}{dx}\right)_{x=0}\frac{1}{\sqrt{x}}+\int_0^x\frac{d^2Z/d\xi^2}{\sqrt{x-\xi}}d\xi\right]-\frac{1}{\lambda_P}\frac{\partial}{\partial x}\int_{-\infty}^{+\infty}d\zeta\int_{-\infty}^{x}\sigma_P f_P d\xi \qquad (40)$$

where

$$f_P=-(1-M_\infty^2)\varphi_{\xi\xi},\ \sigma_P=\sqrt{\frac{\lambda_P}{4\pi(x-\xi)}}\,e^{\left[-\frac{\lambda_P(x-\xi)^2}{4(x-\xi)}\right]}$$

The two alternative expressions for u_P are completely equivalent. The first is more concise and will be used in the following equations, but the second is often somewhat simpler to evaluate. If the free-stream Mach number is unity, the double integral vanishes and u_P can be calculated directly. The result so obtained corresponds to that found by application of Maeder and Thommen's proposal of reference 28. (It should be noted, however, that the general expression for φ given in reference 28 is incorrect owing to improper treatment of plus and minus signs.)

If the free-stream Mach number is not unity, equation (40) is an integral equation, and it might appear that little progress toward a solution has been made. If attention is confined to the vicinity of the airfoil and to Mach numbers near unity, however, it is only necessary to approximate $\varphi_{\xi\xi}$ well locally and it is sufficient to substitute λ_P/k for $\varphi_{\xi\xi}$ or $\partial u/\partial\xi$ in the double integral. The integral can then be evaluated and the following relationship results:

$$u_P=\frac{(1-M_\infty^2)U_\infty}{M_\infty^2(\gamma+1)}-\frac{U_\infty}{\sqrt{\pi\lambda_P}}\frac{d}{dx}\int_0^x\frac{dZ/d\xi}{\sqrt{x-\xi}}d\xi \qquad (41)$$

If, once again, ku_x is restored in place of λ_P so that, in effect, the local value is used at each point, and the subscript P on

u is dropped, a simple nonlinear ordinary differential equation is obtained for u

$$u=\frac{(1-M_\infty^2)U_\infty}{M_\infty^2(\gamma+1)}-\frac{U_\infty}{\sqrt{\pi k(du/dx)}}\frac{d}{dx}\int_0^x\frac{dZ/d\xi}{\sqrt{x-\xi}}d\xi \tag{42}$$

Equation (42) can be written in the following form upon rearranging the terms and squaring both sides.

$$\left[u-\frac{(1-M_\infty^2)U_\infty}{M_\infty^2(\gamma+1)}\right]^2\frac{du}{dx}=\frac{U_\infty^3}{\pi M_\infty^2(\gamma+1)}\left(\frac{d}{dx}\int_0^x\frac{dZ/d\xi}{\sqrt{x-\xi}}d\xi\right)^2 \tag{43}$$

As in the other cases, equation (43) can be solved readily by separation of variables, and the constant of integration can be evaluated by introduction of the additional condition that equation (41) provides the correct location $x=x^*$ for the sonic point, or point where $u=(1-M_\infty^2)U_\infty/M_\infty^2(\gamma+1)$. The result is

$$\left[u-\frac{(1-M_\infty^2)U_\infty}{M_\infty^2(\gamma+1)}\right]^3=\frac{3U_\infty^3}{\pi M_\infty^2(\gamma+1)}\int_{x^*}^x\left(\frac{d}{dx_1}\int_0^{x_1}\frac{dZ/d\xi}{\sqrt{x_1-\xi}}d\xi\right)^2dx_1 \tag{44}$$

where x^* is the value for x for which

$$\frac{d}{dx}\int_0^x\frac{dZ/d\xi}{\sqrt{x-\xi}}d\xi=0 \tag{45}$$

This method of evaluation of the constant of integration is completely analogous to that employed in the analysis of subsonic and supersonic flows, and is necessary in the analysis of flows with free-stream Mach number near 1 in order to avoid infinite pressure gradients at the point of sonic velocity on smooth airfoils. This method, moreover, provides a mechanism for the introduction of direct upstream dependence on airfoil shape in the subsonic region, and its exclusion in the supersonic region. The corresponding relation for the pressure coefficient C_p is obtained by combination of equations (2) and (44) and is

$$C_p=\frac{-2(1-M_\infty^2)}{M_\infty^2(\gamma+1)}-2\left[\frac{3}{\pi M_\infty^2(\gamma+1)}\int_{x^*}^x\left(\frac{d}{dx_1}\int_0^{x_1}\frac{dZ/d\xi}{\sqrt{x_1-\xi}}d\xi\right)^2dx_1\right]^{1/3} \tag{46}$$

An alternative expression in terms of the transonic similarity parameter is

$$\overline{C}_p\equiv\frac{[M_\infty^2(\gamma+1)]^{1/3}}{\tau^{2/3}}C_p=2\xi_\infty-2\left\{\frac{3}{\pi}\int_{x^*}^x\left[\frac{d}{dx_1}\int_0^{x_1}\frac{d(Z/\tau)/d\xi}{\sqrt{x_1-\xi}}d\xi\right]^2dx_1\right\}^{1/3}=2\xi_\infty+\overline{C}_{p_{\xi_\infty=0}} \tag{47}$$

The variation of $\overline{C}_p$ with ξ_∞ expressed by equation (47) is exact, within the approximation of transonic small disturbance theory, for flows with free-stream Mach numbers very near unity, and is associated with the fact that the local Mach number distribution on an airfoil is independent of the free-stream Mach number at values of the latter near unity. This phenomenon has been discussed previously in references 30, 31, 6, and elsewhere.

Once C_p is known, the pressure drag d can be readily calculated by use of the following relation

$$c_d\equiv\frac{d}{\frac{\rho_\infty}{2}U_\infty^2c}\equiv\frac{2}{c}\int_0^c C_p\frac{dZ}{dx}dx \tag{48}$$

Application to single-wedge airfoils.—Sufficient theoretical and experimental results are available at the present time to provide considerable insight into the accuracy and usefulness of equation (46) or (47). The shape for which the greatest amount of information is available is the single-wedge profile for which both theoretical and experimental pressure distributions are available. Thus, consider a single-wedge profile of maximum thickness t and chord $c/2$ as illustrated in figure 9. The ordinates of the airfoil upper surface are

$$\left.\begin{aligned}Z=t\frac{x}{c}=\tau x \quad &\text{for } 0<x<c/2\\ Z=t/2=\tau c/2 \ &\text{for } x>c/2\end{aligned}\right\} \tag{49}$$

and the semiapex angle θ is equal, to the order of accuracy of thin airfoil theory, to τ. Substitution of equation (49) for Z into equations (45) and (46) provides that the sonic point is at the shoulder ($x^*=c/2$) and that the pressure distribution on the surface of the wedge at free-stream Mach numbers near 1 is

$$\overline{C}_p\equiv\frac{[M_\infty^2(\gamma+1)]^{1/3}}{\tau^{2/3}}C_p=2\xi_\infty-2\left(\frac{3}{\pi}\ln\frac{x}{c/2}\right)^{1/3} \tag{50}$$

A plot of the results for Mach number 1 is shown in figure 10 together with the corresponding theoretical results given by Guderley and Yoshihara in reference 32. Although some approximations are introduced in the course of the latter analysis, the results are generally regarded as virtually an exact solution of the equations of transonic small disturbance

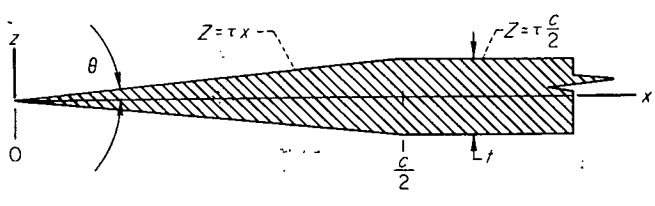

FIGURE 9.—View of single-wedge airfoil and principal dimensions.

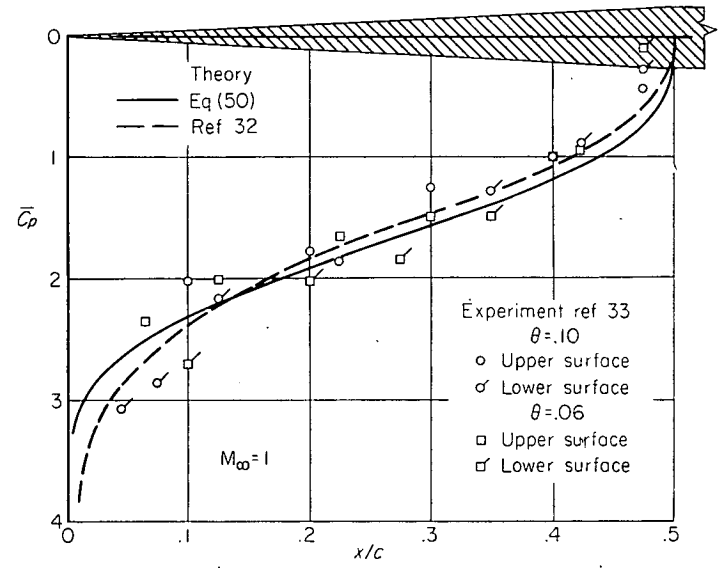

FIGURE 10.—Theoretical and experimental pressure distributions for single-wedge airfoils at free-stream Mach number 1.

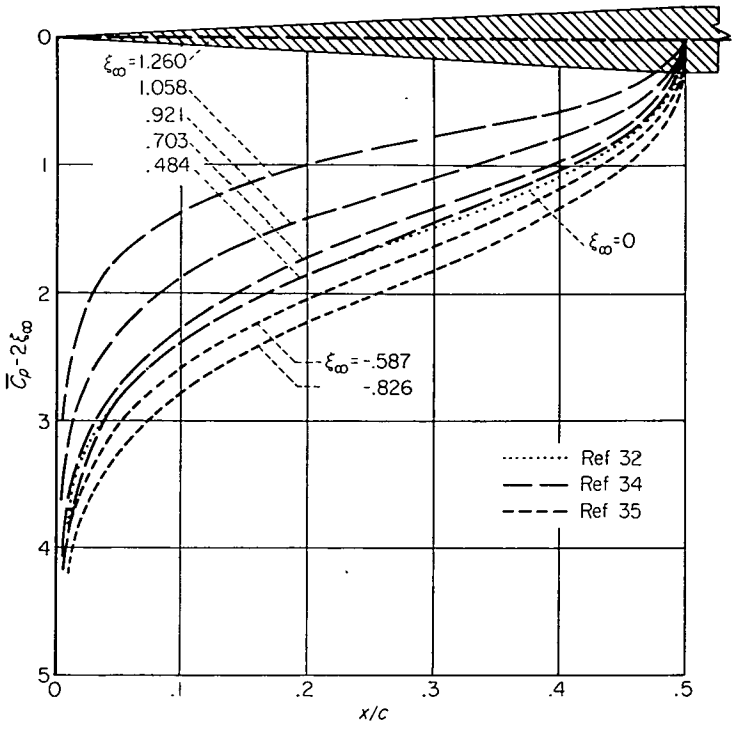

FIGURE 11.—Summary of other theoretical results for transonic flow past single-wedge airfoils.

theory. Also included in figure 10 are experimental results for $M_\infty=1$ obtained in the Langley annular transonic wind tunnel and reported by Habel, Henderson, and Miller in reference 33.

Since the comparisons shown in figure 10 indicate that equation (50) provides an approximate solution for the pressure distribution on a single-wedge profile at $M_\infty=1$ that is probably satisfactory for most purposes, and since the variation of $\overline{C}_p$ with ξ_∞ given by equation (47) or (50) is exact, within the framework of transonic small disturbance theory, at $M_\infty=1$, the principal question remaining in the evaluation of the degree of approximation afforded by use of equation (50) is to define the range of ξ_∞, or Mach number, over which it applies. Accordingly, figure 11 has been prepared to summarize the results given previously by Guderley and Yoshihara for Mach number 1 (ref. 32), by Vincenti and Wagoner for Mach numbers slightly greater than unity (ref. 34), and by Yoshihara for Mach numbers slightly less than unity (ref. 35). The latter two sets of results were obtained by lengthy numerical calculations and, together with the results for Mach number 1, are generally regarded as being very close to those that would be given by exact solutions of the equations of transonic small disturbance theory. The results are plotted in terms of $\overline{C}_p-2\xi_\infty$ so that the pressure distributions for Mach numbers very near unity should determine a single line. It can be seen that the variation of $\overline{C}_p$ with ξ_∞ indicated by equation (47) or (50) holds until the absolute value of ξ_∞ is nearly one-half. At greater values, the results begin to tend toward those associated with purely subsonic or purely supersonic flows, and equations (47) and (50) are no longer applicable.

Experimental measurements of the flow around single-wedge profiles at free-stream Mach numbers both less than and greater than unity have been made by Liepmann and Bryson and reported in references 30 and 31. Results were obtained for three different profiles having semiapex angles of 4½°, 7½°, and 10°. Plots of the experimental pressure distributions for the test Mach numbers closest to unity for each profile are shown in figure 12 together with the theoretical pressure distribution calculated by use of equation (50). Additional experimental data for other Mach numbers are not included on figure 12 since those shown are already for values of ξ_∞ that are somewhat outside the range of validity of equation (50). Only the theoretical results given by equation (50) are included since examination of the data reveals that these results differ less from the theoretical results shown on figure 11, for Mach numbers near unity, than the experimental curves differ from either set of theoretical curves, or even than the experimental curves differ among themselves. Perhaps the most prominent discrepancy is that which occurs near the shoulder. Theory indicates that sonic velocity ($\overline{C}_p-2\xi_\infty=0$) occurs at the shoulder, whereas the experimental data, particularly that of Liepmann and Bryson, consistently indicate that sonic velocity occurs forward of the shoulder. It is interesting to observe that this discrepancy is greatest for the thinnest airfoil tested.

The foregoing results may be contrasted with those obtained by direct use of equation (41) in which case $\overline{C}_p-2\xi_\infty$

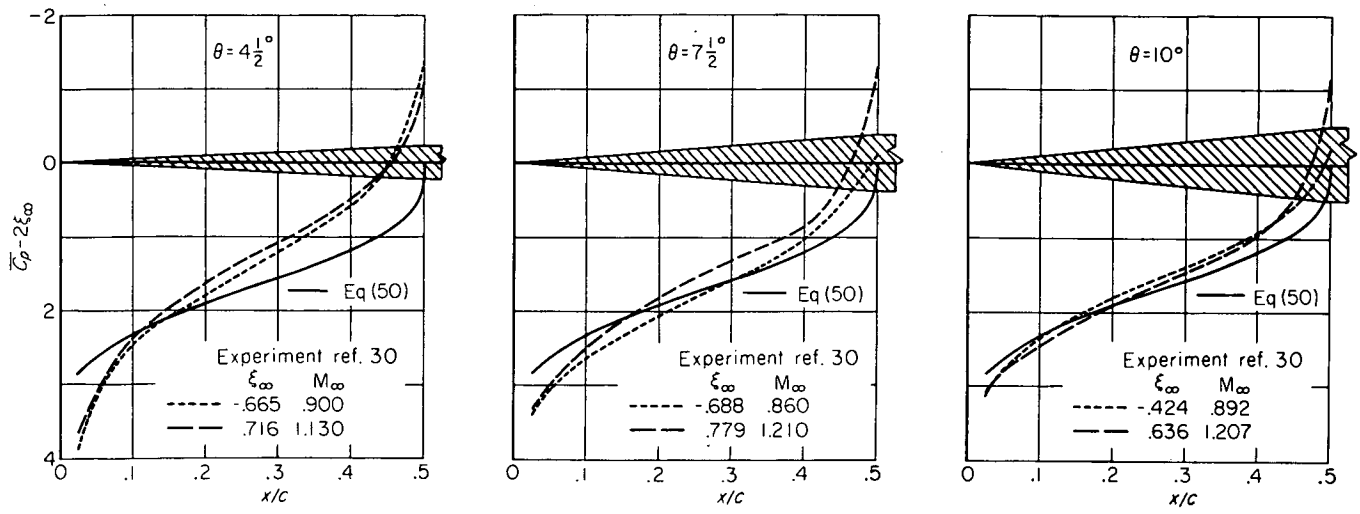

FIGURE 12.—Theoretical and experimental pressure distributions for three single-wedge airfoils at free-stream Mach numbers near 1.

is found to be proportional to $1/\sqrt{\lambda_P x}$. It is clear from this comparison that there is no constant with which λ_P can be replaced that would provide a satisfactory solution for the pressure distribution on a single-wedge airfoil at free-stream Mach numbers near unity.

The pressure drag of single-wedge profiles at Mach numbers near 1 can be found easily by integration of equation (48) with the relations given by equations (49) and (50) substituted for Z and C_p. The result is

$$\frac{[M_\infty^2(\gamma+1)]^{1/3}c_d}{\tau^{5/3}} \equiv \bar{c}_d = 2\xi_\infty + 2\left(\frac{3}{\pi}\right)^{1/3}\Gamma\left(\frac{4}{3}\right) = 2\xi_\infty + 1.758 \quad (51)$$

where Γ represents the gamma function. This result compares very favorably with the value of 1.75 for $\xi_\infty = 0$, or Mach number 1, given by Cole in reference 36 as that obtained by numerical integration of the pressure distribution given by Guderley and Yoshihara in reference 32. Cole's own theory for the drag of a single-wedge airfoil at high subsonic speeds, which is fundamentally somewhat less accurate than Guderley and Yoshihara's theory, gives the value 1.67 for $\xi_\infty = 0$.

Application to biconvex circular-arc airfoils.—In addition to data for three single-wedge profiles, Bryson also gives in reference 30 experimental results for transonic flow around the front half of an 8.8-percent thick biconvex circular-arc airfoil followed by a straight section as illustrated in figure 13. Since the pressure distribution on the curved portion

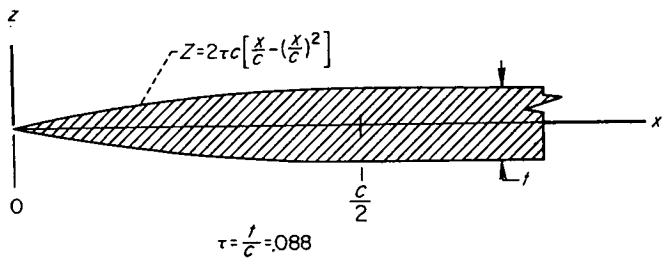

FIGURE 13.—View of a half-circular-arc airfoil and principal dimensions.

of this profile is the same at Mach numbers near unity as that on the front half of a complete circular-arc airfoil having the same thickness ratio, and additional experimental data are available for the latter airfoil although for other thickness ratios, the following analysis is developed for a complete biconvex circular-arc airfoil. It is moreover sufficient, in thin airfoil theory, to approximate the ordinates Z for a circular-arc airfoil by those for a parabolic-arc airfoil, thus

$$\frac{Z}{c} = 2\tau\left[\frac{x}{c} - \left(\frac{x}{c}\right)^2\right] \quad (52)$$

where τ is the thickness ratio as indicated in figure 14. Substitution of this relation for Z into equations (45) and (47) yields the following result for the pressure distribution on the airfoil surface.

$$\bar{C}_p \equiv \frac{[M_\infty^2(\gamma+1)]^{1/3}}{\tau^{2/3}} C_p = 2\xi_\infty - 2\left\{\frac{12}{\pi}\left[ln\left(4\frac{x}{c}\right) - 8\frac{x}{c} + 8\left(\frac{x}{c}\right)^2 + \frac{3}{2}\right]\right\}^{1/3} \quad (53)$$

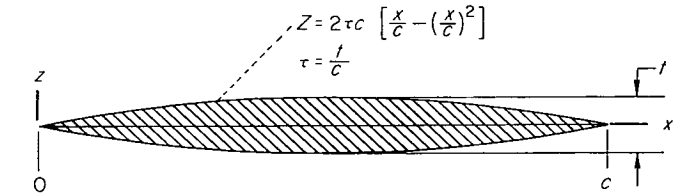

FIGURE 14.—View of a complete circular-arc airfoil and principal dimensions.

Figure 15 shows a comparison of the pressure distributions for Mach numbers near unity calculated by use of equation (53) with those obtained from Bryson's experiments with the half airfoil. As for the single-wedge profile, the results are again plotted in terms of $\bar{C}_p - 2\xi_\infty$ since experimental results are available only for Mach numbers somewhat different from unity. It can be seen by comparison of figures 12 and 15 that the theoretical and experimental results are in much better agreement for the front half of a circular-arc airfoil than for single-wedge profiles. Experimental pressure distributions for transonic flow past four complete biconvex circular-arc airfoils having thickness ratios of 6, 8, 10, and 12 percent have been given by Michel, Marchaud, and Le Gallo in reference 37. Their results for Mach number 1 are plotted in figure 16 together with the theoretical results calculated by use of equation (53). These results are presented in terms of $\bar{C}_p$ because transonic theory indicates that the pressure distributions for all four airfoils should then define a single curve independent of the thickness ratio. Results for Mach numbers other than unity are not included on this plot because the variation of $\bar{C}_p$ with ξ_∞ for small ξ_∞ indicated by equation (47) and subsequent relations is not only simple but is amply verified by the preceding comparisons

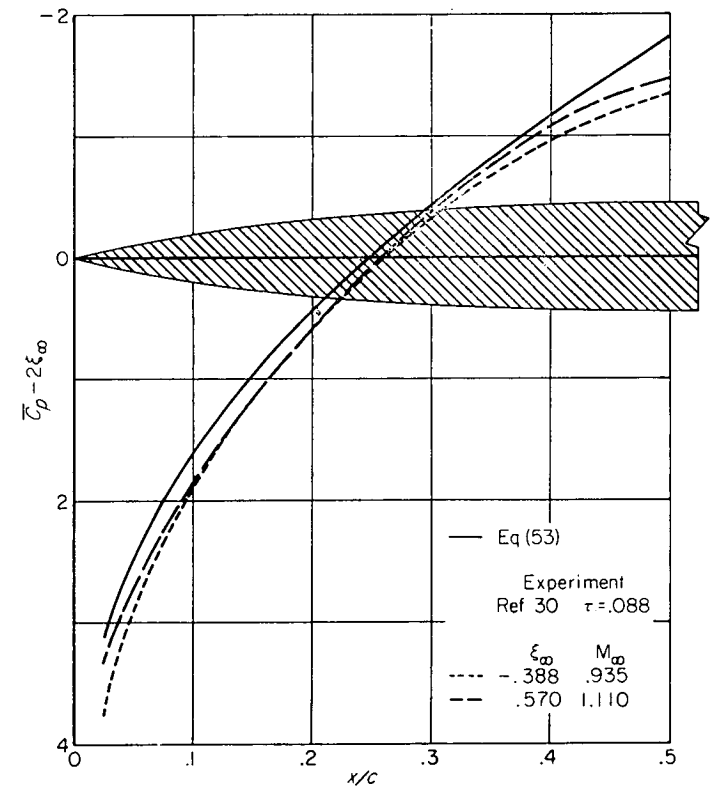

FIGURE 15.—Theoretical and experimental pressure distributions for half-circular-arc airfoils at free-stream Mach numbers near 1.

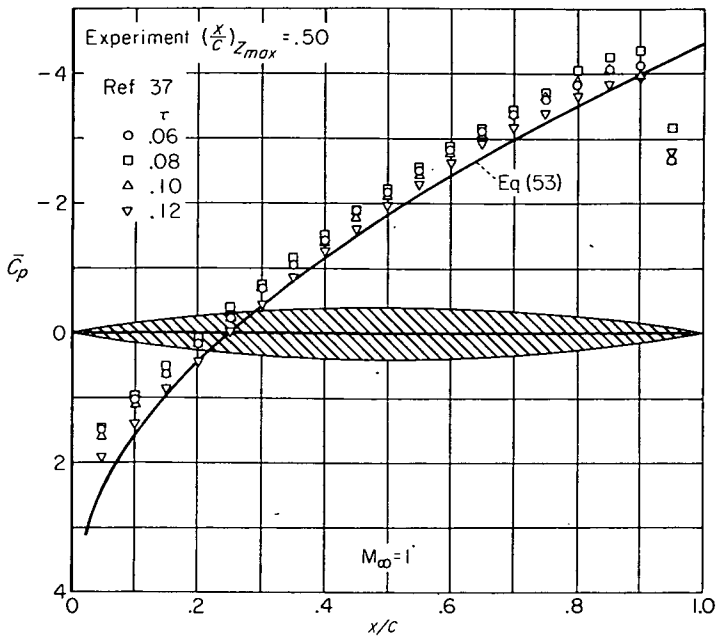

FIGURE 16.—Theoretical and experimental pressure distributions for circular-arc airfoils; $M_\infty = 1$.

and by similar discussions elsewhere in the literature of transonic flow. It can be seen that the theoretical and experimental results are in substantial agreement. The most notable discrepancy is that found near the trailing edge, and can be attributed to flow separation induced by boundary-layer shock-wave interaction. It can also be seen that the agreement between theory and experiment is not so good for the complete airfoils, particularly the thinner ones, as for the half airfoil. Part of the discrepancy for the complete airfoils may possibly be attributed to the experimental technique in which the airfoil is simulated by a bump on the tunnel wall and is hence imbedded in the wall boundary layer. Some comments on this method of testing have been given recently by Carroll and Anderson in reference 38.

The pressure drag of circular-arc airfoils at Mach numbers near 1 has been found by numerical integration of equation (48) with the relations given by equations (52) and (53) substituted for Z and C_p and is

$$\frac{[M_\infty^2(\gamma+1)]^{1/3}c_d}{\tau^{5/3}} \equiv \bar{c}_d = 4.77 \tag{54}$$

The pressure drag of the front half can be evaluated in the same way by changing the upper limit in equation (48) to $c/2$ and is

$$\bar{c}_d = 2\xi_\infty + 1.13 \tag{55}$$

The integrations required to determine the drag results given in equations (54) and (55) were evaluated numerically using Simpson's rule together with an analytic determination of the contribution of the region in the immediate vicinity of the leading-edge singularity. Sufficiently fine intervals were used that the resulting values are estimated to be accurate to within about one digit in the third significant figure, as judged by comparison with the results of similar calculations made with wider intervals. It is necessary to use very fine intervals, particularly near the nose, to achieve such accuracy, and intervals as small as $0.00005c$ were used in some cases.

Application to a family of airfoils having the point of maximum thickness displaced aft of the midchord station.—The primary object of this present section is to present some comparisons of calculated and measured pressure distributions at Mach number 1 on a number of specific airfoils that have the point of maximum thickness aft of the midchord station. The experimental data are from reference 39 by Michel, Marchaud, and Le Gallo, and are for members of the family of airfoils having ordinates given by

$$\frac{Z}{c} = A\left[\frac{x}{c} - \left(\frac{x}{c}\right)^n\right] \tag{56}$$

where A and n are constants for each airfoil and n is greater than unity. The values selected for A and n determine the thickness ratio τ and the location $(x/c)_{z_{max}}$ of the point of maximum thickness according to the relations

$$\left(\frac{x}{c}\right)_{z_{max}} = \left(\frac{1}{n}\right)^{\frac{1}{n-1}} \tag{57}$$

$$\tau = 2A\left[\left(\frac{1}{n}\right)^{\frac{1}{n-1}} - \left(\frac{1}{n}\right)^{\frac{n}{n-1}}\right] = \frac{2A(n-1)}{n^{n/(n-1)}} \tag{58}$$

The biconvex circular-arc airfoils discussed in the preceding section are special cases of the present family that correspond to $n=2$. The point of maximum thickness is located forward or aft of the midchord station depending on whether n is less than or greater than 2. The particular airfoils tested by Michel, Marchaud, and Le Gallo are special cases that correspond to either $n=3.38$ or 6.05 and have the point of maximum thickness at 0.60 or 0.70 chord. As in the earlier work by the same investigators on biconvex circular-arc airfoils, the results were obtained by simulating the airfoil by a bump on the tunnel wall and are again subject to criticism regarding the influence of the wall boundary layer.

Substitution of equation (56) for Z into equations (45) and (46) yields the following result for the pressure distribution on the airfoil surface for Mach number near unity:

$$\bar{C}_p \equiv \frac{[M_\infty^2(\gamma+1)]^{1/3}}{\tau^{2/3}} C_p$$

$$= 2\xi_\infty - 2\left\{\frac{3}{4\pi}\left[\frac{n^{n/(n-1)}}{n-1}\right]^2\right\}^{1/3}\left\{ln\frac{x}{c} - \right.$$

$$\left.\frac{2\sqrt{\pi}\Gamma(n+1)}{(n-1)\Gamma\left(n-\frac{1}{2}\right)}\left(\frac{x}{c}\right)^{n-1} + \frac{\pi[\Gamma(n+1)]^2}{2(n-1)\left[\Gamma\left(n-\frac{1}{2}\right)\right]^2}\left(\frac{x}{c}\right)^{2(n-1)} + \right.$$

$$\left.\frac{1}{n-1} ln\frac{\sqrt{\pi}\Gamma(n+1)}{\Gamma\left(n-\frac{1}{2}\right)} + \frac{3}{2(n-1)}\right\}^{1/3} \tag{59}$$

where Γ represents the gamma function. If m is any positive integer greater than unity, the following relations are useful for evaluation of the gamma function:

$$\left.\begin{aligned} &\Gamma(m)=1\cdot2\cdot3\ldots(m-1)=(m-1)!, \qquad \Gamma(1/2)=\sqrt{\pi} \\ &\Gamma\left(m+\frac{1}{2}\right)=\sqrt{\pi}\,\frac{1}{2}\cdot\frac{3}{2}\cdot\frac{5}{2}\cdot\cdot\left(m-\frac{1}{2}\right), \qquad \Gamma\left(\frac{3}{2}\right)=\frac{\sqrt{\pi}}{2} \end{aligned}\right\} \quad (60)$$

Substitution of $n=2$ in equation (59) reproduces equation (53) for the pressure distribution on biconvex circular-arc airfoils as a special case. Equation (50) for the pressure distribution on a single-wedge airfoil can also be obtained as a limiting case by setting $n=\infty$ and noting that the chord of the wedge is designated here as c rather than $c/2$. Theoretical pressure distributions on the airfoils tested by Michel, Marchaud, and Le Gallo are obtained from equation (59) by substitution of the values 3.38 and 6.05 for n. Figures 17 and 18 show comparisons of the theoretical and experimental pressure distributions for $M_\infty=1$ for the two groups of airfoils. Except for the discrepancy near the trailing edge which can again be attributed to boundary-layer shock-wave interaction, it can be seen that the theoretical and experimental results are in at least qualitative agreement. Some differences occur, however, in the levels of the pressure distribution curves. Comparison with the results for the circular-arc airfoils shown in figure 16 reveals that the same trend is in evidence for those airfoils, although to a lesser degree, and that the difference between the theoretical and experimental results increases as the point of maximum thickness moves rearward. It is not clear at the present time whether this discrepancy is to be attributed principally to the shortcomings of the theoretical or the experimental results.

Application to a family of airfoils having the point of maximum thickness forward of midchord station.—The test program of Michel, Marchaud, and Le Gallo reported in reference 39 and discussed in the preceding section also included tests of each of the airfoils reversed in the wind tunnel so that the point of maximum thickness is located forward of the midchord station. The particular airfoils tested are thus specific cases of the family of profiles described by equation (56) with x/c replaced by $1-(x/c)$; that is, the ordinates are

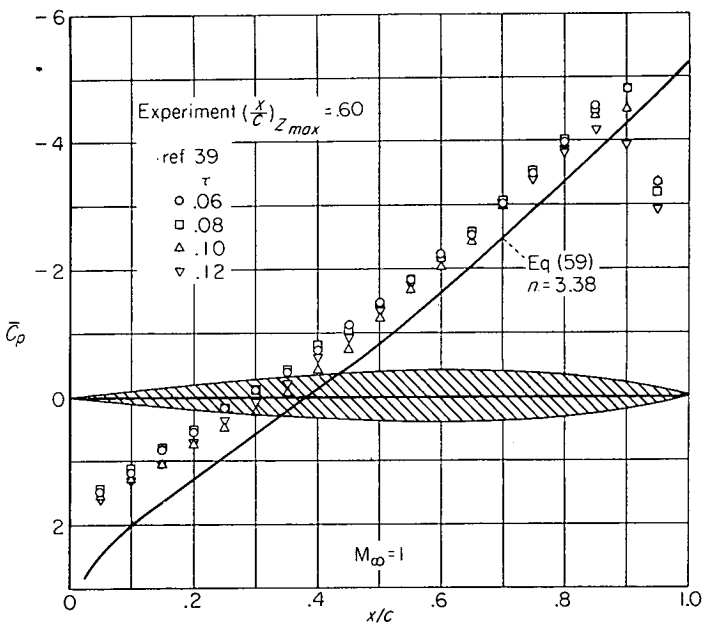

FIGURE 17.—Theoretical and experimental pressure distributions for airfoils having maximum thickness at 0.60 chord; $M_\infty=1$.

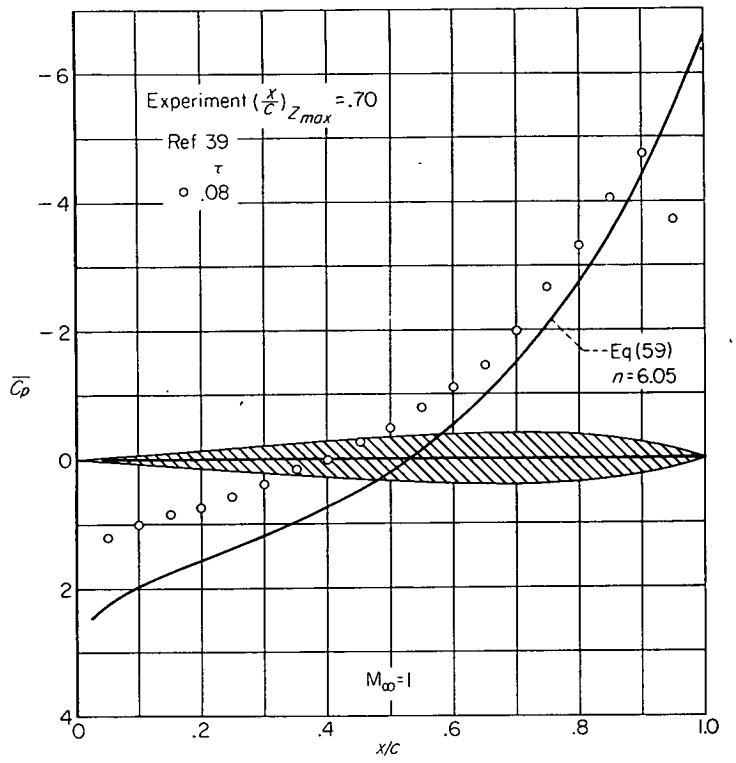

FIGURE 18.—Theoretical and experimental pressure distributions for airfoils having maximum thickness at 0.70 chord: $M_\infty=1$.

$$\frac{Z}{c}=A\left[1-\frac{x}{c}-\left(1-\frac{x}{c}\right)^n\right] \quad (61)$$

where A and n are again constants for each airfoil and n is greater than unity. The values selected for A and n determine the thickness ratio τ and the location $(x/c)_{z_{max}}$ of the point of maximum thickness according to the relations

$$\left(1-\frac{x}{c}\right)_{z_{max}}=\left(\frac{1}{n}\right)^{\frac{1}{n-1}} \quad (62)$$

$$\tau=\frac{2A(n-1)}{n^{n/(n-1)}} \quad (63)$$

Biconvex circular-arc airfoils are special cases of the present family that correspond to $n=2$. The point of maximum thickness is located forward or aft of the midchord station depending on whether n is greater or less than 2. The particular airfoils tested by Michel, Marchaud, and Le Gallo are special cases that correspond to either $n=3.38$ or 6.05 and have the point of maximum thickness at 0.40 or 0.30 chord.

Since the integrations encountered when equation (61) is substituted in equations (45) and (46) for the determination of C_p are more difficult than those encountered in any of

the preceding examples, no general formula will be given for arbitrary n. Two formulas of more restricted generality are given, however. One is applicable when n is any integer greater than unity, the other when n is one-half plus any positive integer. The first is

$$\overline{C}_p=2\xi_\infty-2\left[\frac{3}{4\pi}\left(\frac{n^{\frac{n}{n-1}}}{n-1}\right)^2\right]^{1/3}\left\{\left\{(n-1)^2 ln\frac{x}{c}+2(n-1)\Gamma(n+1)\sqrt{\pi}\sum_{\nu=1}^{n-1}\frac{1}{\Gamma(n-\nu)\Gamma\left(\nu+\frac{1}{2}\right)}\frac{(-x/c)^\nu}{\nu}+[\Gamma(n+1)]^2\pi\sum_{\nu=1}^{n-1}\frac{1}{\Gamma(n-\nu)\Gamma\left(\nu+\frac{1}{2}\right)}\sum_{\mu=1}^{n-1}\frac{1}{\Gamma(n-\mu)\Gamma\left(\mu+\frac{1}{2}\right)}\frac{(-x/c)^{\nu+\mu}}{\nu+\mu}\right\}\Bigg|_{x^*}^{x}\right]^{1/3} \tag{64}$$

where the symbol $|_{x^*}^{x}$ is used to denote the difference between the preceding expression with first x and then x^* substituted for x, that is,

$$f(x)\Big|_{x^*}^{x}=f(x)-f(x^*)$$

where x^*, the location of the sonic point, is found from

$$n-1+\Gamma(n+1)\sqrt{\pi}\sum_{\nu=1}^{n-1}\frac{(-x^*/c)^\nu}{\Gamma(n-\nu)\Gamma\left(\nu+\frac{1}{2}\right)}=0$$

and Γ refers again to the gamma function. The second is

$$\overline{C}_p=2\xi_\infty-2\left[\frac{3}{4\pi}\left(\frac{n^{\frac{n}{n-1}}}{n-1}\right)^2\right]^{1/3}\left\{\left\{(n-1)^2 ln\frac{x}{c}-\frac{B^2\left(1-\frac{x}{c}\right)^{2n-2}}{2n-2}\left(ln\frac{1+\sqrt{x/c}}{1-\sqrt{x/c}}\right)^2+\left[\left(1+\sqrt{\frac{x}{c}}\right)ln\left(1+\sqrt{\frac{x}{c}}\right)+\left(1-\sqrt{\frac{x}{c}}\right)ln\left(1-\sqrt{\frac{x}{c}}\right)\right]\left[-2n(n-1)+\frac{B^2\sqrt{\pi}}{n-1}F(2n-2)\right]+\left[\frac{x}{c}+\left(1+\frac{x}{c}\sqrt{\frac{x}{c}}\right)ln\left(1+\sqrt{\frac{x}{c}}\right)+\left(1-\frac{x}{c}\sqrt{\frac{x}{c}}\right)ln\left(1-\sqrt{\frac{x}{c}}\right)\right]\left[B^2\pi\sum_{\nu=1}^{n-\frac{3}{2}}\frac{F\left(n-\frac{1}{2}-\nu\right)F\left(n-\frac{3}{2}+\nu\right)}{n-1+\nu}\right]-\frac{2n(n-1)}{\sqrt{\pi}}\left(1-\frac{x}{c}\right)\sum_{\nu=1}^{n-\frac{3}{2}}\frac{\left(1-\frac{x}{c}\right)^{n-\frac{3}{2}-\nu}}{\left(n-\frac{1}{2}-\nu\right)F\left(n-\frac{1}{2}-\nu\right)}\left(\frac{1}{n-\frac{1}{2}-\nu}+\sqrt{\frac{x}{c}}\,ln\frac{1+\sqrt{x/c}}{1-\sqrt{x/c}}\right)+\frac{B^2}{n-1}\left(1-\frac{x}{c}\right)F(2n-2)\sum_{\nu=1}^{2n-3}\frac{\left(1-\frac{x}{c}\right)^{2n-3-\nu}}{(2n-2-\nu)F(2n-2-\nu)}\left(\frac{1}{2n-2-\nu}+\sqrt{\frac{x}{c}}\,ln\frac{1+\sqrt{x/c}}{1-\sqrt{x/c}}\right)+2B^2\sqrt{\pi}\left(1-\frac{x}{c}\right)\sum_{\nu=1}^{n-\frac{3}{2}}\frac{F\left(n-\frac{1}{2}-\nu\right)F\left(n-\frac{3}{2}+\nu\right)}{n-1+\nu}\sum_{\mu=1}^{n-\frac{5}{2}+\nu}\frac{\left(1-\frac{x}{c}\right)^{n-\frac{5}{2}+\nu-\mu}}{F\left(n-\frac{1}{2}+\nu-\mu\right)}\left[\frac{1}{n-\frac{3}{2}+\nu-\mu}-\frac{\left(1-\frac{x}{c}\right)}{n-\frac{1}{2}+\nu-\mu}+\frac{x}{c}\sqrt{\frac{x}{c}}\,ln\frac{1+\sqrt{x/c}}{1-\sqrt{x/c}}\right]+2(n-1)B\sqrt{\pi}\sum_{\nu=1}^{n-\frac{3}{2}}F\left(n-\frac{1}{2}-\nu\right)\frac{\left(1-\frac{x}{c}\right)^\nu}{\nu}-B^2\pi\sum_{\nu=1}^{n-\frac{3}{2}}F\left(n-\frac{1}{2}-\nu\right)\sum_{\mu=1}^{n-\frac{3}{2}}F\left(n-\frac{1}{2}-\mu\right)\left(1-\frac{x}{c}\right)^{\nu+\mu-1}\left[\frac{1}{\nu+\mu-1}-\frac{\left(1-\frac{x}{c}\right)}{\nu+\mu}\right]\right\}\Bigg|_{x^*}^{x}\right]^{1/3} \tag{65}$$

where $B=\dfrac{n}{\sqrt{\pi}F\left(n-\frac{1}{2}\right)}$, and $F(\zeta)=\dfrac{\Gamma(\zeta)}{\Gamma\left(\zeta+\frac{1}{2}\right)}$

Attention is called to the fact that ν and μ are positive integers so that when n=(3/2) all the summations drop out.

Again x^* is the location of the sonic point and it is found from

$$n-1-B\left(1-\frac{x^*}{c}\right)^{n-\frac{3}{2}}\sqrt{\frac{x^*}{c}}ln\frac{1+\sqrt{x^*/c}}{1-\sqrt{x^*/c}}-B\sum_{\nu=1}^{n-\frac{3}{2}}F\left(n-\frac{1}{2}-\nu\right)\frac{x^*}{c}\left(1-\frac{x^*}{c}\right)^{\nu-1}=0$$

Substitution of $n=2$ in equation (64) again reproduces equation (53) for the pressure distribution on biconvex circular-arc airfoils. Figures 19 and 20 show comparisons of the pressure distributions measured at Mach number 1 by Michel, Marchaud, and Le Gallo with those calculated by use of equations (64) and (65). The experimental results shown in sketch (s) are for airfoils that have the point of maximum thickness located at 0.40 chord corresponding to a value for n of 3.38. Since results could not be calculated analytically for this value for n, theoretical results are shown for both $n=3.0$ and $n=3.5$. The corresponding locations for the point of maximum thickness can be readily calculated using equation (62) and are 0.423 and 0.394 chord. Similarly, the experimental results shown in figure 20 are for an

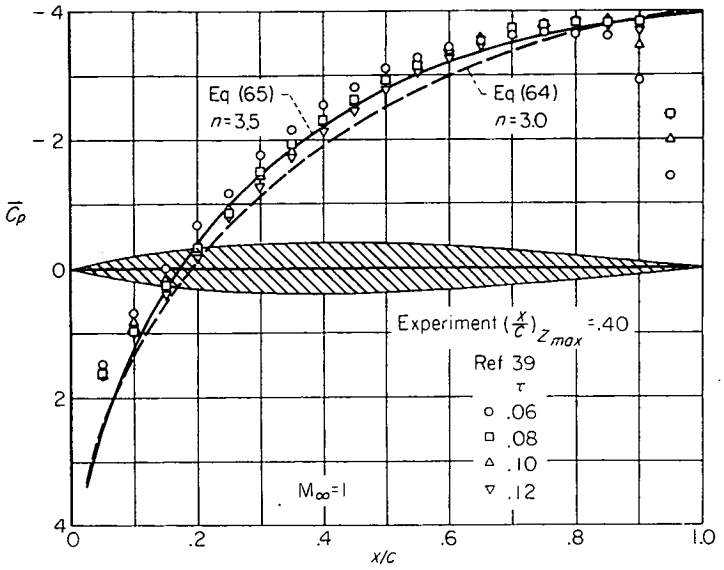

FIGURE 19.—Theoretical and experimental pressure distributions for airfoils having maximum thickness near 0.40 chord; $M_\infty = 1$.

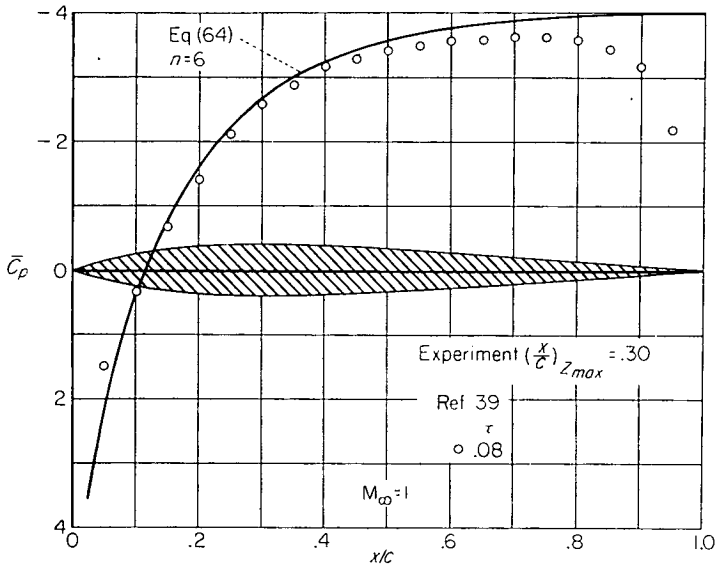

FIGURE 20.—Theoretical and experimental pressure distributions for airfoils having maximum thickness at 0.30 chord: $M_\infty = 1$.

airfoil that has the point of maximum thickness located at 0.30 chord corresponding to a value for n of 6.05; whereas the theoretical results are for airfoils that have the point of maximum thickness located at 0.301 chord corresponding to a value for n of 6.00. These results continue the trend noted in the preceding section that the agreement between the present experimental and theoretical results improves as the location of the point of maximum thickness moves forward along the chord. The principal discrepancy remaining is, in fact, reduced to that near the trailing edge associated with boundary-layer shock-wave interaction, and is therefore beyond the scope of any inviscid theory.

ACCELERATING FLOWS, INVERSE PROBLEMS

Approximate solution of equations for given pressure distribution.—Although all of the preceding discussion is concerned with the calculation of the pressure distribution on an airfoil of specified geometry, an equally important problem in many engineering situations is the design of an airfoil to have a specified pressure distribution at a given Mach number. This poses no new problem in the analysis of purely subsonic or purely supersonic flows by the present methods because the specification of C_p permits the determination of C_{p_L} through application of equation (31) or (17), and the inversion problem is reduced to the familiar inversion problem of linear theory. The necessary relation for flows with free-stream Mach number near 1 can be derived from consideration of equation (42) as an integral equation in which u and du/dx are given and the unknown appears in the integrand of a definite integral. This equation can be inverted readily since it has the same form as the relation encountered in the solution of Abel's integral equation (see, e. g., ref. 40, pp. 483–484). The inversion thus has the form of Abel's integral equation, and is the following in the present application:

$$\frac{dZ}{dx} = -\frac{1}{U_\infty}\sqrt{\frac{k}{\pi}}\int_0^x \left[u - \frac{(1-M_\infty^2)U_\infty}{M_\infty^2(\gamma+1)}\right]\sqrt{\frac{du}{d\xi}}\frac{d\xi}{\sqrt{x-\xi}} \tag{66}$$

The desired relation for the ordinates $Z(x)$ of the airfoil can now be found by a second integration, and is the following if it is assumed that Z is zero at the leading edge ($x=0$).

$$Z = Z^* - \frac{1}{U_\infty}\sqrt{\frac{k}{\pi}}\int_{x^*}^x dx_1 \int_0^{x_1}\left[u - \frac{(1-M_\infty^2)U_\infty}{M_\infty^2(\gamma+1)}\right]\sqrt{\frac{du}{d\xi}}\frac{d\xi}{\sqrt{x_1-\xi}}$$

$$= -\frac{1}{U_\infty}\sqrt{\frac{k}{\pi}}\int_0^x dx_1 \int_0^{x_1}\left[u - \frac{(1-M_\infty^2)U_\infty}{M_\infty^2(\gamma+1)}\right]\sqrt{\frac{du}{d\xi}}\frac{d\xi}{\sqrt{x_1-\xi}} \tag{67}$$

where Z^* is the ordinate at the point x^* where u is zero. It is interesting to note that the two alternative expressions for Z lead to identical results although the apparent regions of dependence, as indicated by the limits on the integrals, are quite different. The same result expressed in terms of C_p or $\bar{C}_p$ is

$$Z = \frac{1}{2}\sqrt{\frac{M_\infty^2(\gamma+1)}{2\pi}}\int_0^x dx_1 \int_0^{x_1}\left[C_p + \frac{2(1-M_\infty^2)}{M_\infty^2(\gamma+1)}\right]\sqrt{-\frac{dC_p}{d\xi}}\frac{d\xi}{\sqrt{x_1-\xi}} \tag{68}$$

or

$$Z = \frac{\tau}{2\sqrt{2\pi}}\int_0^x dx_1 \int_0^{x_1}(\bar{C}_p - 2\xi_\infty)\sqrt{-\frac{d\bar{C}_p}{d\xi}}\frac{d\xi}{\sqrt{x_1-\xi}} \tag{69}$$

A simple application or check of these relations is furnished by substitution for $\bar{C}_p$ of the relation given in equation (50) for single-wedge profiles, whence Z is found to be equal to θx between $x=0$ and $x=c/2$. In the same way, substitution of equation (53) for $\bar{C}_p$ leads directly to equation (52) for the ordinates of a circular-arc airfoil, etc.

Application to airfoils with constant pressure gradient.—An example that permits an additional comparison with an existing theoretical result given by Guderley in reference 41, is furnished by consideration of the problem of determining the shape of an airfoil having a constant negative pressure gradient at $M_\infty = 1$, thus

$$C_p = \frac{dC_p}{d(x/c)}\left(\frac{x}{c} - \frac{x^*}{c}\right) = -\Lambda\left(\frac{x}{c} - \frac{x^*}{c}\right) \tag{70}$$

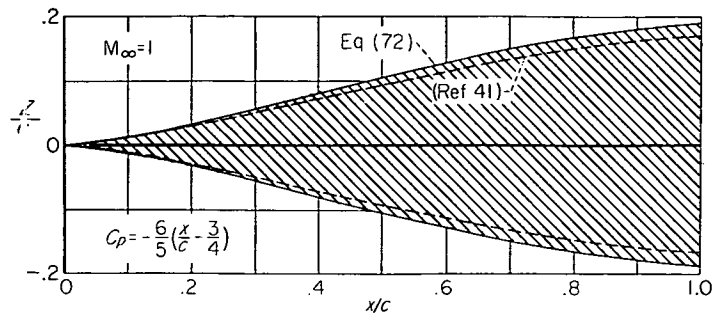

FIGURE 21.—Shape of the forward part of an airfoil having a constant pressure gradient at free-stream Mach number 1, as indicated by present theory and by Guderley.

where $\Lambda = -dC_p/d(x/c)$ is a positive constant. Substitution of this relation for C_p in equation (68) and integration leads directly to the following result:

$$\frac{Z}{c} = \frac{2}{3}\sqrt{\frac{\gamma+1}{2\pi}}\,\Lambda^{3/2}\left[\left(\frac{x}{c}\right)^{3/2}\left(\frac{x^*}{c} - \frac{2}{5}\frac{x}{c}\right)\right] \tag{71}$$

The special case considered by Guderley is obtained by insertion of the values $x^*/c = 3/4$ and $\Lambda = 6/5$, whence equation (71) reduces to

$$\frac{Z}{c} = \left(\frac{3}{5}\right)^{3/2}\sqrt{\frac{\gamma+1}{\pi}}\left[\left(\frac{x}{c}\right)^{3/2}\left(1 - \frac{8}{15}\frac{x}{c}\right)\right] \tag{72}$$

Figure 21 shows a scale drawing of the profile calculated by use of equation (72) and of that given by Guderley. It is evident from the sketch that the present theory indicates larger values for the ordinates Z than are given by Guderley. Although the latter results are given only in graphical form, and are hence difficult to determine with precision, the two sets of values for Z appear to be related by a constant ratio of approximately 9 to 8.[6]

The case considered by Guderley and discussed above results in a shape that does not close at the stern. It can be seen immediately from equation (71), however, that a closed airfoil will result if x^*/c is equated to 2/5, in which case equation (71) reduces to

$$\frac{Z}{c} = \frac{4}{15}\sqrt{\frac{\gamma+1}{2\pi}}\,\Lambda^{3/2}\left[\left(\frac{x}{c}\right)^{3/2}\left(1 - \frac{x}{c}\right)\right] \tag{73}$$

A plot of the results is shown in figure 22.

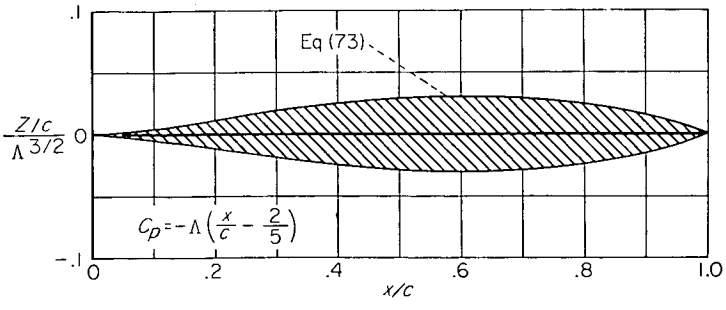

FIGURE 22.—Shape of complete airfoil having a constant pressure gradient at free-stream Mach number 1.

[6] This conclusion is confirmed by a new solution in closed analytic form given by Guderley on page 239 of his book "Theorie Schallnaher Strömungen" published by Springer-Verlag in 1957. Guderley's result has the same functional form as equation (72), but the coefficient in the latter result is greater by a factor $2/\sqrt{\pi} \approx 9.027/8$, after correcting an obvious slip in Guderley's final equation.

DECELERATING FLOWS

Although it is clear that the preceding relations are not appropriate for the analysis of flows with free-stream Mach number near 1 that decelerate smoothly through sonic velocity, it might appear that the proper expressions could be derived by formal application of the procedures described in the preceding section for positive λ_P to the approximate solution of equation (39) for negative λ_P. The analysis leads, in the absence of contributions from shock waves, to the following relation for u at the airfoil surface instead of equation (40)

$$u_P = -\frac{U_\infty}{\sqrt{-\pi\lambda_P}}\frac{d}{dx}\int_x^c \frac{dZ/d\xi}{\sqrt{\xi - x}}\,d\xi + \frac{1}{\lambda_P}\frac{\partial}{\partial x}\int_{-\infty}^{+\infty} d\zeta \int_x^\infty \sigma_P f\,d\xi \tag{74}$$

where

$$f = -(1 - M_\infty^2)\varphi_{\xi\xi}, \qquad \sigma_P = \sqrt{\frac{-\lambda_P}{4\pi(\xi - x)}}\,e^{\left[\frac{\lambda_P(x-\zeta)^2}{4(\xi-x)}\right]}$$

The principal difference between the results for the two cases is that the value of $u(x)$ indicated by equation (74) depends on conditions downstream of the point x, whereas that indicated by equation (40) for positive λ_P depends on conditions upstream of x. This difference is a fundamental property of equation (39) and necessitates a change in the argument required to disregard additional contributions from shock waves, because now it is the oblique shock waves situated downstream, rather than upstream of x, that furnish a contribution to $u(x)$. If, however, there are no oblique shock waves downstream of x, or if the contributions resulting from additional integrals over the shock surfaces are disregarded so that equation (74) can be used as a starting point in the analysis, the following result is obtained by proceeding in a fashion analogous to that employed in the derivation of equation (47) from (40):

$$\overline{C}_p = 2\xi_\infty + 2\left\{\frac{3}{\pi}\int_{x^*}^x \left[\frac{d}{dx_1}\int_{x_1}^c \frac{d(Z/\tau)/d\xi}{\sqrt{\xi - x_1}}\,d\xi\right]^2 dx_1\right\}^{1/3} \tag{75}$$

The symbol x^* again refers to the location of the sonic point and is equal to the value for x for which

$$\frac{d}{dx}\int_x^c \frac{dZ/d\xi}{\sqrt{\xi - x}}\,d\xi = 0 \tag{76}$$

The corresponding relation for the shape of an airfoil associated with a given pressure distribution at some free-stream Mach number near unity can also be found and is the following, again assuming that Z is zero at the leading edge:

$$Z = -\frac{\tau}{2\sqrt{2\pi}}\int_0^x dx_1 \int_{x_1}^c \frac{(\overline{C}_p - 2\xi_\infty)\sqrt{d\overline{C}_p/d\xi}}{\sqrt{\xi - x_1}}\,d\xi \tag{77}$$

No further use is made in this paper of equations (74) through (77) for decelerating flows at free-stream Mach numbers near 1. As will become more evident at a later point in the present discussion, it would appear necessary to use such formulas for the analysis of flows decelerating through sonic velocity, but the region of dependence in these relations is such as either to cast suspicions on their applicability or to require the occurrence of exceptional coincidences. On the other hand, two-dimensional flows that

decelerate smoothly through sonic velocity appear to be very exceptional physically. Further investigation is needed before additional remarks can be made regarding the role of the parabolic case with negative λ_P in the analysis of transonic flows.

The next section will be concerned with an alternative analysis of certain cases in which decelerating flows occur.

COMBINATION OF ACCELERATING AND DECELERATING FLOWS

The calculation of the pressure distribution at Mach numbers near 1 on an airfoil having such a shape that the velocity increases over part of the chord and decreases over the remainder cannot be accomplished by direct application of any of the relations developed in the preceding sections. On the one hand, the parabolic method described for flows with free-stream Mach number near 1 permits the analysis of flows that pass through sonic velocity, but fails when the velocity gradient is zero. On the other hand, the elliptic and hyperbolic methods described for subsonic and supersonic flows permit the analysis of flows with zero velocity gradient, but fail if the local velocity is sonic. The breakdown in each case is associated with the fact that the basic partial differential equation for each case, that is, equation (8), (21), or (39), assumes a degenerate form when λ is zero. Such cases are, nevertheless, interesting and important since they can occur in practical applications, and the present section is concerned with their discussion. The procedure adopted is based on the idea of joining together various of the results derived in the preceding sections in such a way that the failings associated with vanishing λ are avoided, rather than on a complete re-analysis of the problem from a sufficiently general point of view to encompass the entire problem in a single sweep.

In order to fix the ideas, consider the problem of calculating the pressure distribution at Mach number 1 on the airfoil with cusped trailing edge illustrated in figure 23 for which experimental data are available from reference 42 by Michel, Marchaud, and Le Gallo. The front half of this airfoil is the same as that of a biconvex circular-arc airfoil having a thickness ratio of 0.10, but the rear half is shaped in such a manner that an inflection point is located at 0.75 chord and that the trailing edge angle is zero. The ordinates

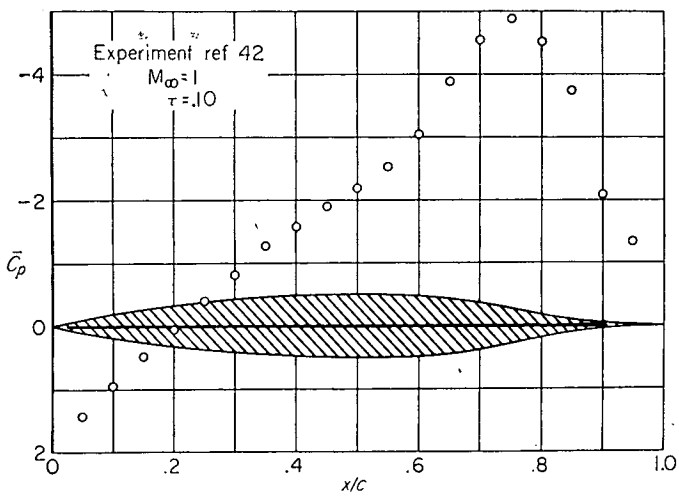

FIGURE 23.—Experimental pressure distribution for an airfoil with cusped trailing edge; $M_\infty = 1$.

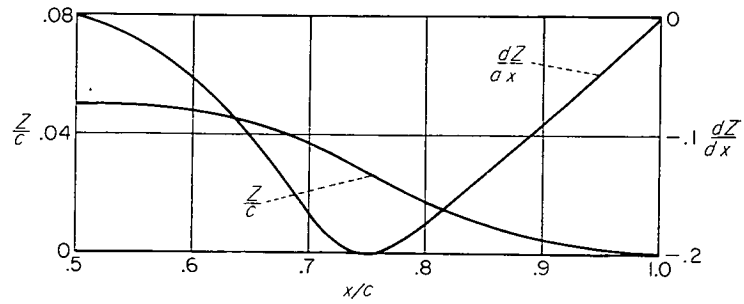

FIGURE 24.—Chordwise variation of ordinate, Z, and slope, $\frac{dZ}{dx}$, for the rear half of the airfoil shown in figure 23.

and slopes of the rear half of this airfoil are shown graphically in figure 24. No analytic expression is given in reference 42 for the ordinates of the rear half.

The pressure distribution on the front part of the airfoil where the passage through sonic velocity occurs can be calculated by use of equations (45) and (46), since it does not depend on the shape of the rear half of the airfoil. This means that the pressure distribution on the front half of the airfoil described above is given specifically by equation (53) for x/c between 0 and ½. It is clear that the pressure distribution on the entire rear half of the airfoil cannot be determined by use of equations (45) and (46) because the results so calculated indicate a point of zero pressure gradient in the vicinity of the inflection point. Although this detail, in itself, is not incorrect, it signals the breakdown of the parabolic method that occurs when λ is zero. Positive evidence of the breakdown is provided by the fact that the calculated pressures decrease downstream of the point of zero pressure gradient rather than increase as indicated by the experimental data shown on sketch (w) or by simple considerations of supersonic flow. These results, furthermore, cannot be joined to those obtained by use of equations (75) and (76) for the part of the airfoil downstream of the point of zero pressure gradient because the two sets of equations do not indicate the same location for this point. This situation should not be too surprising since the procedures should not be expected to fail abruptly when λ is precisely zero, but gradually as λ approaches zero.

There exists another possibility for the determination of the pressure distribution on the rear half of the present airfoil by joining together solutions. It is to use the formulas developed for supersonic flow, but with the final constant of integration adjusted so that the pressure is equal, at the point of connection, to that given by the solution for the forward part of the airfoil. This procedure corresponds to the use of simple wave theory for the calculation of the difference in pressure between an arbitrary point on the rear of the airfoil and the point of connection. In this way, the following equation results for the pressures on the rear of the airfoil at Mach numbers near unity:

$$\bar{C}_p - 2\xi_\infty = -2\left\{\left[-\left(\frac{\bar{C}_p(X) - 2\xi_\infty}{2}\right)\right]^{3/2} - \frac{3}{2\tau}\left[Z'(x) - Z'(X)\right]\right\}^{2/3} \tag{78}$$

where Z' refers to dZ/dx, and $\bar{C}_p(X)$ is the value of $\bar{C}_p$ at $x = X$.

The most convenient point for joining the two solutions in the application described in figures 23 and 24 is at $x/c=0.50$. Then the pressures on the forward half of the airfoil can be calculated directly by use of equation (53), the values of $(\overline{C}_pX)$ and $Z'(X)$ are

$$\overline{C}_p(X)=\overline{C}_p\left(\frac{c}{2}\right)=2\xi_\infty-2\left[\frac{6}{\pi}(-1+ln4)\right]^{1/3},\ Z'\left(\frac{c}{2}\right)=0 \quad (79)$$

and the following expression results for the pressures on the rear half of the airfoil at Mach numbers near unity:

$$\overline{C}_p\equiv\frac{[M_\infty{}^2(\gamma+1)]^{1/3}}{\tau^{2/3}}C_p=2\xi_\infty-2\left[\sqrt{\frac{6}{\pi}(-1+ln4)}-\frac{3}{2\tau}\frac{dZ}{dx}\right]^{2/3} \quad (80)$$

Figure 25 shows a comparison of the experimental pressure distribution for Mach number 1 given by Michel, Marchaud, and Le Gallo in reference 42 and the corresponding theoretical values calculated using equations (53) and (80) together with the values for dZ/dx given in figure 24. The theoretical and experimental results bear about the same relationship to each other as those shown previously for biconvex circular-arc airfoils although effects of boundary-layer shock-wave interaction extend over a larger fraction of the chord of the cusped airfoil. This difference is in agreement with the results obtained from schlieren photographs and given in reference 42 that indicate that the shock wave meets the airfoil, at Mach number 1, at 78-percent chord for the cusped airfoil and at 95-percent chord for the biconvex circular-arc airfoil of the same thickness ratio.

It is apparent that the pressures computed over the rear half of the airfoil by using equation (80) will tend to be somewhat too negative because the use of this relation corresponds to the use of simple wave theory and hence disregards the influence of a family of incoming compression waves arising from the sonic line. Some idea of the magnitude of this effect can be gained by examination of figure 26 which shows a comparison of the pressure distribution on biconvex circular-arc airfoils at Mach number 1 calculated using equation (53) for the entire airfoil, with those calculated using equation (78) for various fractions of the chord.

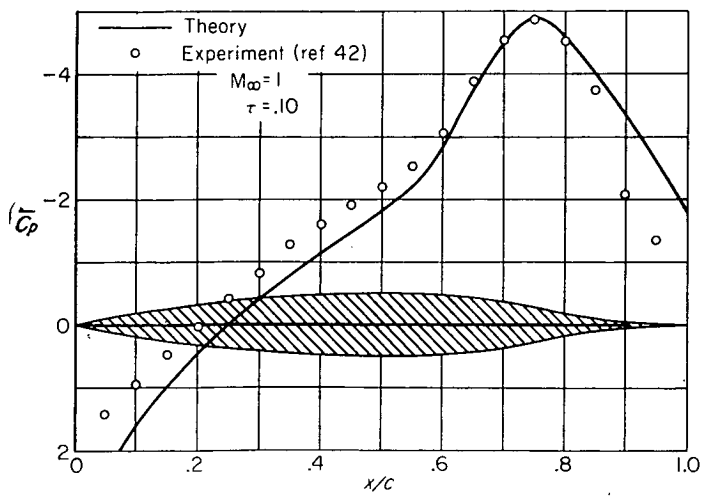

FIGURE 25.—Theoretical and experimental pressure distribution for the airfoil shown in figure 23; $M_\infty=1$.

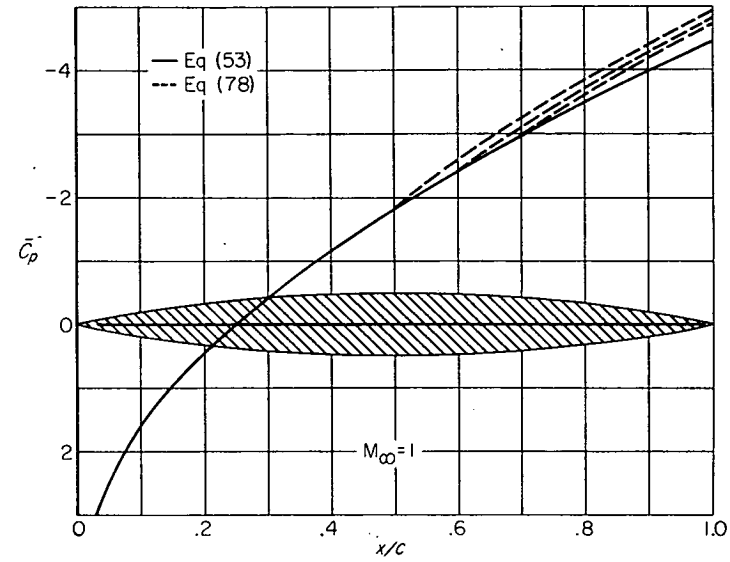

FIGURE 26.—Comparison of pressure distributions for the rear part of a circular-arc airfoil as indicated by the parabolic and hyperbolic methods; $M_\infty=1$.

A further example involving accelerating and decelerating flows at Mach number 1 is furnished by examining the case of the symmetrical double-wedge airfoil of arbitrary thickness ratio for which a solution has been given by Guderley and Yoshihara in reference 32. Figure 27 shows a plot of their result together with the corresponding result calculated by the procedures described above. The result for $0<x<c/2$ is calculated by use of equation (50). That for $c/2<x<c$ is calculated by use of the following equation which is obtained from equation (78) by equating $\overline{C}_p(X)$ to 0, $Z'(X)$ to $\bar{\tau}$, and $Z'(x)$ to $-\tau$.

$$\overline{C}_p=-2(3)^{2/3} \quad (81)$$

The difference between the two pressure distributions on the rear half of the airfoil is again the result of the neglect,

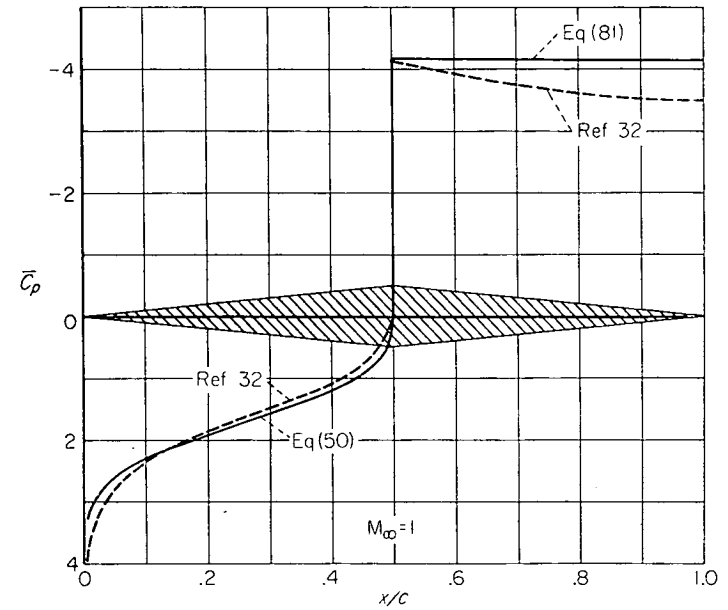

FIGURE 27.—Comparison of the pressure distributions for a double-wedge airfoil as indicated by the present theory and by Guderley and Yoshihara; $M_\infty=1$.

in the present analysis, of the contribution of the family of incoming compression waves arising from the sonic line.

It is evident from these three examples that the present procedure of joining solutions is capable of yielding results that are at least qualitatively correct and that, although somewhat greater accuracy is undoubtedly desired, this procedure may be useful until such time as a more general analysis of accelerating-decelerating flows is accomplished.

COMPARISON OF RESULTS FOR MACH NUMBER 1 WITH THOSE FOR OTHER MACH NUMBERS

The remainder of this report is concerned with the discussion of some selected examples that illustrate the relation between results for Mach number 1 and those for other Mach numbers. This discussion is divided into two parts. The first is concerned with comparisons of pressure distributions on the same airfoil at different Mach numbers, and the second with pressure drag.

PRESSURE DISTRIBUTION

Attention is directed in this section to comparisons, for a number of airfoils, of the theoretical pressure distribution for Mach number 1 with that for the highest Mach number for purely subsonic flow and that for the lowest Mach number for purely supersonic flow. Pressure distributions for these two Mach numbers, designated more briefly as the lower and upper critical Mach numbers, respectively, are of particular significance not only because they represent the results associated with the bounds of the transonic range, but also because they are typical of the pressure distributions for all purely subsonic or purely supersonic flows. All of the theoretical results shown are calculated by application of the general expressions derived in the present paper. The results for Mach number 1 are the same as discussed in detail in the preceding section. Subsonic pressure distributions are calculated by use of equation (28), and supersonic pressure distributions by use of equation (15). The lower critical Mach number is determined from equation (30) by replacing $C_{p_{i_{cr}}}$ with the most negative value of C_{p_i} that occurs in each case, and solving for M_∞. The upper critical Mach number is determined from equation (16) by replacing $(dZ/dx)_{cr}$ with the value of dZ/dx at the leading edge and solving for M_∞.

Consider, first, the single-wedge airfoil for which the pressure distribution at Mach number 1 is given by equation (50) and illustrated graphically in figure 10. Figure 28 shows a comparison of this result for the specific case of a wedge having a semiapex angle θ of 0.10 radians with those for the upper and lower critical Mach numbers. The lower critical Mach number is, of course, zero because the velocity is sonic at the corner for all free-stream Mach numbers less than the upper critical. The pressure distribution for Mach number 0 is given by

$$C_p=C_{p_i}=-\frac{2\theta}{\pi}\,ln\,\frac{2x/c}{1-2x/c} \tag{82}$$

The three curves shown on figure 28 suffice to show that the pressure distribution on a single-wedge airfoil at Mach

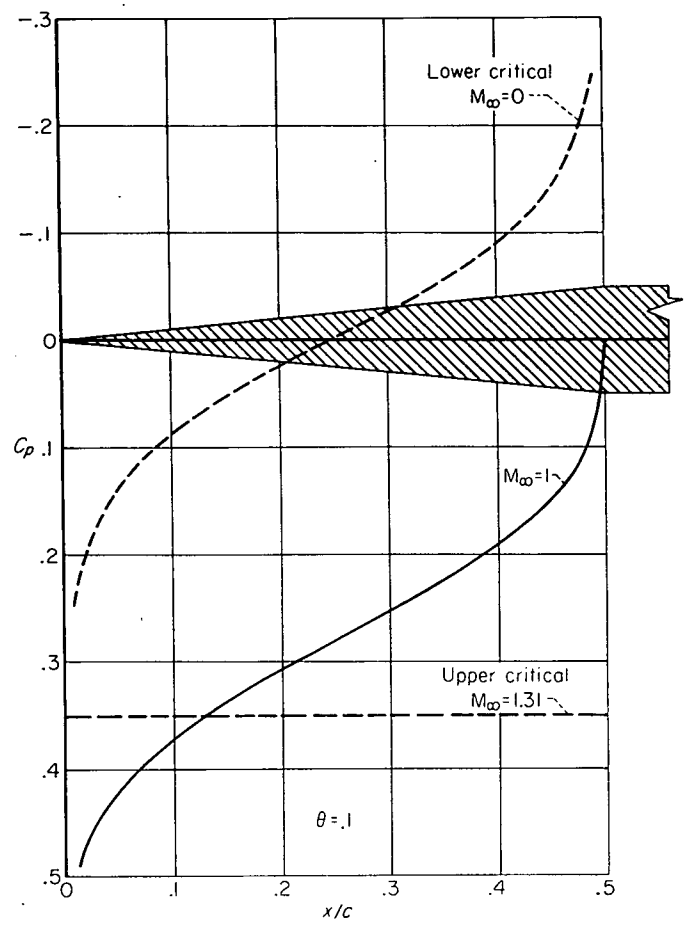

FIGURE 28.—Summary of pressure distributions for upper and lower critical Mach numbers and for Mach number 1. Single-wedge airfoil with a semiapex angle, θ, of 0.10 radian.

number 1 bears a much closer resemblance to that at the lower critical Mach number than to that at the upper critical Mach number. It is interesting to note, moreover, that the difference between the pressure distribution at Mach number 1 and that at Mach number 0 is very nearly constant across the chord.

Consider, next, the half circular-arc airfoil for which the pressure distribution at Mach number 1 is given by equation (53) and illustrated graphically in figure 15. Figure 29 shows a comparison of this result with those for the upper and lower critical Mach numbers. The computation of the pressure distribution for the lower critical Mach number involves the use of the following expression for C_{p_i} which is obtained by integration of the auxiliary relation of equation (28) with Z replaced by the expression given in equation (52) for $0<x<c/2$ and by $\tau c/2$ for $x>c/2$:

$$C_{p_i}=-\frac{4}{\pi}\tau\left[1+\left(1-\frac{2x}{c}\right)ln\,\frac{2x/c}{1-2x/c}\right] \tag{83}$$

The results illustrated in figure 29 display a remarkable property that the subsonic part of the pressure distribution at Mach number 1 differs from the pressure distribution at the lower critical Mach number by nearly a constant, and that the supersonic part of the pressure distribution differs from the pressure distribution at the upper critical Mach number by nearly the same constant, although of opposite sign.

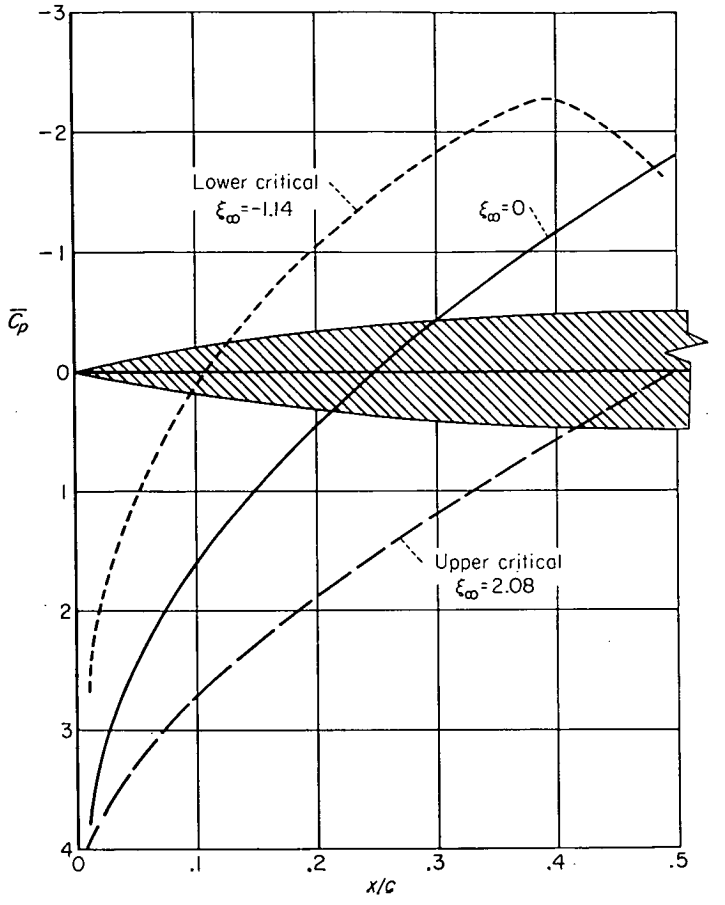

FIGURE 29.—Summary of pressure distributions for upper and lower critical Mach numbers and for Mach number 1 for half-circular-arc airfoils.

In order to investigate this difference further, the pressure distributions at the upper and lower critical Mach numbers have been calculated for the complete biconvex circular-arc airfoil and each of the four related airfoils having maximum thickness forward and aft of the midchord station for which the results for Mach number 1 are shown in figures 16 through 20. The results are shown in figure 30. It can be seen that the three pressure distributions for each airfoil bear the same general relationship to each other as noted above, although the difference between the pressure distributions is not always quite so constant as is observed for the wedge and circular-arc profiles.

PRESSURE DRAG

Once the pressure distribution is known for a given airfoil, the pressure drag can be obtained directly by integration of equation (48). The corresponding expression in terms of $\bar{c}_d$ and $\bar{C}_p$ is

$$\bar{c}_d \equiv \frac{[M_\infty^2(\gamma+1)]^{1/3}}{\tau^{5/3}} c_d \equiv 2\int_0^1 \bar{C}_p \frac{d(Z/t)}{d(x/c)} d\left(\frac{x}{c}\right) \qquad (84)$$

Although the present theoretical results only permit the calculation of pressure drag for Mach numbers near 1 and for Mach numbers greater than the upper critical, these results, together with existing theoretical and experimental results, can be used to sketch the variation of pressure drag with Mach number throughout the transonic range. The airfoil for which the most information is available is, of course, the single-wedge profile for which an approximate solution for Mach numbers less than 1 has been given by Cole (ref. 36) and improved recently by Yoshihara (ref. 35), that for Mach number 1 by Guderley and Yoshihara (ref. 32), and that for Mach numbers greater than 1 by Vincenti and Wagoner (ref. 34), and experimental data have been given by Liepmann and Bryson (refs. 30 and 31). Figure 31 shows a plot of these results, all in terms of the reduced parameters $\bar{c}_d$ and ξ_∞ and recast into the form consistent with the present formulation of the basic equations for transonic flow (see ref. 5, 6, or 9 for additional information on this point), together with the results computed by use of the present theory. The new results are indicated by the solid lines, the former by dashed lines and by data points. The short vertical lines on the data points indicate Bryson's estimate of the experimental accuracy of the data. As can be seen, the only point of difference between the present results and the previously existing results is at Mach numbers slightly in excess of the upper critical, and results from the error incurred in approximating the pressure jump through the bow shock wave by simple wave theory (i. e., by eq. (15) rather than eq. (6)). The positive slope of the drag curve at $\xi_\infty=0$, or Mach number 1 is in agreement with the result indicated by equation (51) and is typical for airfoils that do not close at the rear.

Figure 32 shows a summary of the comparable information for the front half of a biconvex circular-arc airfoil followed by a straight section, for which experimental data have been given by Bryson in reference 30. The theoretical values are again indicated by a solid line, and the experimental values by data points.[7] Although the amount of information available is much less than for the single-wedge airfoil, the results for both cases show striking similarity.

Results for half airfoils are not typical of those for complete airfoils, however, as can be seen by comparison of the preceding results with the corresponding theoretical and experimental results illustrated in figure 33 for complete biconvex circular-arc airfoils. The experimental results are those given by Michel, Marchaud, and Le Gallo in reference 37 and are obtained by integration of equation (48) together with experimental values for the pressure distribution. The most prominent difference concerns the slope of the curve of $\bar{c}_d$ versus ξ_∞ at $\xi_\infty=0$, or Mach number 1, for which the same procedures that led to positive values for a half airfoil, lead to zero slope for a complete airfoil. It can be seen that the experimental data support these values of the slope in both cases. Although the calculated values for drag are somewhat greater than those measured in the wind tunnel, most of the discrepancy can be attributed to the local effects of shock-wave boundary-layer interaction that occur near the trailing edge. Because this phenomenon depends on Reynolds number and may be of greatly diminished importance at full-scale conditions, Michel, Marchaud, and Le Gallo in-

[7] The experimental values shown in figure 32 differ somewhat from those given originally in figure 21 of reference 30 because of the correction of some inaccuracies in the calculation of the drag from the experimental pressure distributions given in figure 20 of reference 30. Although no explanation is known for the substantial negative drag indicated at subcritical Mach numbers and its existence must be indicative of some shortcomings of the experimental technique, its occurrence is an unmistakable consequence of the measured pressure distribution. That this is so can be seen at a glance by comparison of the measured pressure distribution with that indicated by linearized compressible flow theory, for which the drag is zero.

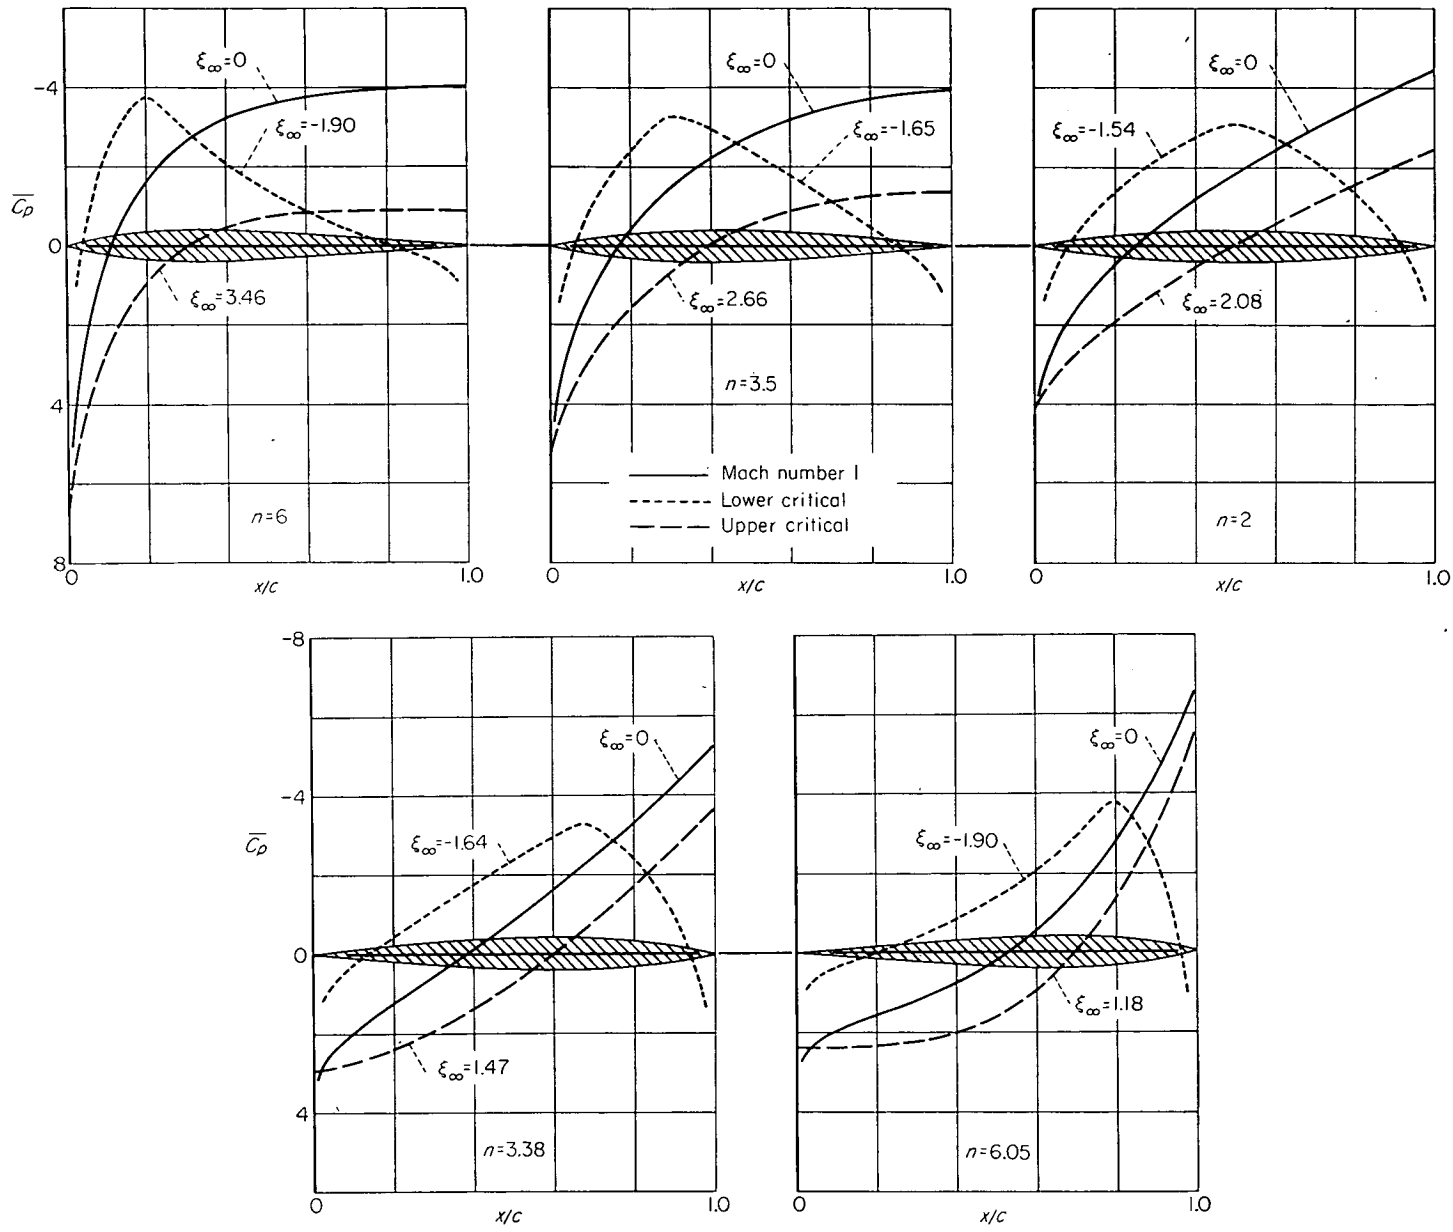

FIGURE 30.—Summary of pressure distributions for upper and lower critical Mach numbers and for Mach number 1 for a series of airfoils with different positions of maximum thickness.

troduced, in the discussion of their experimental results, the concept of "extrapolated drag" to represent the drag that would occur in the absence of separation. This quantity is calculated by consideration of a pressure distribution that differs from the experimental pressure distribution in the vicinity of the trailing edge as a result of the replacement of the pressures actually measured by those obtained by extrapolation of the trends indicated at stations upstream of the separation point. Accordingly, the values for "extrapolated drag" given by Michel, Marchaud, and Le Gallo are also shown on figure 33. As might be expected, the theoretical values for drag are in better agreement with the values for "extrapolated drag" than with those obtained directly from the actual measurements.

The results for biconvex circular-arc airfoils are typical of those for other complete airfoils. Attention is called, however, to the fact that the experimental values given by Michel, Marchaud, and Le Gallo in reference 39 for the airfoils that have the point of maximum thickness located forward of the midchord station are not so reliable as those they give for airfoils that have a more rearward location of the point of maximum thickness. This reduction in accuracy results from the facts that the method of testing and the fixed spacing of the orifices tend to diminish the accuracy with which the contribution of the region near the leading edge can be evaluated, and that the contribution of this region is, at the same time, of increased importance.

Figure 34 shows a summary of the calculated results for the pressure drag of the two families of airfoils described by equations (56) and (61) with values for n ranging from 1.5 to 6. For this range of n the airfoils described by equation (61) have a range of location for the point of maximum thickness that extends from about 0.30 to 0.55 chord, and those described by equation (56) have a range of locations extending from about 0.45 to 0.70 chord. In addition to lines for

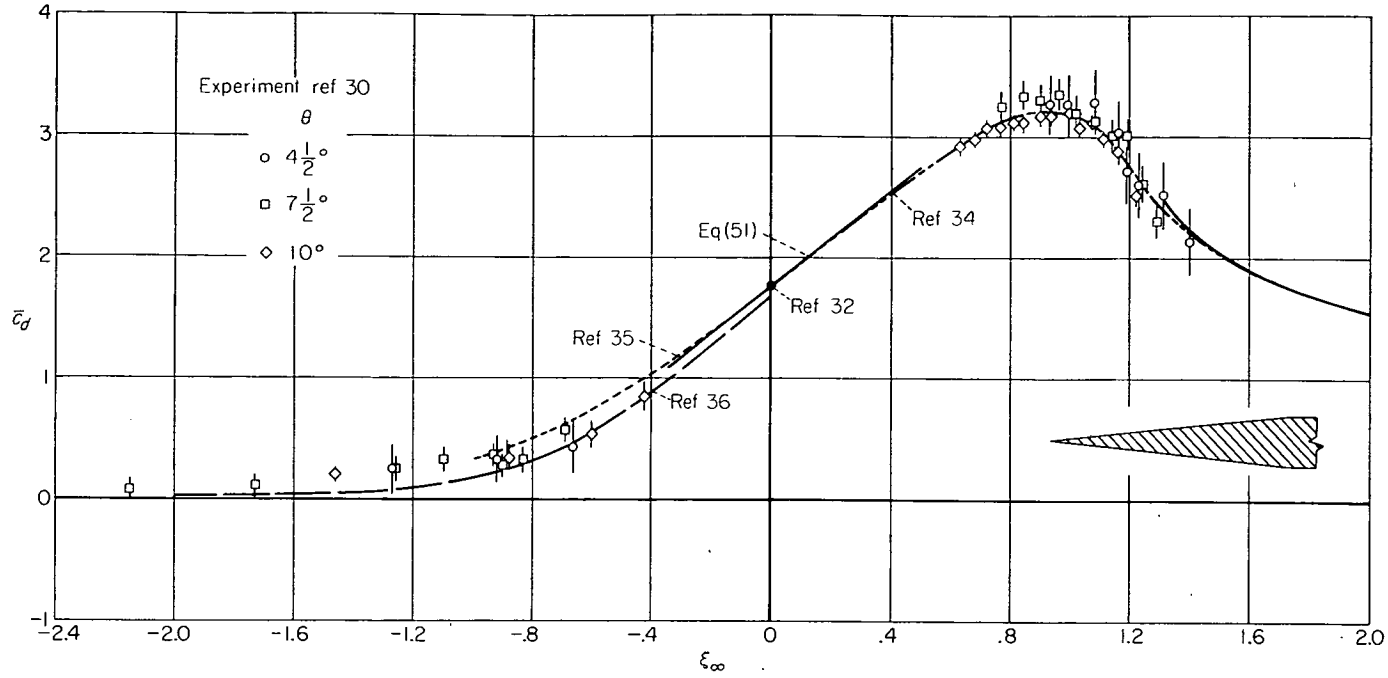

FIGURE 31.—Summary of theoretical and experimental results for the drag of single-wedge airfoils.

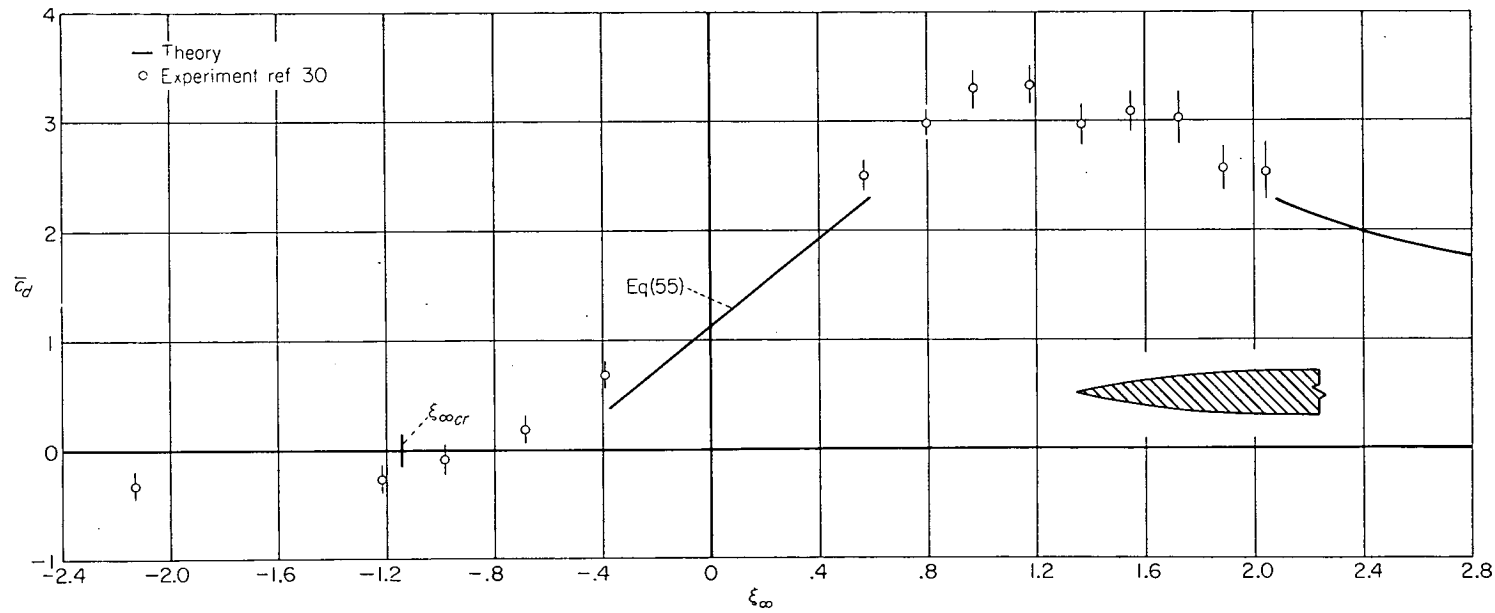

FIGURE 32.—Summary of theoretical and experimental results for the drag of half-circular-arc airfoils.

constant ξ_∞, which correspond to lines of constant Mach number for a group of airfoils having the same thickness ratio, a line is also shown for $\xi_{\infty cr}$, which corresponds to the line for the lowest Mach number for which the flow is purely supersonic. It can be seen that the variation of pressure drag with the location of the point of maximum thickness at Mach number 1 is quite different from that indicated by lines of constant ξ_∞, or Mach number, for purely supersonic flows, but is rather similar to that indicated by the line for $\xi_{\infty cr}$. An interesting feature of the results for purely supersonic flow is that the drag is not the same in forward and reverse flow, as is indicated by linearized compressible flow theory (see ref. 43 or 44).

CONCLUDING REMARKS

It appears worthwhile, in conclusion, to summarize and contrast the alternative discussions presented in the main text and in the Appendix of the general procedures involved in the approximate solution of all the problems treated in this paper. The arguments presented in the Appendix are based essentially on the idea of diminishing the importance of the higher order terms, and hence concentrate on the

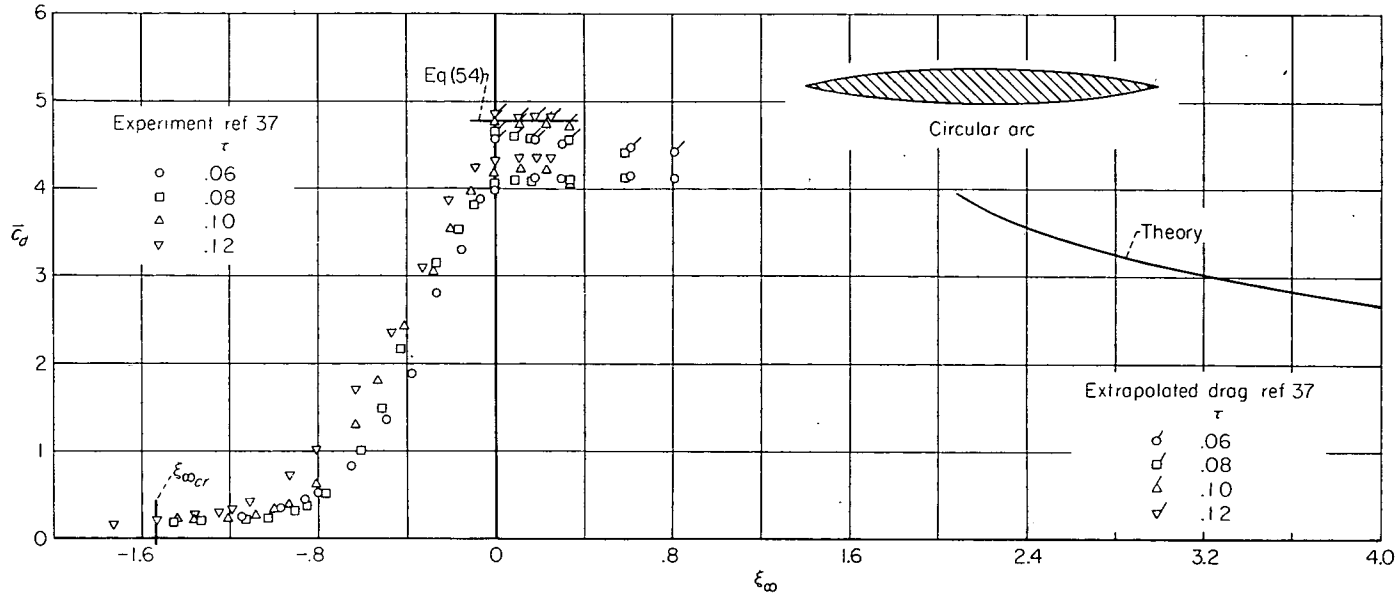

FIGURE 33.—Summary of theoretical and experimental results for the drag of complete circular-arc airfoils.

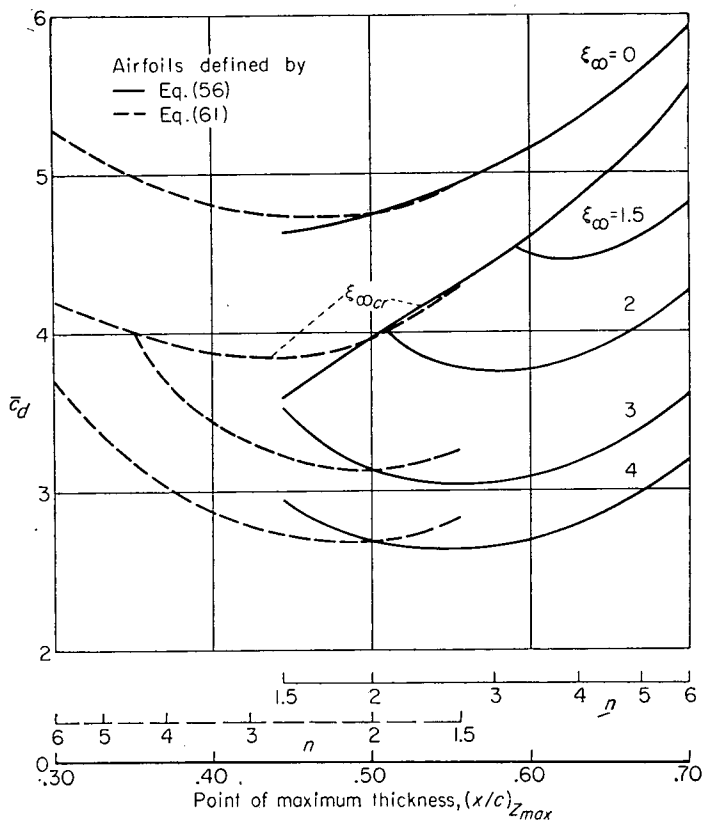

FIGURE 34.—Summary of theoretical results for the drag of two families of airfoils having various positions for the point of maximum thickness.

contributions stemming from the double integral of the integral equation appropriate for each case. The arguments presented in the main text lead to the same conclusions, but are based essentially on the idea of linearizing the transonic equation in a small region by replacing part of the nonlinear term by a constant λ, and then introducing different values for λ for different points in the field. This procedure might be considered equivalent, in some sense, to the replacement of the original nonlinear equation by a different linear differential equation for each point. Results obtained by solution of the equations at this stage depend, of course, on the choice of λ and must be assembled in order to determine the final results. This step is accomplished in each case by putting the results into such a form that a first-order nonlinear ordinary differential equation is obtained upon substituting for λ the quantity it originally replaced. At this point, the equations encountered coincide with those obtained following the procedures described in the Appendix and the remainder of the analysis proceeds in identical manner. In the cases considered herein, the differential equation is always of sufficiently simple form that it can be integrated analytically and the result expressed in closed analytic form. This integration implicitly introduces the assumption of continuity of the velocity or pressure distribution and leads, upon evaluation of a single constant of integration, to the final result.

APPENDIX A

REINSPECTION AND ANALYSIS OF METHOD OF APPROXIMATION

INTRODUCTION

The methods used in the main text of this paper are appealing for their brevity and for the efficiency with which approximate solutions of the nonlinear equations of transonic flow theory are found. These methods are not entirely satisfying to the critical reader, however, because certain elements appear to be arbitrary and there is no a priori way in which the accuracy of the approximations can be judged. Both the virtue and weakness of these procedures are the result of introducing the essential simplifications at the beginning of the analysis. If the introduction of approximations is deferred to the end, the relations that occur in the initial stages of the analysis are, of course, more complicated than those presented in the main text. Consideration of these relations is, however, essential for an understanding of the basis for the method of approximation.

The following discussion of the approximate solution of problems of transonic flow theory is based on consideration of integral equations derived from the differential equations of transonic flow theory by standard application of Green's theorem. Since the details of each of the three cases, hyperbolic, elliptic, and parabolic, are somewhat different, each case is considered separately. In each case, exact relations are retained as long as possible and the approximations, when introduced, are seen to be closely related to those employed in the method of successive approximations commonly used in the determination of higher approximations in compressible flow theory. The following paragraphs will be concerned at the outset with the derivation of integral equations for each of the three cases, and subsequently with the discussion of the simplification and approximate solution of these equations.

DERIVATION OF INTEGRAL EQUATIONS

All of the subsequent analysis proceeds from Green's theorem. There are many forms of Green's theorem, but a sufficiently general form for all of the present purposes is that associated with the linear operator $\overline{L}(\Omega)$ defined as follows (ref. 45, pp. 244–247):

$$\overline{L}(\Omega)=\overline{A}\Omega_{xx}+\Omega_{zz}+\overline{B}\Omega_x \tag{A1}$$

where $\overline{A}$ and $\overline{B}$ are constants. Green's theorem states that the following relation holds between any two arbitrary functions Ω and ψ having continuous first and second derivatives:

$$\iint_{\overline{R}}[\psi\overline{L}(\Omega)-\Omega\overline{M}(\psi)]\,d\overline{R}=-\oint_{\overline{C}}\left[\overline{\Lambda}\left(\psi\frac{\partial\Omega}{\partial\nu}-\Omega\frac{\partial\psi}{\partial\nu}\right)+\overline{B}\psi\Omega\cos(n,x)\right]ds \tag{A2}$$

in which $\overline{R}$ refers to the interior of an arbitrary region bounded by the curve $\overline{C}$, as shown in figure 35, $\overline{M}$ is called the adjoint differential operator

$$\overline{M}(\psi)=\overline{A}\psi_{xx}+\psi_{zz}-\overline{B}\psi_x$$

$\overline{\Lambda}$ represents the quantity

$$\Lambda=\sqrt{\overline{A}^2\cos(n,x)+\cos^2(n,z)}$$

and $\partial/\partial\nu$ stands for a derivative in the direction ν, and can be written as a linear differential operator.

$$\frac{\partial\Omega}{\partial\nu}=\Omega_x\cos(\nu,x)+\Omega_z\cos(\nu,z)$$

The direction ν is called the conormal, and its direction cosines are related to those of the normal n according to

$$\overline{\Lambda}\cos(\nu,x)=\overline{A}\cos(n,x)$$

$$\overline{\Lambda}\cos(\nu,z)=\cos(n,z)$$

HYPERBOLIC CASE

The initial step in the present derivation of the integral equation appropriate for the discussion of the hyperbolic case is to subtract $\lambda_H\varphi_{xx}$ from both sides of equation (3), and to write the resulting equation as follows:

$$-\lambda_H\varphi_{xx}+\varphi_{zz}=(M_\infty{}^2-1+ku-\lambda_H)\varphi_{xx}=f_H \tag{A3}$$

The symbol λ_H refers to any positive finite constant. The form of Green's theorem associated with the linear operator

$$\overline{L}(\varphi)=\overline{L}_H(\varphi)=-\lambda_H\varphi_{xx}+\varphi_{zz} \tag{A4}$$

will now be applied, whence

$$\overline{A}=-\lambda_H,\qquad \overline{B}=0,\qquad \overline{M}_H(\varphi)=\overline{L}_H(\varphi) \tag{A5}$$

The quantity Ω is now identified with the perturbation potential φ, and ψ with an elementary solution of $\overline{M}_H(\psi)=0$,

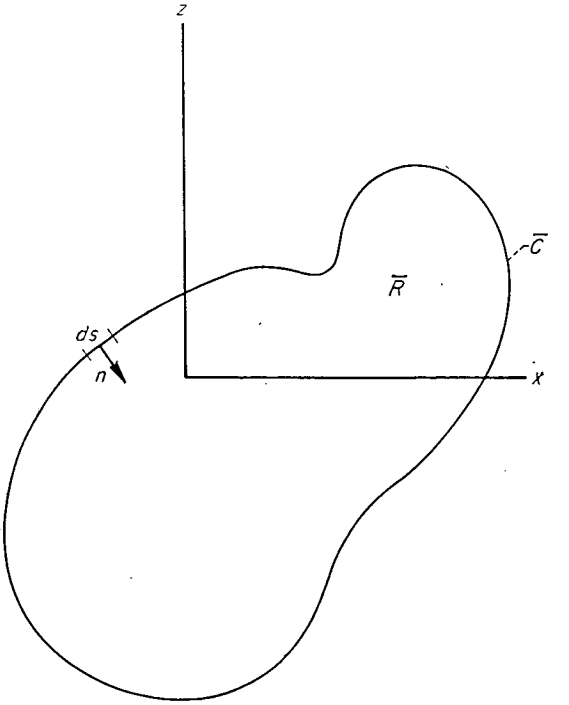

FIGURE 35.—Region of integration.

in particular with the unit supersonic source σ_H defined as follows:

$$\psi=\sigma_H=\begin{cases}-\dfrac{1}{2\sqrt{\lambda_H}} & \text{for } (x-\xi)^2\geq\lambda_H(z-\zeta)^2 \quad \text{(A6a)}\\ 0 & \text{for } (x-\xi)^2<\lambda_H(z-\zeta)^2 \quad \text{(A6b)}\end{cases}$$

If the region $\overline{R}$ is so selected that the inequality expressed in equation (A6a) holds throughout, equation (A2) reduces to

$$-\int_{\overline{C}}\overline{\Lambda}_H\frac{\partial\varphi}{\partial\nu_H}ds=\iint_{\overline{R}}\overline{L}_H(\varphi)d\overline{R}=\iint_{\overline{R}}f_Hd\overline{R} \qquad \text{(A7)}$$

in which $\overline{\Lambda}_H$ and ν_H refer to the special forms of $\overline{\Lambda}$ and ν consistent with equation (A4) or (A5), the running coordinates of integration are ξ,ζ, and the field point at which φ is to be evaluated is x,z. Equation (A7) is now applied to the region indicated in figure 36. Note that the wing, wake, and shock waves must be excluded from the region of integration. It should be noted that figure 36 is only a schematic illustration to help define the quantities involved in equation (A7), and that the shock wave, indicated as a detached bow wave, might instead be attached to the leading edge, to the trailing edge, or situated somewhere along the chord. The single shock wave illustrated in figure 36 could, moreover, be replaced by a complicated system of shock waves. The region $\overline{R}_H$ may likewise be considered to consist of a single region, or as the sum of a number of regions as typified by adding to $\overline{R}_H$ the region situated upstream of the bow wave

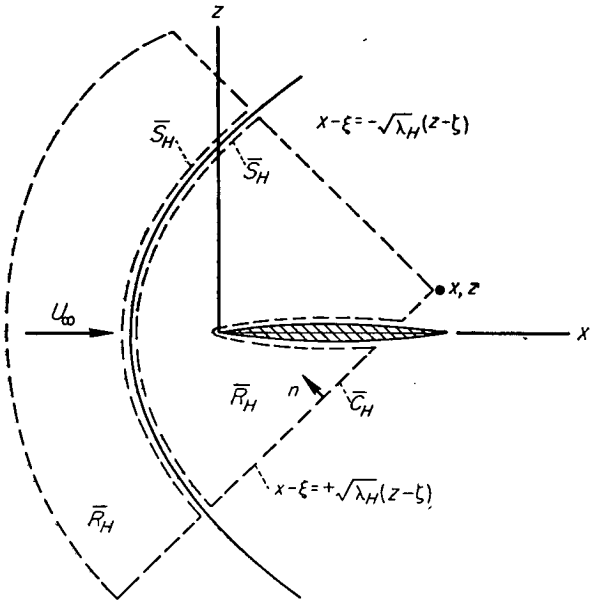

FIGURE 36.—Region of integration for the hyperbolic case.

and within the dotted lines of figure 36. In any case, the general considerations remain the same, and the following integral equation is obtained for φ at an arbitrary point x,z:

$$\varphi(x,z)=\left[\frac{1}{-2\sqrt{\lambda_H}}\int_0^{x-\sqrt{\lambda_H}|z|}\Delta\frac{\partial\varphi}{\partial\zeta}d\xi+\frac{\Delta\varphi(x-\sqrt{\lambda_H}|z|)}{2}\right]-\frac{1}{2\sqrt{\lambda_H}}\int_{\overline{S}_H}\overline{\Lambda}_H\delta\frac{\partial\varphi}{\partial\nu_H}d\overline{S}_H-\frac{1}{2\sqrt{\lambda_H}}\iint_{\overline{R}_H}f_Hd\overline{R}_H \qquad \text{(A8)}$$

where

$$\Delta\frac{\partial\varphi}{\partial\zeta}=\frac{\partial\varphi_u}{\partial\zeta}-\frac{\partial\varphi_l}{\partial\zeta}, \qquad \Delta\varphi=\varphi_u-\varphi_l$$

in which u and l refer to conditions on the upper and lower sides of the wing and wake, where

$$\delta\frac{\partial\varphi}{\partial\nu_H}=\frac{\partial\varphi_a}{\partial\nu_H}+\frac{\partial\varphi_b}{\partial\nu_H}$$

in which a and b refer to conditions on the two sides of the shock wave $\overline{S}_H$, and where

$$\overline{\Lambda}_H\frac{\partial\varphi}{\partial\nu_H}=-\lambda_H\frac{\partial\varphi}{\partial\xi}\cos(n,x)+\frac{\partial\varphi}{\partial\zeta}\cos(n,z)$$

ELLIPTIC CASE

The integral equation appropriate for the discussion of the elliptic case can be derived by use of procedures analogous to those described in the preceding paragraph for the hyperbolic case. The initial step is to add $\lambda_E\varphi_{xx}$ to both sides of equation (3), and to write the resulting equation as follows:

$$\lambda_E\varphi_{xx}+\varphi_{zz}=[\lambda_E-(1-M_\infty{}^2-ku)]\varphi_{xx}=f_E \qquad \text{(A9)}$$

As in the hyperbolic case, the symbol λ_E refers to any positive finite constant. The form of Green's theorem associated with the linear operator

$$\overline{L}(\varphi)=\overline{L}_E(\varphi)=\lambda_E\varphi_{xx}+\varphi_{zz} \qquad \text{(A10)}$$

will now be applied, whence

$$\overline{A}=\lambda_E, \qquad \overline{B}=0, \qquad \overline{M}_E(\varphi)=\overline{L}_E(\varphi) \qquad \text{(A11)}$$

The quantity Ω is now identified with φ, and ψ with an elementary solution of $\overline{M}_E(\psi)=0$, in particular the unit subsonic source defined by the function

$$\psi=\sigma_E=\frac{1}{2\pi\sqrt{\lambda_E}}ln\sqrt{(x-\xi)^2+\lambda_E(z-\zeta)^2} \qquad \text{(A12)}$$

In this way equation (A2) reduces to

$$-\int_{\overline{C}}\overline{\Lambda}_E\left(\sigma_E\frac{\partial\varphi}{\partial\nu_E}-\varphi\frac{\partial\sigma_E}{\partial\nu_E}\right)ds=\iint_{\overline{R}}\sigma_E\overline{L}_E(\varphi)d\overline{R}=\iint_{\overline{R}}\sigma_Ef_Ed\overline{R} \qquad \text{(A13)}$$

in which $\overline{\Lambda}_E$ and ν_E refer to the special forms of $\overline{\Lambda}$ and ν consistent with equation (A10) or (A11), the running coordinates of integration are ξ,ζ, and the field point at which φ is to be determined is x,z. If equation (A13) is now applied to the region $\overline{R}_E$ surrounding the wing, wake, and shock waves, as illustrated in figure 37, and the a priori assumption is made that the perturbation field attenuates sufficiently fast with distance to negate the contribution of the surface integral over the large circle in the limit as the radius goes to infinity, the following integral equation is obtained for φ at an arbitrary point x,z:

$$\varphi(x,z)=\int_0^\infty\left(\sigma_E\Delta\frac{\partial\varphi}{\partial\zeta}-\Delta\varphi\frac{\partial\sigma_E}{\partial\zeta}\right)d\xi+\int_{\overline{S}_E}\sigma_E\overline{\Lambda}_E\delta\frac{\partial\varphi}{\partial\nu_E}d\overline{S}_E+\iint_{\overline{R}_E}\sigma_Ef_Ed\overline{R}_E \qquad \text{(A14)}$$

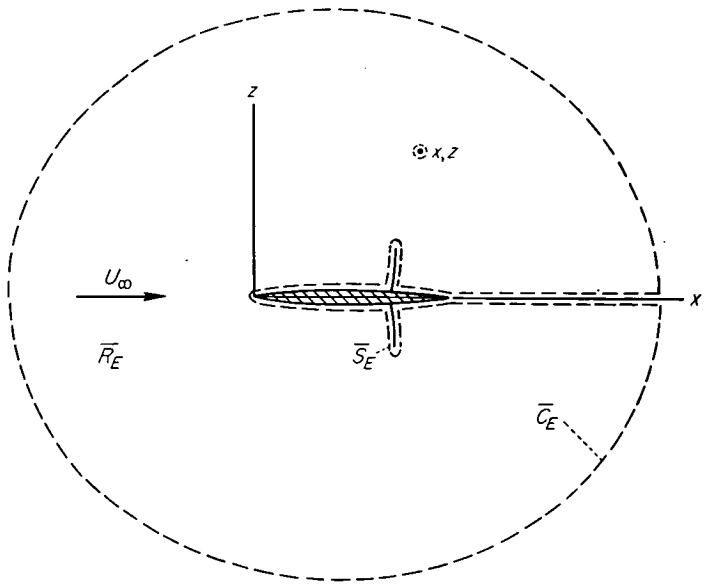

FIGURE 37.—Region of integration for the elliptic case.

where $\Delta\varphi$ and $\Delta(\partial\varphi/\partial\zeta)$ have the same meaning as in equation (A8), but where

$$\delta\frac{\partial\varphi}{\partial\nu_E}=\frac{\partial\varphi_a}{\partial\nu_E}+\frac{\partial\varphi_b}{\partial\nu_E}$$

in which a and b refer to conditions on the two sides of the shock wave $\bar{S}_E$, and where

$$\bar{\Lambda}_E\frac{\partial\varphi}{\partial\nu_E}=\lambda_E\frac{\partial\varphi}{\partial\xi}\cos(n,x)+\frac{\partial\varphi}{\partial\zeta}\cos(n,z)$$

PARABOLIC CASE

The initial step in the derivation of the integral equations appropriate for the discussion of the parabolic case is to subtract $\lambda_P\varphi_x$ from both sides of equation (3), and to write the resulting equation as follows:

$$\varphi_{zz}-\lambda_P\varphi_x=(M_\infty^2-1)\varphi_{xx}+(k\varphi_{xx}-\lambda_P)\varphi_x=f_P \qquad \text{(A15)}$$

The symbol λ_P refers again to a finite constant, which may be either positive or negative. The form of Green's theorem associated with the linear operator

$$\bar{L}(\varphi)=\bar{L}_P(\varphi)=\varphi_{zz}-\lambda_P\varphi_x \qquad \text{(A16)}$$

will now be applied, whence

$$\bar{A}=0, \quad \bar{B}=-\lambda_P, \quad \bar{M}_P(\varphi)=\varphi_{zz}+\lambda_P\varphi_x \qquad \text{(A17)}$$

The quantity Ω is again identified with φ, and ψ with an elementary solution of $\bar{M}_P(\psi)=0$, in particular with the function

$$\psi=\sigma_P=\begin{cases}\sqrt{\dfrac{\lambda_P}{4\pi(x-\xi)}}\,e^{\left[-\frac{\lambda_P(z-\zeta)^2}{4(x-\xi)}\right]} & \text{for } \dfrac{\lambda_P}{x-\xi}\geq 0 \qquad \text{(A18a)}\\ 0 & \text{for } \dfrac{\lambda_P}{x-\xi}<0 \qquad \text{(A18b)}\end{cases}$$

This function assumes a role in the analysis of the parabolic case that is analogous to that of the unit subsonic and supersonic sources in the elliptic and hyperbolic cases. In mathematical literature, the linear partial differential equation $\bar{L}_P(\varphi)=0$ with positive λ_P arises in the study of heat conduction, and the function σ_P is often referred to as a unit heat source. If the region $\bar{R}$ is so selected that the inequality expressed in equation (A18a) holds throughout, equation (A2) reduces to

$$-\int_{\bar{C}}\left[\bar{\Lambda}_P\left(\sigma_P\frac{\partial\varphi}{\partial\nu_P}-\varphi\frac{\partial\sigma_P}{\partial\nu_P}\right)-\lambda_P\sigma_P\varphi\cos(n,x)\right]ds$$
$$=\iint_{\bar{R}}\sigma_P\bar{L}_P(\varphi)d\bar{R}=\iint_{\bar{R}}\sigma_P f_P d\bar{R} \qquad \text{(A19)}$$
